We now come to the present practice of engineers, by which different descriptions of boilers are constructed and arranged to suit various purposes. How far these numerous forms and combinations fulfil the necessary requirements, the engineer will, it is presumed, be able to decide, from the accurate experiments, abstract reasoning, and practical results which we have adduced.

Marine Boilers.—Fig. 885 shows an example of the high-type modern marine boiler, as designed by N. P. Burgh, and illustrated in his

practical work on Marine Engineering, to which we are indebted for many of our examples of marine boilers. The fire-box and combustion-chamber are partially separated by a brick bridge. The tubes have a slight rake inclining upwards at the smoke-box end, this end being the final evaporator. The vertical tubes in the upper portion of the smoke-box are for superheating. The fire-bars are inclined towards the inner extremities for two purposes, the one to assist the action of stoking or agitating the fire, and the other to accelerate the draught—it being remembered that the greater portion of the draught enters below the bars. Fig. 886 shows an enlarged front elevation of the same, half complete and half in section.

Figs. 887, 888, 889, show an end elevation, sectional plan, and sectional elevation of the boilers fitted in H.M.S.S. 'Vigilant,' 'Wanderer,' and 'Osprey,' by Maudslay, Sons, and Field. The disposition of the boilers in the hull is represented by the elevations, the plan referring to only one

boiler. The fire-boxes are fore and aft of the shell at the side. The combustion-chambers, one to each grate, are at right angles with the fire-boxes; the tubes are arranged in a line with and outside each fire-box, thus forming a return action. A longitudinal flue is introduced, extending throughout the length of the boiler, so as to render the final uptake common to the smoke-boxes. On referring to the sectional elevation, it will be seen that this flue is the same height as the smoke-box, a divisional water-space causing a complete separation. The fire-box is contracted at the base-line, also the side and bottom of the shell are angularly connected. This form of construction is due to the beam of the hull for which the boilers were designed.

The details are:—Two boilers of 100 h.p. collectively; length of shell, 19 ft. 4 in.; width of one shell, 9 ft. 6 in.; height of shell, 5 ft. 10 in. There are four fire-grates, each grate being 6 ft. 4 in. long by 2 ft. 10 in. wide. The fire-box is 3 ft. 6 in. deep at each end. 192 of the tubes are 6 ft. 6 in., and 192 6 ft. in length. The total number of tubes is 384, each tube being 2½ in. outside diameter.

Fig. 890 represents a boiler with tubes, made by Maudslay, Sons, and Field, for H.M.S.S. 'Mutine' and 'Chameleon.' The boiler is of 66 h.p.; the shell is 9 ft. 8 in. long, 18 ft. 4 in. wide, and 7 ft. 6 in. high. There are four grates, each grate being 5 ft. 10 in. long by 2 ft. wide. The fire-box is 3 ft. 10 in. deep. Total number of tubes 262, each tube being 6 ft. long and 2½ in. outside diameter. There are two grates to each cluster of tubes, placed near the outer side of the shell. The combustion-chamber is at right angles with the grate. The tubes are placed in the centre between the fire-boxes. The smoke-boxes are at the boiler-front between the inner fire-boxes.

Sectional plan.

Figs. 891, 892, 893, 894, show elevation, plan, and sections of the two boilers of H.M.S.S. 'Reindeer' and 'Perseus,' by J. and G. Rennie. They are of 130 H.P. Length of shell, 16 ft.; width, 10 ft. 6 in.; height, 7 ft. 6 in.; six fire-grates, 5 ft. 6 in. long by 2 ft. 10 in. wide; fire-box, 4 ft. 6 in. deep; 528 tubes, each tube being 6 ft. long and $2\frac{1}{2}$ in. outside diameter.

Sectional elevation.

Sectional plan.

Section at C, D.

Figs. 895, 896, show elevation and section of the boilers made by J. and G. Rennie for S. S. S. 'General Murillos' and 'General Victoria.' There are four boilers, of 200 h.p. collectively. Each shell is 12 ft. long, 10 ft. wide, and 7 ft. high. There are eight grates, each grate being 5 ft. 9 in. long by 3 ft. wide. The fire-box is 3 ft. deep in front, and 2 ft. at back. There are 628 tubes, 6 ft. long and $2\frac{1}{2}$ in. outside diameter.

Figs. 897, 898, show the tubular boiler made by James Watt and Co. for the Bombay Steam Navigation Company. It is of 30 h.p. The shell is 7 ft. 1 in. long, 11 ft. wide, and 8 ft. 6 in. high. It has two grates, 4 ft. 9 in. long and 2 ft. 2 in. wide. The fire-box is 3 ft. deep. Number of tubes 144, each tube 4 ft. 11 in. long, $2\frac{1}{2}$ in. outside diameter. The doors seen under the grate at the back, Fig. 898, are for the admission of air beyond the bridge, a suitable framework being fitted in the fire-box. The gear shown by the dotted lines and in the dome relates to the safety-valve. Fig. 897 shows the combustion-chamber, smoke-box, and uptake, in section. It will be seen that the tubes connecting the combustion-chamber and smoke-box are at an incline; this is for the purpose of accelerating the draught. The uptake is curved and surrounded by the steam; this renders partial superheating attainable without extra detail or expense.

Figs. 899, 900, show the boilers made by James Watt and Co. for the S.S. 'Tyrsaad.' They are of 120 h.p. The shell is 8 ft. long, 15 ft. wide, and 10 ft. high. There are eight grates, 7 ft. long and 2 ft. wide. The fire-box is 3 ft. deep in front, and 3 ft. 3 in. deep at back. There are 520 tubes, each tube being 5 ft. 8 in. long and $2\frac{1}{2}$ in. outside diameter.

Figs. 901, 902, 903, 904, represent the two boilers made by James Watt and Co. for H.M.S. 'Hornet.' They are of 100 h.p. Length of shell, 16 ft. 6 in.; width of one shell, 9 ft. 6 in.; height of shell, 7 ft. 6 in. Six grates, each grate 5 ft. 3 in. long by 2 ft. 4 in. wide. The fire-box is 3 ft. deep in front, and 3 ft. 6 in. at back. There are 440 tubes, each 5 ft. 6 in. long and $2\frac{1}{2}$ in. outside diameter.

The tubular boiler invented by Edward N. Dickerson is shown in Fig. 905. It has two series of tubes, W and S, through one of which series the water passes, and upon the exterior of which

Fig. 910 represents a modification of the marine boilers shown in Figs. 907, 908. In this boiler the heating-surface is increased, and the circulation promoted by the two sets of tubes M and N

placed in the flue *c*. The bridge *d* is made to contain water, and it is connected to the corrugated roof *c* by pipes *d*².

Figs. 911, 912, show an elevation and plan of two boilers designed by N. P. Burgh for a gun-boat. They are of 100 h.p. collectively. The shell is 19 ft. 9 in. long, each shell 12 ft. wide and 5 ft. 9 in. high. There are four grates, 6 ft. long and 3 ft. wide. The fire-box is 3 ft. deep. There are 780 tubes, 400 being 5 ft. 9 in., and 380 7 ft. 6 in. long; outside diameter of each tube, 2½ in.

The boilers made by Maudslay, Sons, and Field, for H.M.S.S. 'Ajax' and 'Edinburgh,' are shown in plan, Fig. 913. In each ship there are two, of 450 h.p. collectively. The shell of each boiler is 34 ft. 6 in. long, 15 ft. 6 in. wide, and 9 ft. 10 in. high. There are twelve fire-grates, each grate 6 ft. 4 in. long and 3 ft. wide. The fire-box is 3 ft. 6 in. deep in front, and 4 ft. 2 in. at back. Number of tubes, 1506; each tube 4 ft. 10 in. long, 2½ in. external diameter.

Figs. 914, 915, exhibit elevations of the boiler designed by N. P. Burgh for a steam yacht. It is of 25 H.P. The shell is 11 ft. 6 in. long, 7 ft. wide, 7 ft. high; one fire-grate, 6 ft. long, 2 ft. 9 in. wide; fire-box, 2 ft. 9 in. deep. Number of tubes, 72; each tube 8 ft. long and $2\frac{1}{2}$ in. outside diameter.

E. Humphrys' marine boiler is shown, Figs. 916, 917. The uptake is constructed in such a manner that a number of vertical tubes may be placed in it, the uptake forming part of the main boiler. The vertical tubes serve as a superheating apparatus, and render unnecessary any pipes or valves for conducting the steam to the superheater.

Fig. 917 shows the tubes and smoke-box. Directly above the tubes a plate is fastened, and another plate is placed near the roof, the plates being connected by the vertical tubes and stays. The passage of the steam is indicated by the arrows.

The boilers represented in Figs. 918 to 921 are fitted in H.M.S. 'Oberon,' 260 H.P., and were designed by Capt. A. A. Cochrane and at Woolwich Factory respectively. The length of shell in Capt. Cochrane's boiler, Figs. 918, 919, is 12 ft.; width of shell, 11 ft. $6\frac{1}{2}$ in.; number of steel tubes, 915; length of steel tubes, 3 ft. 3 in.; outside diameter of steel tubes, $1\frac{1}{2}$ in.; actual weight of boiler, 20 tons 7 cwt.; actual weight of water, 12 tons 8 cwt. 1 qr.

932.

933.

Stationary Boilers.—The boiler shown in Figs. 934, 935, was designed by A. W. Williamson and L. Perkins for very high pressure steam with great expansion. It supplies steam to an engine of 60 H.P., which works at a pressure of 500 lbs. to the square inch.

The boiler consists of a number of horizontal straight wrought-iron tubes A, welded at the ends, and connected with one another by smaller vertical pipes B. These tubes contain the water to be evaporated, and the steam, whilst the fire is outside them. It is essential that the larger tubes be horizontal or nearly so, and that each of them be connected to the next tube by means of two of the connecting-pipes. The boiler contains five layers of the larger tubes of $2\frac{1}{2}$ in. internal and 3 in. external diameter; the connecting-pipes are $\frac{7}{8}$ in. internal and $1\frac{3}{8}$ in. external diameter. In working, the water-level is in the middle layer of tubes, as shown by the dotted line in Figs. 934, 935; it remains free from the violent undulations which occur frequently in boilers where the internal space is not divided off. It is probable that a circulation establishes itself in the water, which rises with the bubbles of steam through the vertical connecting-pipe at one end of the tube, and descends by itself through that at the other. The gases from the fire pass backwards and forwards between the layers of tubes, as shown by the arrows in Fig. 935, and remain long enough in contact with them to allow of a very good absorption of the heat. In another similar boiler used for some time, there were eight layers of tubes above the fire. The boiler is thus made up of a number of vertical subdivisions arranged side by side, each containing five to eight parallel tubes. The several sections are all connected together at the bottom, by means of a cross tube C, with connecting-pipes to each section, through which the water finds the same level in all the sections. The steam is taken off through a similar cross tube D at the top of the boiler, with a connecting-pipe to the highest tube of each section. All the sections are proved with water pressure up to 3000 lbs. the square inch.

The boiler has about 12 sq. ft. of grate-surface, but the total area of the air-spaces between the bars does not amount to more than is supplied by 6 sq. ft. of ordinary grate-surface; and accordingly the fire is large but slack. The total heating-surface amounts to 882 sq. ft. The capacity is about 40 cub. ft., half of which is water-space and half steam-room. The whole boiler is firmly held together by cast-iron girders, and encased in non-conducting sides and top made of four thicknesses of light plate riveted together and kept about $\frac{3}{4}$ in. apart by ferrules, so as to form three closed air-chambers. This arrangement is specially adapted for marine boilers.

The flue from the boiler is made to pass through a box containing the three cylinders of the engine, passing first down the small or high-pressure cylinder, then up the middle one, and finally acting on the low-pressure cylinder. The temperature of the gases in this box varies from 400° to 500° Fahr. After leaving the box, they pass downwards through a vertical square flue 10 ft. long, giving up their remaining heat to the feed-water which is forced up through a wrought-iron coil of $\frac{3}{4}$ -in. pipe contained in the flue, having 200 sq. ft. of heating-surface. At the bottom of this flue the gases enter a vertical iron funnel of 40 ft. height and 24 in. diameter. The heat is so completely abstracted by the feed-water coil, that after leaving it the gases have never been found hotter than 100° Fahr.

This small quantity of heat in the chimney gave sufficient draught to cause the evaporation of 83 cub. ft. of water an hour in the boiler; but by the aid of a small fan, driven by a belt from the main shaft of the engine, the evaporation was usually kept at 15 cub. ft. an hour. The evaporating power of the boiler was tested by means of a water-meter, and in an experiment of 5 hours' duration 390 lbs. of anthracite coal evaporated 420 galls. of water, which is about $10\frac{3}{4}$ lbs. of

water the lb. of coal. There is no doubt that a larger boiler with small proportionate loss of heat by radiation to the outer air would give a still more favourable result.

Fig. 936 is an elevation, and Fig. 937 a plan, both in section, of Thomas Dunn's vertical boiler.

a is the shell, *b* the grate, *c* the fire-box; *t* is a large pipe which is kept full of water, the communication between the water-space surrounding the fire-box being effected by the branch pipes *t'*: to the outside of the tube *t*, and to the inside of the fire-box, are riveted T or angle irons, to hold in position the fire-clay or other slabs *t''*, shown in Fig. 937; these slabs and the tube *t* form the partition to separate the up-draught from the down-draught; and the fire-clay of the slabs when red-hot ignites the smoke, and consumes it before it arrives at the flue *u* communicating with the chimney.

Dunn's vertical boiler with two fire-grates is shown in Figs. 938, 939. *a* is the shell, *b b* the grates, *c* the fire-box, divided in the centre by the two water-partitions *W, W*, the space between which forms the down-flue. The upper end of the partitions *W, W*, is partially closed by a perforated fire-clay top *W'*, the object of which is to ignite the inflammable gases, and to prevent the passage of smoke into the down-draught flue. At the bottom of the down-flue are placed the pipes *V*, through which the feed-water passes, and is thus partially heated in passing to the boiler.

Figs. 940 to 944 illustrate a very novel and useful arrangement, introduced by Hawksley, Wild, and Co., of Sheffield. It consists in building a furnace for puddling, heating iron and steel or other material, inside the boiler-flue, thereby utilizing the waste heat.

A is the steam-dome; *B*, furnace-door, the doors are placed on both sides of the furnace, so that it can be worked as a right or left hand furnace, or, in case of long forgings, right through; *C*, firing-hole door; *D*, fire-brick lining of furnace; *E*, furnace-bed; *F*, slag-bridge; *G*, tapping-hole for furnace-slag; *H*, heat-retainer for furnace-neck; *I*, circulating water-tubes; *K*, flange arrangement, for expansion, contraction, strengthening, reducing flue, and retaining the heat.

Robert Daglish and Co.'s multitubular boiler is shown in Figs. 945, 946, 947. *A, A*, is the stop-valve with safety-valve, *B* steam-dome, *C* manway and cover, *D* chimney and damper, *E* steam-gauge, *F* water-gauge and gauge-cocks, *G* feed-valve and pipes, 'mud-hole for clearing out.

Samuel Smart and Co.'s vertical syphon water-tube boiler, shown in Figs. 948, 949, is of simple construction, consisting of a cylindrical shell with internal cylindrical fire-box, from the crown of which the water-tubes are suspended, hanging free into the fire. Every part of the boiler is easy of access for the purpose of cleaning; and as no strain is thrown upon any part by expansion or contraction, the tubes being fixed at one end only, the boiler is less liable than many other kinds to get out of order, and a great source of expense, in the shape of repairs, is thereby avoided.

Into each of the water-tubes a syphon is inserted, which extends down into the water-space of the boiler a short distance beyond the ends of the tubes. These syphons act as circulating tubes when the boiler is at work, supplying the water-tubes constantly with water from the water-

938.

939.

940.

Side elevation.

casing, where it has a tendency to keep cooler than in the upper part of the boiler, but by means of the circulation through the syphons the temperature is equalized.

The tubes used under ordinary circumstances, in stationary and marine boilers, are of an external diameter of $1\frac{1}{2}$ in. and $2\frac{1}{4}$ in., with the exception of the portable boilers, in which smaller tubes are used.

Stationary.

Portable.

In the portable boiler, Fig. 949, the water-space surrounding the fire-box is omitted for the sake of lightness, and the hanging tubes are simply enclosed in a sheet-iron casing which carries the fire-grate. The central flue is carried down below the grate, and a water-space of the shape of an inverted cone is constructed around this flue, with short lateral flues for the escape of the smoke. Into this water-space the ends of the syphon tubes are taken, and the action will be precisely as in the stationary boiler already described. The blow-off cock is situated at the bottom of the conical water-space, and into the bottom opening of the flue the exhaust-pipe of the engine is fitted so as to close the opening, the nozzle of the exhaust-pipe terminating just above the lateral smoke-flues, and the exhaust steam is by this arrangement made to produce a powerful blast. In cases where even this central cone adds too much to the weight of the boiler it is dispensed with, and the circulation and blowing out is provided for by means of a peculiar arrangement of two-way cocks, and the boiler is made without any water-casing at all.

By using very small tubes in these boilers, a large amount of heating-surface can be put into a very small space; and as the boiler contains only a small quantity of water, which is made to circulate very rapidly over a large surface in very thin streams, steam is generated in a few minutes, and with a good blast in the chimney a quantity of steam is supplied for any length of time.

Howard's boiler, Figs. 950, 951, 952, 953, consists of a series of vertical tubes, 4 ft. 6 in. long and 7 in. in diameter, of wrought iron, welded, and closed at the upper end by flat plates less than half an inch thick welded in. Round the lower end of these tubes a heavy ring of cast iron with two projecting lugs is fixed. The tube is roughened at the lower end for a length of about 4 in., it is then placed in a mould and the metal cast about it. There results so perfect a union that the tube and the pipe are virtually rendered one. The tubes are disposed in transverse rows in a flue intervening between the furnace proper and the chimney. The lower ends of all the tubes in a transverse row are united by a cast-iron tube about 10 in. in diameter outside, and of considerable thickness. This tube is further strengthened by transverse perforated partitions. It will be seen that on the upper side of each cast-iron tube, flat pieces, or pedestals, are cast. In each of these is turned an annular groove as wide as the end of the vertical tube is thick, say $\frac{3}{4}$ in., and of considerable depth. The ends of the vertical tubes project slightly beyond their cast-iron base rings, and this projection fits into the circular channel before referred to. The end of the tube is turned off in the lathe.

In two opposite corners of the squares or pedestals on the cast-iron tube, recesses are made, and into each of these is slipped a heavy gun-metal tapped nut. These nuts can be drawn out or put in laterally, but they are held down by the cast iron of the pedestal which overhangs them on three sides. The base rings of the vertical tubes have lugs cast on them, which, when the tube is put in place, correspond with the gun-metal nuts to which they and the tube with them are secured by two bolts, one on each side, screwed into the nuts. Before the tube is put in place, a ring of composition, made of lead and tin, is dropped into the annular groove, and on this the end of the tube rests; and being forced down by the two bolts at opposite sides, makes a joint tight at any pressure which the tubes can sustain, and yet one which may be made and broken ten times in the day if necessary.

Each tube has within it an internal one, similar to that introduced by Ogle, rising up through the water-space, dividing the water into annular and central columns. The current of heated

950.

951

952.

953.

gases impinging upon the tubes, causes the water in the outer spaces to rise to the top and flow down to the bottom of the inner tubes; in consequence, a most active circulation is kept up in every part of the boiler.

From the upper ends of the tubes a short piece of welded gas-pipe rises. This pipe serves to carry off the steam to the main steam-pipe. Between every double row of generating tubes one steam-pipe is fixed horizontally, and the short tubes are bent over by an easy curve and screwed on to the sides of these secondary steam-pipes. All the secondary pipes open into one large pipe running at right angles to them. On this is fixed the safety-valve, and to a flange at one end the steam-pipe to the engine, or, where more boilers than one are used, a branch of that pipe is fixed. The effect of this arrangement is that the generating tubes are only secured at one end, and can, therefore, expand or contract as they like without imposing any strain on any part of the boiler. The steam-pipes are also free to move as they wish, the curve in the small pipes from the generating tube providing sufficient elasticity to meet any demands which are likely to be made on them. The cast-iron bottom mains can expand and contract as they please, and in any direction.

The manner in which the feed-water is introduced will be easily comprehended. Each transverse main has its own supply-pipe.

The furnace consists of the fire-chamber proper, which contains the grate, covered by a heavy brick-arch. In front of this is the tube-chamber, answering very much to the hearth of a puddling furnace; and under this last the flues are returned before going to the chimney. It is one of the distinguishing principles of this boiler, that no joint of any kind is exposed to the action of the fire, or heated products of combustion, while they retain a temperature much above that of the steam within the boiler. In order to carry out this object, the tiers of vertical tubes are set as follows:—The transverse cast-iron mains rest on side walls, and a central wall which establishes a wheel draught; the mains are fixed rather closely together, and, as soon as they are put in place, cast-iron plates are laid between them on flanges or ribs cast on the sides of the mains for the purpose; on these are laid bricks and fire-clay to such a height as to cover the junctions of the tubes with the mains effectually; the lower half of the mains project into the under-flues and absorb the last dregs of heat from the gases on their flight to the chimney. On the upper ends of the tubes wrought or cast-iron plates are also laid, and these are covered with six or eight inches of sand to keep in the heat. By taking off the sand and removing a couple of plates, access may always be had to the interior of the tube-chamber. It will be remarked that the whole tube, steam-space and all, being exposed to the heat, its upper portion would be liable to rapid destruction. To prevent this a provision apparently insignificant, but really very important, is introduced, in the shape of certain screens of fire-clay, which extend across the tube-chamber and protect the upper portions of the tubes from the impact of the flame.

954.

Fig. 954 is a longitudinal section of one of Thomas Dunn's boilers. The lower portion of this boiler is at right angles to the upper portion, and is contained in a chamber or pit of fire-brick: the products of combustion on leaving the flue surround the lower part of the boiler, A, B, C, and

escape to the chimney by the flue B. In this boiler the fire-brick bridge rests upon a hollow perforated cast-iron chamber, within which is a sliding wedge block; this block is now shown open to admit air behind the bridge, and it can be closed from the front of the boiler by the handle and rod shown in the figure. The pipes for heating the feed-water are placed in the flue; and as these pipes are connected to the upper and lower sides of the flue, there will be a constant circulation in the feed-water pipes.

Charles T. Boardman's arrangement for a boiler consists of two cylindrical boilers A A, Figs. 955, 956, placed side by side, and one inclined tubular boiler B, arranged below the rear portions of the

cylindrical boilers, to which it is fastened by the water-legs C C. The object of this arrangement is to provide for the collecting and retaining of the sediment contained in the water in the coolest portion of the generating apparatus. An air-duct *h* and a mixing-chamber H for the admission of air from the ash-pit, L, to mix with the gases of combustion, are also peculiar to this boiler. D D are walls for setting; E, the pier; F, connected parallel upright walls; *g*, the return flue; G, the fire-place; I, J, the bridge-walls; *d d*, flues.

Fig. 957 is a longitudinal vertical section of the Field boiler. The furnace is constructed of brickwork in the ordinary manner, a large flue or chamber being formed at the back, into and

through which the heated products of combustion pass to the chimney. Across this flue or chamber are placed a number of inclined cast-iron tubes *a*, connected by flanged joints with bolts and nuts at their higher extremities to a longitudinal cast-iron tube *b*, constituting the main steam-space. A corresponding longitudinal cast-iron tube, similarly connected to the lower ends of the inclined tubes, and protected by brickwork from the direct action of the products of combustion, serves as an equivalent for the water-casing employed in the ordinary vertical Field boiler, and constitutes a receptacle for the collection and deposit of sediment. The under-sides of the inclined cast-iron tubes have bosses cast upon them, as shown, and tapering holes are bored, into which the wrought-iron Field tubes, *d*, are drifted in such manner that they hang down into the flue. On the upper part of the inclined pipes are formed a number of bosses, through which holes are drilled above each of the Field tubes, and rather larger in diameter than the latter, thus affording ready means of access not only to them but likewise to other parts of the interior of the boiler. Each hole is closed by a tapering plug, secured in its position by two bolts and nuts. The radiation of heat is prevented by iron plates resting on ledges above the inclined tubes, and covered with ashes. Cast-iron plates are placed across the upper and lower parts of the flue, for directing the course of the products of combustion, so that they may impinge in the most efficient manner upon the Field tubes, the circulation of the water in which is of a very perfect character.

Wright's diagonal seam boiler is shown in Fig. 958. It will be observed that in this boiler no three corners meet; this renders the boiler much stronger than the ordinary straight seam boiler.

Figs. 959, 961, show sections of Hawksley, Wild, and Co.'s single-flued, and Fig. 960 cross-section of their double-flued boiler. The flue is strengthened by flanging the smaller rings of plate; each flange in this flue is an expansion-joint, which allows the separate rings to expand and contract without increasing the steam upon the ends or shell of the boiler. A, Fig. 961, shows the combustion-chamber.

961.

Martin Benson's high-pressure boiler is shown in Figs. 962 to 964. Fig. 962 is a front elevation, showing the receiver and circulating pump; Fig. 963 is a longitudinal section of the boiler; and Fig. 964 a transverse section at right angles to Fig. 963.

The boiler is composed entirely of tubes, A, Fig. 963, arranged in a series of horizontal rows over the fire. BB are doorways at the front and back of the boiler, for fixing, disconnecting, and taking out the tubes. C, Fig. 962, is the water and steam receiver; D the circulating pump, which draws its supply of water from the receiver C, and is worked by the small donkey-engine E above. F is the main supply-pipe from the circulating pump, to which the lowest tubes of each section of the boiler are connected. G is the main delivery-pipe, to which the top tubes of each section are joined, and into which the water and steam together are delivered from the tubes and thence discharged into the upper part of the receiver C.

The steam generated in the tubes is driven up with the water through the tubes and discharged through the pipe G into the receiver C, where the steam and water are separated; and the water is then again taken by the circulating pump and returned into the tubes. In starting the boiler, the receiver is supplied with water until its level reaches the fifth or sixth row of tubes from the bottom, as shown by the dotted line; as the circulating pump is standing still at first, in consequence of having no steam to work it, the slide-valve is allowed to be lifted off its face by the pressure of the water, and lets the water flow past the pump direct through into the tubes. The fire is then lighted and steam raised from the water in the tubes, which starts the circulating pump to work.

Benson's boiler was first introduced in the United States, but the one we have described has for many years supplied steam for a 60-H.P. steam-engine at James Russell and Sons' works at Wednesbury.

Fig. 965 shows one of Loader and Child's boilers. The principal feature of this boiler is the introduction of a reservoir or steam-chest in the centre or heart of the boiler, which receives the steam as it is generated, thereby providing dry, and, to a considerable extent, superheated steam; and at the same time the action of this boiler is to throw a thin body of water to the heating-surfaces, by which means steam is rapidly generated by a small quantity of concentrated heat.

The boiler, Fig. 965, is the one which Loader and Child construct for small purposes. It has a cast-iron vertical case, with a copper cone or shell; the supply-tank is formed round the case and sides, and is heated by the flues on the reverse side. By this means much of the heat is utilized. The boiler shown in Fig. 965 is usually heated by gas when not more than 2-horse power is required, but this boiler is easily arranged so that ordinary fuel may be employed.

Locomotive Boilers.—We give, with some alterations, the following illustrations of locomotive boilers from Zerah Colburn's valuable work on 'Locomotive Engineering.'

In a locomotive boiler the outside and inside fire-boxes are made, the former of iron and the latter of copper. The water-space between them, and which completely surrounds the inner fire-box, is closed at the bottom by a square bar. This bar is bent and welded to the proper form, to extend around the bottom of the inside fire-box, and it is riveted and tightly caulked to both fire-boxes. The water in the water-spaces is in free communication with the rest of the water in the boiler; and thus the flat sides of the respective fire-boxes are exposed to the full pressure of the steam, which tends to burst the outside fire-box, and to collapse the inside fire-box. These flat sides, by themselves, would be unable to resist the strain upon them; but as the strain upon the respective fire-boxes is in opposite directions, and necessarily equal for equal areas of surface, tie-bolts, or, as they are called, stay-bolts, are screwed through the plates at frequent intervals, so as to connect the two fire-boxes securely together, the ends of the stay-bolts being also riveted, or spread out by hammering so as still further to increase their holding power.

The flat top of the inside fire-box is of course equally weak with the sides. It could not be satisfactorily secured by stay-bolts to the roof of the outside fire-box, and it is stiffened, therefore, by a series of iron bars, placed on edge, and of considerable depth, and which are firmly connected to the roof or crown of the inside fire-box by rivets. The roof, therefore, can only be crushed downwards by bending these bars, which are of great strength, at the same time. These bars usually extend in the direction of the length of the fire-box, as shown in Fig. 966; but they may extend across it, as shown in section on the roof of the inside fire-box in Fig. 967. These stay-bars bear on the fire-box only for a short distance at each end, iron rings or washers being

interposed between them and the roof-plate at the points where the bolts or rivets which secure the bars pass through. This permits the water to circulate under the bars, and prevents the roof-plate from being burnt, as it would be if the water were excluded from the whole under-surface of the stay-bars.

A horizontal grate of thin and deep bars is fitted across the bottom, forming the bottom of the fire-box; and a door is made to open into the fire-box from the foot-plate. The opening for the door has to be made through the plates of both fire-boxes; and in order to keep the water-space tightly closed, a ring of iron, of which the inner diameter corresponds with that of the door, is riveted between the outside and inside plates.

Thin brass tubes, generally 2 in. in diameter, and from 10 ft. to 12 ft. long, are employed to conduct the hot gases from the fire-box to the chimney, the number of tubes varying, according to the size of the engine, from 100 to 200, or more. The arrangement of these tubes, the uppermost row of which is covered by from 6 in. to 8 in. of water, is shown in all our sections of locomotive boilers. The front plate of the inside fire-box and the front plate of the cylindrical portion of the boiler are accurately drilled, to receive the ends of the tubes, which pass through the plates, and are made steam-tight within them by means of ferrules of wrought or cast iron, which are driven into the ends of the tubes, so as to force them tightly into contact with the interior surfaces of the holes in the tube-plates. Such is the tightness with which the tube-ends are thus secured in their plates, that not only is there no leakage of water, as long as the joints are kept in good order, but the tubes serve as ties to prevent the respective tube-plates from being forced outwards, as they otherwise would be, by the pressure of the steam. Through that portion of the boiler above the tubes a number of tie-bolts extend longitudinally from the smoke-box tube-plate to the back-plate of the fire-box, to hold these plates together against the pressure of steam tending to force them apart.

The tubes lead into a closed chamber, formed upon the front end of the boiler, and called the smoke-box. Although the smoke-box has a removable door in front, this is tightly closed when the engine is ready for working, and then there is no inlet of air to the smoke-box except through the tubes, and no outlet except by the chimney.

Before steam is raised, and when the boiler is empty, it is first filled with water to the height of a few inches above the fire-box, by means of a hose connected with a cock placed on any convenient part of the boiler. In order to know when the water is at the right height there are two gauge-cocks fixed in the back-plate of the fire-box, towards the engineman's foot-plate, the one cock a few inches above, and the other as much below the proper level of the water within the boiler. These cocks have steam-tight fittings connecting them with a glass tube, within which the water, having free access from the boiler through the lower cock, is free to rise and fall, the surface of the water in the glass being under the pressure of the steam, freely admitted from the boiler through the upper cock. The water within the gauge-glass thus has the same level as that in the boiler; and the engineman has only to look at this glass to see what the height of the water is.

To prevent cinders and live coals from falling through the fire-grate upon the line, and partly for another reason, an *ash-pan* is fixed beneath the fire-box, and a few inches off the rails.

It is often important, when the engine is standing, to prevent any access of air to the fire-box; and hence the ash-pan is made to fit tightly to the fire-box on all but the front side. This side is opened or closed at pleasure by a hinged plate, called the damper, which is adjusted by a rod worked from the foot-plate. When the engine is running rapidly, with the damper open, a slight advantage is also gained by the rush of air into the ash-pan. At 60 miles an hour, or 88 feet a second, the pressure of the air against the moving surface would be over 1 oz. a square inch, or 9 lbs. a square foot. For countries where much snow falls, it is necessary to have a damper also at the hind end of the ash-pan, as otherwise it would soon become choked with snow when there was more than a few inches in depth of this upon the ground. In going forward, the front damper is then closed and the hind one opened.

The particulars we have just given are well illustrated by Fig. 966, which is a section of a boiler designed for a goods locomotive by John Ramsbottom. Fig. 966 also shows the steam-dome and steam-pipe.

Fig. 967 indicates the type of boiler used for passenger locomotives by the Rogers Locomotive and Machine Works, U.S.

Fig. 968 represents the boiler designed by Joseph Beattie, and used on the London and South-Western Railway, for burning coal without smoke. The fire-box is divided by an inclined water-partition into two compartments, each having its own door, fire-grate, ash-pan, and damper. The principal fire is maintained in the box nearest the foot-plate. The gases rising from the coal are

met by a number of fine streams of air entering through the perforated door, and both the gas and air rise through a grating of fire-clay tiles into the upper part of the second fire-box, on the grate of which coal is burnt only slowly, with a slight and carefully-regulated admission of air through the front damper.

The mingling air and gases are deflected downwards by a hanging water-bridge, over a fire-brick arch and through a series of fire-clay tubes into a combustion-chamber 4 ft. 6 in. long, from which more than 375 small boiler-tubes lead into the smoke-box.

The boiler shown in Fig. 969 was designed by John Haswell for the Austrian State Railways. It is used in steep-gradient locomotives for curves of 275 ft. radius.

Fig. 970 shows the form of boiler constructed by James Cross for passenger engines on the St. Helen's Railway.

Fig. 971 represents the boiler for a passenger locomotive constructed by Robert Stephenson and Co. for the Stockton and Darlington Railway.

Fig. 972 is the type adopted on the South-Eastern Railway for coal-burning coupled passenger-engines.

Fig. 973 exhibits a boiler for a goods engine used by John Wakefield on the Great Southern and Western Railway, Ireland.

Of all the boilers we have enumerated, none is superior to the *Whittle* boiler.

BOLSTERS. FR., *Estampes, perçoirs*; GER., *Lochscheiben*; ITAL., *Cuscinetto*.

Bolster.—In carpentry, a short piece of wood, Fig. 974, interposed horizontally between the head of a post and a beam which it supports. It is also called a *corbel-piece*, as it shortens the bearing between the posts. The chief use, however, of a bolster is to prevent the head of the post crushing into the part of the beam which rests on it, when the latter is heavily loaded. Bolsters are generally used in timber bridges, masons' scaffolding, and so on.

The term bolster has also been applied to the pieces of timber placed across the ribs of the centering of an arch to support the voussours; but these are more generally known by the name of *laggings*, for which see **CENTERING**.

BOND. FR., *Appareil, Assemblage*; GER., *Mauerverband*; ITAL., *Legamento dei mattoni*.

Bond is a mode of connecting two or more bodies by overlapping.

In *Brickwork* and *Masonry*, it is the mode by which a number of small pieces are combined to form a large mass so that no joint in a course shall occur over a corresponding joint in the next course, which is termed breaking joint.

Bricks are usually in length about twice their width, and in thickness about one-third of the length. For bonding, however, the latter dimension is not of much importance, provided it is uniform in all the bricks of a course.

When a brick is so placed in a wall that its greatest dimension is at right angles to the face, it is called a *header*, and when parallel to the face it is called a *stretcher*.

The methods of bonding brickwork generally adopted in England, are known as Old English Bond, Flemish Bond, and, to a limited extent, Garden-wall Bond.

In Old English Bond, Fig. 975, a course of headers alternates with a course of stretchers.

In Flemish Bond, Fig. 976, headers and stretchers are placed alternately in *each* course.

In Garden-wall Bond, Fig. 977, one header is placed at the end of every three stretchers in each course.

Of the three methods of bonding, the Old English is the strongest, and takes less time to build than Flemish Bond; the joints are more uniformly broken than in the others, fewer *bats* or broken bricks are required to make the work solid, it contains more headers, and consequently there must be a better tie between the face and heart of the wall.

3 Bks.

Figs. 978, 979, 980, 981, and 982, show sections of walls in Old English Bond, from one to three bricks in thickness, with mode of bonding the heart of such walls.

Flemish Bond is considered to have a neater appearance; and in cases where a wall is faced with bricks of a superior quality, a less number is required than in Old English Bond.

Fig. 983 is a course of bricks laid in Old English, and Figs. 984 and 985 are courses laid in Flemish Bond; in the former the bricks all fit close together, and none of them require to be broken, or snapped, as it is termed, except the closer, the reason for which will be explained

presently. In the latter the headers must either be snapped, as in Fig. 985, or the heart of the wall filled up with small pieces of bricks, as in Fig. 984.

Garden-wall Bond is, as the term implies, chiefly used in the one-brick walls so frequently seen between the back-yards or gardens of town residences. The necessity of preserving a fair face on *both* sides of the wall is the cause of this bond being used, as, owing to the difficulty of procuring bricks all of one size, it is impossible to build a wall one brick thick in which both of the sides can be worked fair, in either English or Flemish Bond, particularly the former. This is shown in Fig. 986, which is a course of headers laid in English Bond.

Fig. 987 shows how, by the use of Garden-wall Bond, this irregularity in the size of the bricks is rendered less apparent.

One-brick walls are frequently built in Flemish Bond, but one-half of the headers require to be snapped, which leaves no more cross-tie than Garden-wall Bond, while the longitudinal tie is not so good.

In half-brick walls stretchers only are used; this is called chimney bond.

In Belgium and north of Germany the system of bond used is that called Kruisverband, Figs. 988 and 989.

The heading and stretching courses are as in Old English Bond, but the alternate stretching-courses *break joint*, while the joints of the corresponding heading-courses fall one over the other as in Old English Bond. As more of the joints are broken than in the other method described, this bond is considered to be the strongest of any. It does not, however, present so uniform an appearance as the Flemish or Old English.

The French Corps du Génie prefer to build the face of their walls with all headers, as in Fig. 990; but to obtain a tie between the face and heart of the wall, they place alternately in each course a half-brick, or *bat*, as shown in Fig. 991.

This mode they assert has the advantage of offering more resistance to disruption than any other. The longitudinal tie, however, is not so complete as in the English and Belgian systems, the joints being about one-tenth more numerous, and the waste occasioned by cutting the bricks is greatly to its disadvantage.

In the heart of a thick wall it is considered advantageous to lay occasionally a course of bricks

in a direction inclined to the face, as in Fig. 992. It is known by the name of Diagonal Bond, and when the direction of the brick is reversed in the next course this system adds strength to the wall; but it is attended with the disadvantage of having to cut the bricks to fit the back of those on the face.

From the fact that bricks are made in width equal to half their length, it becomes necessary, in order to break joint between the bricks of two adjoining courses, whether they be laid as headers or stretchers, to insert a quarter-brick in one of them at starting. This is called a king-closer, and is usually inserted in Old English Bond after the first brick is laid in the heading-course, and in Flemish Bond after the first headers. They are shown in Figs. 975 to 977.

In the French, and sometimes in the Belgian methods of bonding, the same result is obtained by starting one of the two adjoining courses with a stretcher cut to three-quarters of the usual length, called a queen-closer.

The bond adopted in *Ashlar* masonry is similar to the bond used in brickwork; closers, however, are seldom used in masonry, as the stones in the courses can be cut to any length required to make a perfect bond.

Diagonal Bond.

Plan.

In walls of rubble masonry from 1 ft. to about 3 ft. thick, it is usual to have at intervals of from 4 to 6 ft. a stone called a thorough, which runs from the back to the front, and so binds the wall together; but in thick walls, owing to the great length of the stone required, two stones of as great length as can be procured are made to lap in the middle of the wall; and in very thick walls, where stones cannot be found long enough to lap in this way, a third stone *b*, Fig. 993, called a tail or heart bond, is used to connect the two bond-stones or binders in the face of the wall.

Various special modes of bonding have been adopted in works of masonry where great strength is required, as in sea-walls and similar constructions. That used by Smeaton in building the Eddystone lighthouse consisted of a system of dovetailing and dowelling, for a detailed description of which the reader is referred to his account of this great work. See CONSTRUCTION. MASONRY.

Bond-Course.—A course or horizontal layer of some material built at intervals into a wall in order to strengthen it.

When of brickwork, and built into rubble-stone or flint walls, it is termed a *lacing course*.

In brick walls built with ordinary mortar, two or three courses of bricks in *cement* are sometimes laid below the floor-line of the basement story of dwellings to prevent damp rising. In this case they would be called a damp course.

Formerly, courses of wood-bond, called chain-bond, were much used in building where there were usually one or more tiers to each story. The size was about $8\frac{1}{2}$ in. wide by $5\frac{1}{2}$ in. high, or equal to the space occupied by a course of brickwork two bricks in height and two in width.

These bond-timbers went all round the walls and cross-walls, and through openings, from which they were afterwards cut out. They were connected at the angles, and no doubt tended much to strengthen the building for a time; but sooner or later decay set in, and the destruction of the building was the consequence. That and the increased danger from the effects of fire rendered chain-bond objectionable, which has in later years caused it to be almost abandoned.

Common bond of fir, $4\frac{1}{2}$ in. wide by $2\frac{1}{2}$ to 3 in. thick, is now more generally used, less as a bonding-course than a means of fixing battens or other finishings which are nailed against the wall.

When common bond is used solely for fixing battens, it is called *ranging-bond*, and is usually placed at intervals of from 18 in. to 3 ft., according to the strength of the battens.

Though common bond is open to the objections urged against chain-bond, but in a lesser degree, its use is preferable to plugging the walls where much of the latter is required, or even to the insertion of wood bricks, which are only short pieces of common bond about the size of an ordinary brick. The act of driving plugs shakes the wall, and destroys the adhesion between the bricks and mortar, and wood bricks shrink in time and drop out.

Ranging-bond should project a little beyond the face of the wall to permit a free circulation of air at the back of the battens or other work which has been fixed to it.

Common bond is usually described in specifications to be put all round each story in one or more tiers; all joints to be properly lapped at least 6 in., and the angles halved and notched or coggled. No bond-timber should be permitted in an underground story, as its decay would be more rapid and the danger to the brickwork resting upon it greater than in the upper stories.

When walls require strengthening by the use of bond-courses, *hoop-iron* is much to be preferred to wood. By its use Isambart Brunel, in 1835, managed to construct two half-arches of brickwork in *lias-lime* mortar, projecting 40 ft. from each side of a single pier, without any support at the other end.

Although only $4\frac{1}{2}$ ft. wide on top, after another 20 ft. in length had been added to one end, a

counterpoise of $28\frac{1}{2}$ tons was added to the other; yet it bore this enormous weight for upwards of three years, and probably would not then have given way if it had not been for a considerable settlement which had taken place in the foundations. Cracks appeared in the work, and, the wet getting in, it expanded during a severe frost, and so caused the failure of this wonderful piece of construction.

Several pieces of hoop-iron, $1\frac{1}{2}$ in. wide and $\frac{1}{4}$ th of an in. thick, were used; also pieces of fir, $1\frac{1}{2}$ in. square, which did little more than assist in retaining the bricks until sufficient adhesion had taken place with the mortar to allow the hoop-iron to take effect.

Hoop-iron bond had also been used by Brunel in the large circular shafts, 50 ft. in diameter, leading to the Thames Tunnel, which were built above ground, and lowered into their places—a depth of 42 ft.—by excavating underneath, an operation successfully performed without a crack or flaw, which was considered to be due in a great measure to the use of the hoop-iron.

To prevent decay when in contact with the wet mortar of the walls, the hoop-iron should be well coated with a mixture of tar and pitch, and afterwards with sand. The form in which it was most generally used in building is that known as Tyerman's Patent Hoop-iron Bond, from $1\frac{1}{2}$ to $2\frac{1}{2}$ in. wide, and from No. 6 to No. 15 Birmingham wire-gauge in thickness. It is prepared from the ordinary hoop-iron by notching it at intervals of 12 in. on both sides alternately, Fig. 994, and turning in succession, in contrary directions, a triangular piece, so as to form claws, which catch in the brickwork and effectually prevent its being drawn out by any force short of tearing the iron asunder. In modern practice, however, the notching has been considered unnecessary.

Tiers of two or more strips, according to the thickness of the wall, laid at every 3 ft. in height, have been considered sufficient in most cases. The mode of laying each tier is to place a strip on every half-brick in the thickness of the wall, continued over the whole length of the work, regardless of openings, as in wood-bond. Afterwards the parts across the openings are cut so as to leave a short piece protruding, which should be turned down against the face of the *jamb*. At all junctions it should be lapped, and the pieces carefully hooked to each other.

In footings or in thick walls exposed to great strains, strips of hoop-iron should be laid diagonally, interlacing with those laid in a longitudinal direction.

Bonding-courses of dressed stone have been used with advantage; they should be cramped together at each joint.

The ancient Romans used a large flat tile, about 2 ft. long by 18 in. wide, laid at intervals of about 4 ft. in height. Bonding-courses of this description, however, are more applicable to rubble masonry than to block-stone or brickwork.

Bonding-bricks are bricks of greater length than those of which the wall is built. They are used in hollow walls to tie the two faces together. Their length should be as much longer than the ordinary brick as the space over which they bond.

Some very effective bonding-bricks have been introduced by a London manufacturer, the ends of which are of a dovetail shape, Fig. 995; and, where the precaution is taken to cut the adjoining bricks to fit, nothing can be more effective.

These bricks are usually made non-absorbent, by being glazed, so that damp cannot be conveyed by them from the outer to the inner skin of the wall.

When ordinary bricks are used in this way for bonding, they should be dipped in boiling pitch, or tar, to prevent the damp passing from wall to wall.

BONE-MILL. FR., *Moulin à os*; GER., *Knochenmühle*; ITAL., *Frantoio delle ossa*.

The mill invented by E. P. Baugh for grinding bones, ores, and other hard substances, is shown in Figs. 996 to 1001. Baugh's improvements refer to that class of cast-iron grinding mills, the cutting and triturating surfaces of which are made in the form of a frustum of a cone. The shell and burr are constructed of a number of cast-iron grinding sections, fitted and held together in a peculiar manner (which will be described presently), so that the sections can be readily removed to make way for others; the dress of the mill being thus rendered changeable to suit the substances to be ground; while the mill itself is more economical, both as regards its original construction and its lasting properties, and the variety of substances which it may be arranged to grind, than mills of the ordinary construction. The grinding sections of the shell are backed by an exterior casing, between which and the base, to which the casing is secured, are confined the sections, so that the latter can be readily disconnected from the mill. The several sections of the burr are secured to a block between a lip or ring, or other projection, at or near the lower edge of the latter, and a ring fitted to the vertical shaft, which carries the burr so that the sections can be readily detached. The ring, which aids in securing the grinding sections of the burr, has grinding teeth formed thereon, and a breaker or stirrer is fitted to and turns with the vertical shaft of the mill; provision being made for rendering it easily detachable therefrom, so that different forms of breakers may be applied to the mill. Certain detachable sections are used, acting in conjunction with the breaker for preliminary grinding; these sections being fitted to and backed by a casing, and held in position by a cap-plate secured to the same, and carrying the bearing for the vertical shaft which carries the burr. The vertical shaft, with its burr and other appendages, are supported on

994.

995.

a sliding step controlled by a lever and an adjustable weight, which tends to elevate the burr, but is limited in this tendency by a screw or other adjustable stop, the burr by this arrangement being maintained in the desired proximity to the shell, but being prevented from coming in contact therewith and injuring the grinding surfaces; the burr, at the same time, being at liberty to yield, should a piece of iron or other refractory material find its way between the grinding surfaces. In order to reduce friction and facilitate lubrication, a double cone of steel is interposed between the bottom of the vertical shaft and the bottom of the step in which the shaft turns.

Fig. 996 is a half section and elevation of the improved mill; Fig. 997 is a sectional plan of the upper portion of the mill; Fig. 998 is a similar view of the lower portion; and Figs. 999 to 1001 are details, which will be referred to hereafter. A is the base-plate of the mill, secured to a foundation B, and on this plate are fitted suitable bearings *aa* for the horizontal shaft *c*, the latter being furnished at one end with a fly-wheel, and between the bearings *aa* are fast and loose pulleys *bb'*. At the opposite end there is a bevelled pinion F, gearing into a bevel-wheel G, which is so secured to a vertical shaft H, that both must turn together, while the shaft is at liberty to slide up and down through the boss of the wheel. This shaft has its lower bearing in a step I, shown on a larger scale at Fig. 1001 in a casing V, and which is secured to the base-plate A, as are also four columns J J, which support the lower plate K of the mill and its superstructure.

To the vertical shaft H is secured the burr of the mill, which consists of the block L, of cast iron, and the detachable cast-iron grinding sections *e*, the block being of the form, or approximating to the form, of the frustum of a cone, the sections conforming in shape to that of the block, and being secured thereto in the following manner:—Round the lower edge of the block there is a ring *f*, and against the inside of the upper projecting portion of this ring bear the lower ends of the detachable cast-iron sections *e*, the latter having at their upper ends lips or flanges bearing on the top of the block, and confined thereto by set screws or bolts *h*. The form of each section is such, that one section will fit accurately against the adjacent section, the whole of the sections thus forming a continuous grinding surface.

The shell of the mill also consists of a number of cast-iron grinding sections *i*, fitted together edge to edge, and backed by an outer casing *M*, of the form, or approximating to the form, of a frustum of a cone, to which casing the sections are fitted, and by which they are held in place, the lower ends of the sections being confined between the flange *j* of the casing *M*, and the flange *k* of the cast-iron ring *N*, by bolts *m*, which secure together the casing and the ring, the latter being confined to the plate *K* by bolts *n*. In the present instance the case *M* is carried upwards in the form of an inverted frustum of a cone, and is lined with detachable cast-iron sections *p*, which are held in place by the cap-plate *P*, secured to the top of the casing *M*, this plate having openings *ss*, and a central boss *g*, through which the shaft *H* passes, and in which it turns.

A stationary nut *Q*, connected to the boss of the cap-plate *P*, receives a screw *R*, the upper end of which is provided with a hand-wheel *S*. It will be seen that the shaft *H* has a feather *t*, adapted to a groove in the block *L* of the burr, and to a similar groove in the ring *g* of Fig. 1000, above which a sleeve *T* is fitted to and turns with the shaft, as it has a groove to receive the feather. To the sleeve is fitted what may be termed the breaker, Fig. 999, which consists of a boss *U*, having one or more projections *u*, the sleeve having grooves adapted to keys or feathers in the boss of the breaker, Fig. 997. Both the breaker *U* and the sleeve *T*, as well as the ring *g* and the burr, are confined by a nut *v* adapted to screw threads on the vertical shaft *H*.

The foot-step bearing *I*, previously alluded to, consists of a cast-iron box, arranged to slide in the cylindrical casing *V* secured to the base-plate *A*, and is furnished with a steel bush *x*, in which turns the lower end *x* of the vertical shaft *H*. Between the bottom of the shaft and the bottom of the bush intervenes a double cone *x'*, of hardened steel, made somewhat less in diameter than the shaft, as shown clearly in Fig. 1001.

A lever *W*, passing through a slot in the casing *V*, is hinged at one end to a pin on a stud *y*, secured to the casing, and bears against the under-side of the step *I*, the lever being connected at its opposite end by a link *X* to a lever *X'*, which is arranged for receiving a movable weight, and is hinged to a bracket *Y*, secured to the plate *K*; a set screw, 2, adapted to a nut on a stand, 3, secured to the base-plate *A*, serving to limit the upward movement of the lever *X'*.

Prior to setting the mill in motion, the lever *X'* is so weighted as to more than balance the vertical shaft *H* with its burr and breaker, so that the said shaft may have an upward tendency, which, however, is limited by the set screw, 2, the latter determining the distance apart of the grinding surfaces of the shell and burr. By this arrangement the grinding surfaces are maintained in sufficient proximity to each other to act properly on the material to be ground, but will not come in contact with each other; at the same time, should a piece of iron or steel find its way between the grinding surfaces, the burr and shaft will yield and prevent injury to the mill.

The shaft *H* and its burr and breaker having been caused to revolve in the direction of the arrow, the bones, quartz, or other material to be ground, are passed through the openings *ss* in the cap-plate *P*, to the conical space bounded by the detachable sections *p*. Here, by the combined action of the teeth or dress on these sections, and the revolving breaker *U*, the material is fractured and reduced to comparatively small fragments when it has reached the ring *g*; by the combined action of the teeth on the periphery of which ring, and those near the lower portions of the sections *p*, the material is reduced to a condition which permits it to enter the space between the grinding sections *e* of the burr and those of the shell. As this space becomes gradually narrower towards the lower end of the shell and burr, the material becomes gradually reduced, and finally leaves the grinding surfaces in the desired pulverized condition, and falls into the space within the ring *N* on to the slightly concave surface of the plate *K*, where it is acted on by the revolving sweep, 4, the latter causing the discharge of the ground material through a spout, 5, into any suitable receptacle.

By making the grinding surfaces in sections, not only can both shell and burr be made truly round, but the teeth can be made of the most irregular character; for instance, the teeth or dress can be formed by grooves crossing each other, or some of the grooves may be straight, some curved, others diagonal, according to the nature of the material to be operated on. An indefinite number of changes may be made in the character of the dress when this mode of constructing the grinding surfaces of conical mills is employed, an important advantage, as the dress must be made to suit different materials, and in many cases different qualities of the same material to be ground; a dress for grinding bones, for instance, would be unsuitable in some respects for grinding quartz; and in operating on other substances it may be advisable for the dress of one section to differ from that of another in the same mill. It will thus be seen that the character of the mill may be entirely changed by a simple and speedy change of sections, and that when the teeth of one or more sections have become worn, broken, or otherwise inoperative, their removal, and the introduction of new sections, renews the mill, whereas an ordinary cast-iron mill would, under similar circumstances, have to be discarded.

In removing the grinding sections, the screw *R* plays an important part; for should it be desired to remove the sections *i* of the shell and the sections *e* of the burr, all that is necessary is to first detach the nuts of the bolts *m*, loosen the nuts of the bolts *n*, and the nut *v*, and then operate the wheel *S*, so as to cause the end of the screw *R* to bear on the top of the vertical shaft *H*, and continue to turn the screw until the entire shell of the mill is elevated so far as to permit the withdrawal of the sections of the burr and shell and the introduction of others, after which the shell is lowered by turning the screw in a contrary direction, the nuts of the bolts *m* replaced, and the nuts of the bolts *n*, as well as the nut *v*, tightened.

Should it be necessary to remove the sections *p* only, the nuts are detached from the bolts which confine the cap-plate *P*, and the latter is elevated above the mill by operating the screw *R* when the sections are at liberty. After elevating the cap-plate clear of the shaft, the nut *v*, breaker *u*, and ring *g*, may be readily removed.

It has been found, after repeated experiments, that the double cone *x'* performs most efficiently the duty of distributing to the lower bearing the oil contained in the space between the bottom of

the shaft and the bottom of the step I, at the same time preventing undue friction at the point subjected to the greatest shocks and strains. This mode of interposing the double cone between the bottom of the shaft and the bottom of the step may be applied to the lower bearings of all vertical shafts, to the pivots of swing-bridges and turn-tables, and other objects having a vertical bearing to which great strains are subjected.

For grinding some materials it is not essential that there should be a superstructure M', and detachable sections p, or a breaker above the shell M, a simple hopper being in many cases all that is necessary to receive the material and direct it to the grinding surfaces; the latter, too, may (for grinding some materials) be straight instead of curved. It is preferable in most cases, however, to form teeth on the periphery of the ring g, as shown at Fig. 1000, so that it may serve the twofold purpose of aiding in the preliminary or first grinding, and of keeping the sections c of the burr in place. The lips of these sections e may, moreover, be dispensed with, the ring g bearing directly on the upper edges of these sections. The casing M, too, may be made in sections, or the grinding sections may be backed or held together by a suitable system of metal bands. See AGRICULTURAL IMPLEMENTS, p. 12, Fig. 27.

BOOT-MAKING MACHINERY. FR., *Machines à faire les bottes*; GER., *Maschine zur Anfertigung der Stiefel*.

The introduction of the sewing machine greatly facilitated the operations of boot and shoe manufacturers, and other workers of leather. The principal leather-sewing machines will be found in our article on *Sewing Machines*. But other boot and shoe making machines and tools are also employed to economize labour in this important branch of industry, the most useful and important of which are introduced under the present head.

Fig. 1002 represents Gimson's machine for paring the edges of heels and soles of boots and shoes. This machine consists of two standards A with a stretcher B, a driving-shaft D which gives motion to a spindle e driven with high velocity; on this spindle, discs or circular cutters E are fixed; the boot or shoe is held against the cutter, the uppers being protected by a loose guard which runs in between the upper and the sole. These machines are easily worked; a man can pare at one of them twenty-four dozen pairs a day; they are fitted with an additional counter-shaft for gaining speed, so that these machines may be worked from a shaft of ordinary speed.

A primary operation in boot-making is that of cutting leather into strips for soles and heels. Jean Pierre Mollière's machine for effecting this is shown in Figs. 1003 to 1005. The leather being placed upon a table A, it is slipped under the frame; the traveller K being one of the extremities of the apparatus does not hinder this being done. To cut the edge of the leather straight, the leather is kept in position by means of a ruler M, which is a piece of iron with a longitudinal groove

1002.

1003.

1004.

1005.

in it, in which the curved knife-blade or chisel O works when the ruler is down; and at each end of the groove is provided an opening into which the traveller K can pass. The ruler is

governed by two spring-rods N buried in the thickness of the table, and whose springs always tend to keep it raised: these rods are connected under the table by a yoke P attached to a treadle not shown in the figures.

When the leather is pushed under the rule, the treadle is depressed, thus pressing down the rule and keeping the leather firmly in its place. The handle R is then moved, throwing the parts for moving the chain into gear, and thus setting K in motion and cutting the leather. Arrived at the end, the traveller encounters one of the fingers S attached by levers T to a rod Q, forces it forward, and throws the chain out of gear, thereby arresting the traveller. The traveller is then let up, which will allow the springs N to throw up the ruler M, so as to let the leather pass, which is then cut straight. The workman pulls the leather towards him until its smooth edge comes up to the two pins 3, and then the operation just described is repeated.

In preparing leather for uppers upon C. Rice and S. H. Whorf's plan, Figs. 1006 to 1008, the skin is first introduced between the feed-rollers A, B, of the splitting mechanism, and by them is forced against the knife C; the upper portion of the skin

split by the knife C passes towards and between the draught-rollers D, E, which move it forward between the roller F and a rasper G, which latter roughens the under-surface of it. From the rasper the leather moves over a guide-bar W, between the pressure-roller I and the perforating-roller H; and finally it passes between the roller, and a brush K, which latter revolves through a vessel L containing cement, and applies the cement to the roughened surface.

A machine for cutting out boot and shoe soles, invented by J. W. Hatch and Henry Churchill, is illustrated by Figs. 1009, 1010. A is a shaft carrying at its lower end a shoe B, to which a punch C is secured; shaft A is provided with journals which fit in boxes secured to the front of a slide P, which, fitting in vertical guides in the framing of the machine, receives a vertical reciprocating motion from eccentric pin p, Fig. 1010, on the end of a driving-shaft Q.

When shaft A reaches its highest position, a spur-wheel E comes to gear with a toothed segment F' on the front of a lever F; lever F has its fulcrum in a vertical pin a, and, at the time the shaft A is at its highest position, a cam I strikes the rear end of the lever F and moves it round its fulcrum a a sufficient distance to cause a spur-wheel E with its shaft A to describe half a revolution.

When the shaft A is about reaching its highest position, the square part of it, b, rises above the guide J, and the round part of the shaft d comes in contact with the guide, thus permitting the shaft to describe its half revolution.

The boot-form introduced by Chilcott and Snell, Figs. 1011 to 1013, has a clamp E, which consists of a strip of sufficient length to reach from the nick at f to the top of the front-piece A. This clamp E is prevented from being pulled out laterally by entering a recess g in the nick, and is secured at top by a latch h catching a pin i on the top of clamp E. The inside of the strip is furrowed from end to end, and the recess in which it is received is correspondingly furrowed to hold the material securely. The clamps I, I, fitting to the outside of the front-piece and partly over the clamp E, are attached to screws K K, which fit in female screws in the rod L. This rod L is fastened at its lower end to the bottom part of the front-piece. Its upper end is attached to the front-piece by a plate P in the manner shown in the figures. The plate P is fastened to the front-piece by a screw N, which can be taken out; pins j j serve to hold the clamps I, I, in position.

Figs. 1014, 1015, refer to J. and E. Arthur's machine for cutting uppers and soles from sheets of india-rubber. The endless apron B, which has an intermittent motion, receives the sheet of india-rubber a; the cloth J between the rubber and apron being properly wetted by its passage through a water-trough F. Two endless chains K carry the die-frames d with the heated dies f. The die-frames are pivoted to the chains at g, and are carried by the chains through the stove M and over the roller D. When over the roller D, the sides of the die-frames come under stationary plates h, and are in their onward motion firmly pressed upon the india-rubber, which is thereby drawn over the roller D at the same speed with the dies. The dies cut, or rather melt, through the rubber taking out pieces according to the shape of the dies. The pieces are conducted to the apron G by means of thin fingers (twenty) secured to a swinging frame r, whilst the waste still remaining attached to the piece a passes over rollers l and m, and between m and n, on to the apron o. As soon as the die-frame, after having performed the cutting, comes round the chain-roller b, the extensions v of the frame will strike and pass under the pin x, which throws up the front part of the die-frame so as to make room for the die-frame which passes below.

In Mollière's machine for cutting uppers, Fig. 1016, G is the piston of the steam-cylinder operating the bed I. The skins are laid upon the bed I, and the cutters, consisting of pieces of bent steel, placed upon the skins, and then steam-power applied to lift and press the table, skins, and cutters, against the head-block C, so as to cut pieces corresponding to the shape of the cutters.

With Mollière's machine for rasping and dressing heels and soles, Fig. 1017, the operator applies the bottom of the sole first to the tool T, for the purpose of having the rough parts of the leather and the jags of the nails taken off; the sole is then applied to the tool f, and the heel to a tool v, to finish the dressing. During the whole of the operation the tools are kept turning very rapidly.

1016.

1017.

Figs. 1018 to 1023 refer to Mollière's machine for cutting out, punching, and stamping soles. The cutting out, pricking, and stamping, or numbering of the size of the shoe, is done at one blow, by means of punchers *a*, of the shape of the sole and heel, provided with prickers *d*, and stamps *e* and *P*. *m m* and *o* are the detaching-rods, the rods *m* working through holes *h* in the punching-frames; the punches are operated by eccentrics upon shaft *L*, which eccentrics are so set that the punches will, one after the other, arrive at their lowest or punching position, so as to distribute more equally power and resistance. When the punchers pass upward, the pieces of leather encounter the rods *m*, which are stationary, and are detached by them from the punches. The rod *Q* serves as stamp, and also as detaching-rod for the heel-pieces. The workman holds the strip, and puts it under the puncher; but, as this must be done with great rapidity, the leather finds itself guided and stopped in such a way that it can be instantly moved into its place. The guides to effect this consist of two pieces *r*, forming the sides of a square—one of which is graduated, and has on it the numbers of the sizes. As the puncher is always in the centre, these guides must be governed by a single movement in their approach to and retreat from it. This is done by the following mechanism:—Two pieces *S* slide on a guide-bed, and have an oblique groove, in which plays a pin fixed to the guides *r*; these two pieces *S* are connected by the cross-tie *t*, and controlled by the screw *u*, which, being attached to a bracket, causes the traverse *t* of the pieces *S* to move forward or backward, so that the pieces *S*, by their oblique grooves, push forward the guides. The stopping-piece *x* is supported upon a small axis *v*; it is kept down upon the leather on the flat by the counter-weight *y* attached to the axis, while the puncher is cutting; a spring-catch hitches under the piece *z*, and lifts up the stopper as fast as the puncher rises, which leaves time enough to remove the leather that has been cut; when it gets up as far as it can, the piece *z*, which has described the arc of a circle, lets the catch go; and, being drawn down by the counter-weight *y*, the stopper falls back to its place.

Horace Wing's wrinkling or crimping machine, Fig. 1024, consists of a frame *B*, upon which is arranged a crimping-plate *F*, so constructed as to leave its front end unobstructed. It is pivoted at the inner end to a fulcrum-bolt *H*, and operated by means of a gear-segment *L*, attached to a lever *L'*, engaging with a corresponding gear-segment *I* on the outer end of the lower limb *M*.

Figs. 1025 to 1027 represent Warren Holden's boot and shoe stretcher. If one side of the boot is to be stretched, a knob *n* is attached to one of the parts *e*, and the corresponding side of the boot is properly moistened. The last is then placed within the boot, and the screw *l* is turned, thus forcing apart the sections of the last, and stretching the moistened side of the boot. If the

toe of the boot requires stretching, the link *d* is disconnected by removing the screw *d'*. The turning of the screw *i*, in the position shown by Figs. 1026, 1027, will expand the front ends of the parts. Should the instep require stretching, the levers *jj* are placed in the groove *i*, Fig. 1025, and the levers then expand vertically. When in the groove *g*, the levers are placed horizontally.

Figs. 1028 to 1030 illustrate H. B. Horton's crimping machine. A piece of wet leather having been laid across the jaws, it is, by the raising of them through the lever *D*, forced upon the crimp-form *F*: by the repeated sliding up and down of the jaws on the leather, it is thus smoothed, and embraces the crimp-form. Should there be any thin place in the leather, and the wrinkle not perfectly removed, the nearest set screw *d* is turned, and the wire *bb* made to project beyond the face of the jaw opposite the screw. The angle-iron *G*, clamps *I*, and screw-rod *H*, serve to draw tight the leather on the crimp-form.

Referring to Figs. 1031 to 1033, which show Daugherty's boot-crimp, the slides *L M* fit loosely to the arms of the elbow *G*. The nut *I* is provided with projections *aa*, which extend up each side of the elbow so as to form two inclined planes which correspond with the inside of the clasp *K*, which clasp is perforated so as to traverse freely upon the screw *H*, and the inside of the arms are scored so as to gripe the leather upon the projections *aa* of the nut. The edges of the leather having been inserted between the slides *L M* and clasps *P Q*, and between clasp *K* and nut *I*, the screw *H* is turned, by which means the elbow *G* is moved outward, and with it the clasps, thereby stretching the leather. As the screw is turned, it slips a little on the nut, and slides and draws the clasps on, so that the scored part of the clasps gripes the leather tight. The elbow, and so on, are received in a groove in the crimp-board *A*, formed by projections *E* and *F*.

Thompson's machine for polishing the soles of boots or shoes, Figs. 1034, 1035, is of simple construction, having a polisher or polishers *gh*, made of bone or other proper material, attached to a shaft *f*, which has a reciprocating motion imparted to it in any desirable manner.

Figs. 1036 to 1038 represent A. Swingle's hand pegging-machine. By striking with a hammer upon the top of an awl-driver *C*, the spring-slider *D* is driven up into a handle *A*, splitting a peg from the block which is arranged in the space *L* between the said slider and the peg-wood driver *M*; to the latter is imparted a constant tendency to press the block forward by means of an elastic band *N*. The awl *E* and peg-driver *F* work through holes *I* and *K* in the slider, the principal object of the slider being to draw or force the awl out of the leather sole, or other articles, immediately after having been driven into the same. *G* is an india-rubber spring attached to the lower end of the awl-driver.

Hill's machine for skiving boot and shoe counters is represented, Figs. 1039 to 1041. A lever *A'*, turning horizontally, has its fulcrum upon the upper end of a lever *B'*. Studs *ef*, projecting from lever *A'*, rest respectively against the middle of the rocker-frame *S* and the end of shaft *F*. *B'* turns upon a fulcrum at *g*, and is operated by a foot-treadle below. By means of the levers *A' B'*, the clamp-plate *E* and the rocker-frame *S* are simultaneously moved towards the rotary bed *B*; the clamp-plate being carried into contact with the leather to be skived, while the knife is borne against the thin edge of the clamp-plate and against the edge of the rotary cylinder, so that, whatever may be the thickness of the piece of leather, the knife will be made to adapt itself to that thickness. At the same time that the face-clamp is moved towards the cylinder-bed, the peripheral clamp will also be borne down upon a counter placed on the periphery of the cylinder and between the same and the clamp.

Figs. 1042, 1043, show Zeigler's boot-crimping machines. The jaws are corrugated, so as to work the leather away from the angle of the crimping-iron and into the foot and leg of the boot. The nuts *m* serve to stretch the leather upon the crimping-iron. The slots in the plate *K* are so constructed as, in combination with the segment-gear *M* and rack *J*, to move the foot of the crimping-iron into or between the jaws twice as fast as they move the leg, and to give the foot a compound motion which, in combination with the corrugations in the jaws, works the leather in the required direction to crimp it properly.

J. P. Mollière's machine for cutting the edges of boot and shoe soles is referred to in Figs. 1044 to 1047. This plan consists in arranging two revolving tools *G* and *h*, both of the same construction, only *h* being of larger size than *G*. The side of the shoe is first held against tool *G*, placing the edge of the guard-plate *a* between the upper and the sole. The shoe being thus slipped along to the point, and the same way with the other side of the shoe, the edge of the sole is finished with the exception of the heel. The heel is cut by the larger tool *h*, it being provided with a similar guard-plate *K*, in the same manner as the sole.

In working Griffin's machine for cutting out soles, Figs. 1048 to 1051, the operator places his foot on treadle H and moves it up and down, so as to impart to the shaft *c* a reciprocating rotary

1048.

1049.

1050.

1051.

motion, he at the same time holding a strip of leather on the top surface of the table, and against a guide-bar *z*. After each cut, he moves the strip forward against the guide or stop bar. The carriage I has an intermittent reciprocating motion imparted to it, which carries each of the knife-bars K K in succession directly underneath the depressor-bar S, which, descending thereupon, forces the knife-bar and its knife P or R downward towards the cutter-block, and cuts through the leather. Fig. 1051 represents the soles as cut out by the machine. Each knife is elevated from the leather by the springs *a* on the rods that guide its bar K.

In R. H. Thompson's hand machines for pegging, Figs. 1052 to 1055, motion is given to a slide H by striking upon head K. The slide H carries the awl and peg-driver. The peg-driver is intended to drive one peg at the same time that the awl makes the hole for the next peg, the machine being moved the distance from one to the next by a slight pressure of the hand

1052.

1053.

1054.

1055.

in that direction, this distance being measured, and this motion of the machine restricted to correspond, by the spring-spacer T. The point at the lower end of T, being held down by spring W, pierces the leather sufficiently to keep the machine from being easily moved out of place if a slight downward pressure is exerted upon the machine. Just as the slider H completes its descent, the arm O on the slider operates the tumbler P, the latter taking into a notch in the spacer T, and thus withdrawing the spacer from the leather at the time the awl is sunk deepest into it. T has also a slight vibratory motion in a groove in the spacer-plate Y, limited in one direction by the side of the groove, and in the opposite direction by the eccentric adjusting-pin X, by the turning of which the travel of the spacer may be accurately graduated. The spacer bears against this pin; the pressure of the hand in the direction the machine is to move, will, however, move the spacer to the opposite side of the groove; then, as it is raised by each descent of the awl and peg-driver, it will spring forward against pin X, and, as the awl begins to rise, will descend in the same position upon the leather; and when the awl rises so as to clear the leather, the pressure of the hand in that direction overcomes the spring of the spacer, and moves forward the machine for the next peg. The peg-wood is placed between the part G of the feeder and the spring D. This spring-feeder is operated by the head of the screw V, which holds the awl and peg-driver to

the lower end of the slider, and which projects through a slot in the front of the case, striking, as it descends, against a bend in the feeder, and pushing it back so as to give it new hold upon the peg-wood, at the time the wood is held firmly by the cutters and a clamp E.

With Rice and Whorf's apparatus for lasting and applying soles to shoes, Figs. 1056 to 1058, the sole and the upper are first placed together upon a last A, the upper being made to overlap the outer surface of the in-sole, and affixed by cement. The whole being thus prepared, it is next placed within the clamping-bed B, and the parts of the latter closed. The platen of the press is depressed, to carry the punches on the under-side of die *w* into contact with the parts of the upper which overlap the inner sole, so as to make perforations through them, and either into or through the inner sole. The platen C is then elevated, and cement applied to the outer surface of the inner sole and overlapping parts of the upper. The outer sole is laid upon the cemented surfaces, and the slide G moved so as to bring the die *u* directly over the last A. Next, the platen is to be forced down upon the outer sole, so as to press it closely in contact with the shoe, and expel from between the soles the superfluous cement.

Dinsmoor and Bartlett's instrument for chamfering the edges of shoe-soles is referred to, Figs. 1059 to 1061. The piece of leather is laid upon a flat table, and the blade A and spring-presser H are borne down simultaneously upon the leather, while the end of the lever-gauge G turning upon fulcrum *d* is made to rest upon the table. This done, the cutting-edge *a* of the tool is maintained at such an angle from the table as occasion may require, and the tool is pushed forward upon and around that portion of the leather which is to be chamfered. The frame B is fastened to the knife by means of a wedge *a*.

Figs. 1062 to 1064 show J. W. Hatch's machine for cutting out soles. The cutter is attached to a vertical shaft, which is provided with journals to work in bearings in a slide P, moving in vertical guides in a framing C, and receives its vertical reciprocating motion from eccentric pin *a*, at the end of the horizontal shaft D. The shaft in this machine makes only about three-fourths of a revolution in opposite directions alternately, movement being produced by a treadle F, which is a lever of the first order, with its fulcrum *g* at the rear end, secured to the floor or to a suitable bed-plate; the treadle being connected by a rod *o* with a wrist *b*, at the back of the fly-wheel G of the shaft D.

While the machine is at rest, the wrist is always held in one of these two positions by a weight *r* attached to or cast on the fly-wheel, the weight *r* resting upon one of two fixed standards *ff*. In either of these conditions of the wheel and wrist, the treadle is of course raised. The operator stands in front of the machine, in a convenient position for placing the pieces of leather or other material in a proper manner upon the table H for the action of the cutter; and when he depresses the treadle by his foot, he moves the wheel far enough to bring the weight *r* over the centre of the shaft D; but the momentum the weight has acquired in moving to that point carries it past the centre, and then the pressure of the foot being taken from the treadle, it descends by the force of gravity until it reaches the other standard, thus completing the movement of the wheel. This movement of the wheel brings down the cutter and raises it again, and, just before its termination, it moves the lever E to reverse the position of the cutter by the action of one of two projections *dd* upon one of the prongs *ee* of a fork on the rear end of the lever. The prongs *ee* of the fork are at different elevations, and the projections *dd* at different distances from the shaft D, to correspond with the elevation of the prongs *ee*; so that when the wheel moves in the direction of the full arrow shown in Fig. 1062, the projection *d* may pass under the higher prong *e* and strike the lower prong *e*, thus throwing the lever to the position shown in Fig. 1063; but when the wheel moves in the direction of the dotted arrow, the projection *d* may pass over the lower prong *e* and strike the higher prong *e*, thus throwing the lever to the position the reverse of that shown in Fig. 1063. The movement thus given to the lever takes place just before the weight comes in contact with the standards *ff*, and is just sufficient to give half a revolution to the punch-shaft. To keep the cutter-shaft from turning back too soon, the friction of a bar *h* is applied in a yoke I; on the top of the framing, between the top of the yoke I and the bar *h*, the lever E works snugly, and the bar is forced up against the lever to produce the necessary friction by two india-rubber springs *ii*, one at each end. Stop-screws *jj* are also applied to the yoke I, to stop and regulate the movement of the lever.

Polishing or burnishing the edges of heels and soles with Mollière's machine, Fig. 1065, is performed in the following manner:—The steam passes from the boiler through a pipe *x* and into branch pipes *x*, one for each burnishing-tool *p*, and can be let into the hollow shaft *l* and the chamber *p* within the tool *p*, by opening the cock *u*. A number of these tools of slightly varying sizes are arranged in line, and each tool kept rapidly revolving. The polishing is effected by presenting the edge of the sole or heel to the revolving polishing-tool and pressing it gently upon it.

Mollière's arrangement for mounting uppers on lasts is shown in Figs. 1066, 1067. It consists of an adjustable frame I and a thumb-screw G, armed with its tooth-clamp H, which, pressing vertically upon the inner portion only of the heel, holds the last securely in its position, and gives free access to the parts of the last on which any work is to be done by the apparatus.

Jackson's machine for cutting out uppers, Fig. 1068, consists of a frame A, to which is attached a cross-head E; this cross-head is raised and lowered by the action of the shaft in the centre, the wheels I and the levers G. The leather is fed in at D on the platen B; the cutters being fixed to the cross-head, and guided in their descent by the indicators T, T.

Fig. 1069 represents Ellison's boot-holder, which consists of a curved arm A reaching from the sole of the foot to the top of the leg L, where it is fixed. This is used in combination with the lever B provided with a last-shaped foot, a handle K and a ratchet C to operate with a pawl D.

Fig. 1070 shows E. M. Dickinson's machine for holding uppers. It consists of a forked clamp B, arranged on the frame A, and hinged at one end. It is operated by the lever C working the rod *d*, the yoke *k*, and the springs *J*, *i*.

Drew's pattern for cutting boots, Fig. 1071, consists of two pieces of sheet metal A, B, of rectangular form, connected together by hinges; and two other pieces of the same material attached to the former in such a manner as to be capable of being adjusted laterally, one of the over-pieces D having a foot portion provided with a wing connected to it by means of hinges.

The apparatus, designed by O. J. Warren, for crimping, Fig. 1072, is applied to the bench by a swivel process, which permits the whole to be turned to the right or left as the work proceeds. The curved bar G, which supports the form P, upon which the leather is crimped, has its groove lined with india-rubber Q, which prevents the wrinkling of the leather while undergoing the stretching process. A spiral spring is employed to hold together the two parts of the clutch or yoke N, R, and thus retain the work rigidly in any position; but at the same time adapts the clutch to be disengaged to allow the shaft to be turned to bring the work into convenient positions for the operator. The nut K on the screw *k* of shaft B is connected with the yoke N through the medium of the collar L, so as to allow the yoke to be turned independently of the nut. F is a sleeve on shaft B, provided with a projection *j*, and is used in combination with the notched hub G, the collar H, and the spring I. The coupling by which the shaft B is attached to the bench is composed of a plate C, secured to the bench by a screw D, and provided with a socket *a* to receive a pintle of a fork which is fastened to the sleeve F by pivots.

Gustins' movable jack for boot-making is shown in Figs. 1073, 1074. The arms *h*, *f*, of the frame A, have supports, as *i*, for the toe and heel of the boot, and admit of rotation on a pivot at A. The bolt C and the friction-washer *o* prevent a too ready and easy movement of the yoke A upon the bolt in a horizontal plane. The crank-stop *d*, sliding in the blocks *e*, *e*, with the holes in the segment C, Fig. 1074, permit the instrument to be inclined for working purposes.

Referring to Fig. 1075, which shows J. H. Belser's machine for shaping heels, *g* is a toe-clamp, *h* its latch fastened to a standard *e*, which is provided with an adjusting screw *f*, and attached to a shoe-holder A. The knife C works through a rocker-tube E by means of the slider D, which is adjusted so as to act in combination with the arrangements shown at H and G. The position of the heel whilst being shaped is shown clearly at C.

Fig. 1076 shows a side elevation of a machine for cutting out and pricking soles and heels, by Craven and Carrack, of Leeds. The parts A are standards or framework braced together by the table B; C is a shaft, actuated by pulleys *c* through intermediate wheels *a*, *b*. Cams on the shaft C impart a reciprocating motion to the slides D working in V-grooves *d*. The slides are connected by the cross-head E, to which are secured the frames *e*, which carry the wood blocks and guides *f* and *g*. The wood blocks *f* are bound with a hoop of wrought iron, and are adjusted in any desired position by means of set screws *g* in the V-races of the frames *e*. The guides *g*, provided with set screws, are to prevent the leather from being thrust too far either laterally or longitudinally. On

the table B adjustable frames *x* are placed, which carry the clips *h*. These clips support the knives *j*, and may be adjusted by set screws, according to the size of sole or heel required, having V-edges which slide in the frames *x*. The parts *kk* are two spring-clips to stiffen the knives *j*.

1076.

The prickers are not shown, but simply consist of a framework of pricks or needles, of the same contour and pitch as the required line of nails, fastened to the wood blocks and piercing the leather in their descent. The knife *j* and its adjustments will be seen more clearly by referring to the detached plan of the framework *x*, Fig. 1077.

The machine being set in motion, a piece of leather is placed by the attendant over one of the knives, the cross-head descending, the pressure of the wood block cuts the sole or heel required, which drops through the knife and the aperture in frame *x* and table B into any convenient receptacle.

The operation of fastening a sole to an upper was for some time the most difficult portion of boot manufacture by machinery. It has now, however, been greatly simplified by an adaptation of the sewing machine invented by John Keats and W. S. Clark, and termed by them the Crispin Machine.

The leading features of this machine are the combination of a hook and a shuttle, instead of a needle and a shuttle. This arrangement allows of the thread being thoroughly saturated with the wax, which does not get squeezed out, as in passing through the eye of a needle. Further, the hole made in the leather is no larger than the size of the hook, because the hook has no thread in it while piercing the material. Thus, a thicker thread can be used than with the needle. The stitch, which is formed on the surface of the leather, is a twisted lock-stitch, one of the firmest made. The machine is arranged to be driven by steam-power, and the motion can be instantly stopped by a foot-lever at any point of the stitch, so that the workman has the free use of his hands.

Fig. 1078 is a perspective view of the post Crispin, which is used for welted boot sole sewing. Fig. 1079 shows the "arm Crispin," which is employed in heavy work, such as closing heavy uppers, belt-sewing, harness work, and so on. The hook is first fixed by turning the machine by hand until the line cut across the edge of the needle-bar L at the lower end, pointed at by the arrow, is on a level with the bottom end of the slide, and then fixing the hook with its point on a

1077.

level with the point of the divider A, care being taken to have the notch which receives the thread at right angles with the arm of the machine. After the large bobbin is charged with thread and placed in position, the cover and hook-plate at the end of the arm are drawn off, and the thread brought over the guide-pulleys until it reaches the pulley B; it is then passed through the eccentric hole in the small gear-wheel. The thread is then drawn forward and passed through the hole in the hook-plate, the cover and plate being replaced. To thread the shuttle, the bobbin has to be placed in it, with the long centre end foremost. The thread is then passed through the upper slot over the bar and through the lower slot, and then through one of the round holes. The operator then places the shuttle upon the slide, and puts down the hinged stop C. He raises the

1078.

1079.

pressure-foot by means of the lever D, and puts the work under the hook so as to be moved from left to right. After the machine is charged with waxed thread, the gas G is turned on, and lighted through the holes in the side of the arm, and also the jets behind the shuttle-race, until the machine is sufficiently warm to make the wax soft, care being taken not to let the flame come in contact with the casting, as this produces soot, which destroys the heating-power of the gas.

A counter-shaft mounted in the frame under the table being put in motion by the driving-belt, the machine is started by pressing the foot-lever, thereby bringing the pulley covered with leather into contact with the internal pulley mounted on the end of the driving-pinion. The moment the pressure with the foot is withdrawn, the machine instantly stops. Suitable tension of hook-thread is obtained by the thumb-screw M. The feeder is adjusted and kept to push in the required

direction by the round vertical bar being pinched with the thumb-screw E; an angle of 45° to the arm is found most convenient. The pressure is adjusted to the thickness of the work by means of the double screw-nut F. The amount of pressure is adjusted by the screw G. The feeder is adjusted to the thickness of the work by turning the screw H. The length of the stitch is regulated by turning the screw I, which is secured by the lock-nut K. To remove the large bobbin, the pin N is taken out; the tension-spring then forces it out.

The Pricking Machine, designed by Gimson and Co., of Leicester, is used for making small holes in the bottom of the soles and heels of boots and shoes to receive the rivets. It is contrived so that the distance the holes are apart can be varied according to the number of rivets required. It consists of a standard A, Fig. 1080, through which is a small crank-spindle; the treadle B is attached to the crank, and the driving-wheel C is fixed at the other end of the crank-spindle; the motion is imparted by a cord G from this wheel to a worm-shaft; the worm gives the upright spindle D a revolving motion, and the crank E gives to the arm F a chopping motion; the boy works the treadle with his foot, and with his hands presses the sole against the guide tooth wheel D; this wheel, revolving slowly, moves the sole the required distance as each prick is made by the arm F.

Gimson's Eccentric Press.—This machine, Fig. 1081, is used for cutting up leather, and is constructed for the use of four men; the cross-head E moves upwards and downwards, and receives its motion from the driving-shaft A, which

has a pinion attached, and works into the internal toothed wheel B, which wheel is keyed to the eccentric shaft C; the eccentrics are fitted with straps connected to a stretcher—this is fixed to the side D, attached to the cross-head E; the screws H are movable, and can be adjusted by the man to suit the depth of the knife and range of the cutting-tools; wooden blocks G are used to cut upon; the leather is placed on the block, the knife being put on by the man, who also pushes it under the cross-head which comes down upon it and cuts out the sole; the block is then pulled from under the knife, placed on another part of the leather, and the process repeated.

BORING AND BLASTING. FR., *Action de forer et de faire sauter par une mine*; GER., *Das Bohren und Sprengen einer Mine in Bergwerken*.

Boring for Minerals.—There is but little difference in the system of boring for minerals or boring for water; the kind of rock to be penetrated does not even cause any material difference to be made in the means or tools by which it is done. A hole of 3 in. diameter is in all cases sufficient for a test on a mineral vein. In the U.S. the hemp or manilla rope is used for boring. This is called the Chinese method, because the Chinese have practised boring in that manner since our knowledge of them. The Germans penetrate the rock by means of iron rods, of 1 in. square or more. These rods are screwed together in lengths of 10 or 12 ft. This mode of work causes the operation to be rather expensive, on account of the price of tools and machinery, and it is not very expeditious. The same method was followed by other European nations, and formerly in this country. In recent works of this kind, wooden rods have been used with greater advantage than iron. These rods are long slender poles of pine wood, often 30 and more feet long, mounted with iron and screwed together; they have the advantage of being light and elastic, so as to cause less concussion and consequently less repair than iron rods. Rods offer no advantage over the rope but that of longer durability, and the earth may be penetrated to a greater depth by means of them than by ropes. The latter are limited on account of strength to about 1000 ft., while rods may be driven down to 2000 ft. and deeper. We will describe an apparatus which may be used either for hemp-rope or wire-rope, which was made originally for hoop-iron by the well-known metallurgist, F. Overman, it being cheaper, and served the same purpose as ropes of either kind.

At A, in Fig. 1082, is represented a log of oak wood, which is set perpendicularly so deep in the ground as to penetrate the loose gravel, and pass a little into the rock, so as to stand firm in its place; it is well rammed by gravel, and the ground levelled so that the butt of the log is flush with the surface of the ground, or a few feet below. Through this log, which may be, according to the depth of loose ground, from 5 to 30 ft. long, a vertical hole is bored by an *auger* of a diameter equal to that of the boring in the rock. On the top of the ground, on one side of the hole, is a windlass, whose drum is 5 ft. in diameter, and the cog-wheel which drives it 6 ft.; the pinion on the crank-axle is 6 in. This windlass serves for hoisting the spindle or drill, and is of a large diameter, in order to prevent short bends in the iron, which would soon make it brittle. In all cases where iron, either hoop-iron or wire-rope, is used, the diameter of the drum of the windlass must be sufficiently large to prevent a permanent bend in the iron. On the opposite side of the windlass is a lever of unequal leverage about one-third at the side of the hole, and two-thirds at the opposite side, where it ends in a cross or broad end in case men do the work. The workmen, with one foot on a bench or platform, rest their hands on a railing, and work with the other foot the long end of the lever. In this way the whole weight of the men is made use of, who work with great ease. The lift of the bore-bit is from 10 to 12 in., which causes the men to work the treadle from 20 to 24 in. high. Below the treadle T is a spring-pole S fastened under the platform on which the men stand; the end of this spring-pole is connected by a link to the working-end of the lever, or the hoop-iron directly, and pulls the treadle down. When the bore-spindle is raised by means of the treadle, the spring-pole imparts to it a sudden return, and increases by these means the velocity of the bit, and consequently that of the stroke downwards.

The spindle is represented in Fig. 1083, a piece of square cast iron, or wrought iron, of from 200 to 300 lbs. weight for a hole of 3 in. diameter. For larger holes, of 5 or 6 in. diameter, its weight must be increased to 800 or 1000 lbs. At one end of the spindle the hoop-iron or rope is permanently fastened by screws or rivets; at the other end the bore-bit is inserted in a round hole and fastened by a flat key. The spindle may be provided at each end with a head, in the

form of a cross, but these are unnecessary appendages; a simple square rod of iron, whose diagonal section is equal to the diameter of the hole, is all-sufficient for the purpose. The lengths or parts of the hoop-iron may be made as great as possible, and should be of the best fibrous charcoal iron;

puddled iron, even if fibrous, soon gets brittle in the course of time and work. For a spindle of 300 lbs., hoop-iron of 2 in. by $\frac{1}{16}$ is sufficiently strong; for heavier spindles it may be somewhat stronger. The ends of the hoops are fastened together by means of small rivets and drilled holes, and this riveting ought to be renewed at least every two months, because the repeated vibrations cause the iron to get brittle, which is the case at the joints more than in the run of the iron. At the upper end, where the hoop is fastened to the lever, there is a length of hoop-iron nearly equal to one length or part, at one end of which is an eye permanently fastened; this fits in a hook at the lever, and also in a hook at the drum. This loose part of the strap is fastened to it by means of pinch screws, as shown in Fig. 1084; by this means the hoop may be made longer and shorter, as

the bottom of the bore sinks down; the letting out, of course, can be performed only while the work is stopped. If we want to let out while the treadle is in motion, which is necessary in soft rock, a screw about 1 ft. long is provided at the end of the treadle, which may be turned while the machine is in operation. The bore-bit has been shown in Fig. 1083 as it is fastened to the spindle. This is a simple, flat chisel, whose edge is steeled with good cast steel, and a little rounded, so as to play always in the centre of the hole. If the chisel is too round, or pointed in the middle, the hole is liable to get narrow in the bottom; if the edge is straight, the hole generally widens with its depth. Other forms of the bit are of little use, they merely cause trouble and loss of time. The bit must be fastened very firmly in the spindle, and the shoulder of it fit closely to it, or both are liable to get out of order. When the spindle is to be lifted from the pit, the end of the hoop is taken from the treadle and hitched to the drum, which is set in motion. The hoop must be prevented from winding over the hook's eye, or the pinch screws, for that would cause short bends in the iron, and permanently injure it. The drum must be so high above the hole that the spindle may be lifted entirely above the bore-log. For these reasons the upper end of the latter is frequently found to be some feet below the surface of the ground.

The operation of boring is simple; when the hole through the bore-log is sunk, the spindle is let down, hitched to the treadle, and the latter set in motion, which labour two or three strong men can readily perform. If but 10 or 12 inches lift is imparted to the bit, from 30 to 40 strokes may be made in one minute. If a good hop-pole is appended, from 30 to 45 strokes may be made by men, and from 80 to 100 by a steam-engine. The rock is thus penetrated by repeated blows, of which from 50 to 100 are sufficient to sink 1 in. deep in soft slate and shale; from 500 to 1000 in sandstone rock, and from 10,000 to 20,000 strokes in graywacke or gneiss. Even as many as 30,000 and 40,000 blows have been struck to penetrate 1 in. deep in hard graywacke. Iron pyrites are almost impenetrable; and the best plan is, if the vein is but a few inches thick, to break it by heavy strokes of a blunt steel point, directed so as to break off pieces from the mineral. When a certain depth, say 1 ft., or 2 ft., is penetrated, the *débris* of rock, ground into dust, and floating as fine sand in the water of the hole, must be removed, which is done by the pump; this instrument is represented in Fig. 1085; it is a sheet-iron cylinder, of from 3 to 4 ft. long, and $\frac{1}{4}$ or $\frac{1}{2}$ in.

1085.

smaller in diameter than the diameter of the hole, so that it may pass down easily; it is provided at its bottom with a strong iron ring riveted firmly, and soldered to the sheet iron; upon this ring is fitted a valve, which may be a poppet-valve, or a ball, or, what is equally as good as any, a trap-valve formed of a piece of sole-leather or strong india-rubber, provided with a piece of metal to make it heavy and shut close. Metal valves do not shut well, for often coarse sand gets into the pump, which does admit of a hard valve to shut, while a light valve of soft matter will press the sand out, or at least close sufficiently tight to prevent the mud from flowing out. This bucket is gently let down upon the bottom of the well by means of a small rope, a wire-rope, or a hoop-iron tape; it is then rapidly moved up and down a few times by hand, and raised. This latter operation is best performed by a small windlass, erected purposely for the pump. The strong windlass is too heavy and slow for this operation. When the pumping has been repeated two or three times, we may suppose at least all the heavy sand is removed from the bottom of the well. Pumping ought to be performed after the water has been for a while at rest, early in the morning or after meal times. This operation is very simple and effectual. The pump in being raised rapidly from the bottom of the well causes a strong current of water to pass vertically down; this stirs all the heavy sand in the bottom, and even pieces of iron and steel which may accidentally fall into the well, and brings them into the pump. Many other devices have been proposed for this purpose, but we know of nothing superior to this simple machine. See ARTESIAN WELLS.

Where a steam-engine is at command, as is generally the case at salt-wells, the operation may be performed with ease, and cheaply. Is a water-wheel or a mill at the place where a hole is to be sunk, the expenses are very small, one man attending the whole operation. In most cases it does not make much difference where the hole is driven down, if not too far off from the outcrop, so as not to miss the ore deposit. If the extent of a mass or vein is known, and we want merely to know the depth from a certain point, in order to calculate the expenses of a shaft before we sink it, it may be profitable to erect a steam-engine for boring, in case the depth is considerable. Horses or mules may be also employed at a common horse-whim to do the work; this, however, is not much cheaper than manual labour, but the work may be done faster. In case a steam-engine, water-wheel, or horse-power is used, a shaft with *cams* or *tappets* must be provided, which latter press upon the treadle instead of the feet of men. If in this arrangement the shaft with tappets

can be so arranged as to be moved farther off, or closer to the treadle, it is recommended; for if changing stratified rock is met with, different heights of stroke or change of lift is required; soft rock or slate cannot bear as strong blows as hard rock. In this case the spring-pole must be strong enough to balance the whole weight of spindle, and rope or iron belt; so as to keep it suspended when at rest. The large drum for winding up the rope may serve as an axle for tappets; the latter are then fastened to the large cog-wheel, and lift the treadle directly, or, what is the same, the end of the rope or iron belt. The crank-shaft, on which the handles are, serves in this case as a driving-shaft, driven by pulleys and belt from the engine, the water-wheel, or horse-power.

Turning the spindle, or bit, is a necessary operation which is much favoured by a hemp-rope, not so much by a wire-rope, not at all by hoop-iron, or by rigid bars of iron or wood. In striking the bottom of the well by the sharp chisel, it is to turn around the axis of the spindle, or its own axis, in order to cut a round hole; the more rapid this operation is performed, the more correct is the work, and the faster it proceeds. The hemp-rope, in lifting the spindle, is stretched, and endeavours to untwist, setting the spindle in a rotary motion, in which it continues until its return to the bottom of the well. At the head of the spindle there is a loose eye, or swivel, in which the rope is fastened: the rope will return, when slackened, and assume its twist again. This operation, however destructive to the rope, performs the rotary motion of the bit more perfectly than any other means. The rigid rod, and the hoop-iron or wire-rope, must be turned by hand, if no machinery is expressly prepared for the purpose. If turned by hand, which is done by means of a cross-handle above the bore-log by a small boy, it ought to be done rapidly; each stroke ought to have more or less than a whole revolution. If this operation is not properly attended to, the bit is very apt to cut rifles or flutes, particularly in stratified rock, which are very troublesome in the progress of the work.

Accidents.—It may happen that the belt, rope, or the rod breaks, or the bit or spindle is injured, and leaves parts of steel and iron in the hole. If the latter is the case, and the pieces broken off are not too large, the most expeditious plan is, to take a dull hard bit and pound the iron into such small pieces as may be removed by the pump. Is the belt or rod broken, the operation is not difficult, but in the latter case tedious. The hoop-iron, or a hemp or wire rope, is easily drawn up, which is most conveniently done by the following machine. In Fig. 1086 is represented a pair of tongs, which are fastened to the main rope R, which is slackened in letting down the tongs. W is a single wire, or a small hemp-rope, such as a bed-cord, or the pump-rope. When the tongs are so far down as to be below the broken end of the rope, the wire W is pulled so as to open the tongs, after which the belt R is turned round its axis. The lips L of the tongs, forming a basket, sweep now the circumference of the hole, and draw the broken rod into their grasp; when such indications are perceived at the upper end where the workman is turning the belt R, the wire W is suddenly slackened, and the sharp steel lips will bite the iron or hemp; the whole is now lifted by the windlass, and the broken ends mended. With a wrought-iron spindle, hardly anything can happen; a cast-iron spindle may break; but if made of a square form, there is so much room on the four flat sides as to admit two sharp-pointed bits of the tongs, which may fasten in it sufficiently so as to lift it. More vexatious than such breaks is the crumbling of rocks, particularly if these rocks are hard or tough. If the spindle has a little space at its upper end, and a piece of rock falls down from a higher place and wedges in between the spindle and the walls of the well, it causes often long delay and much labour to remove such small stones. Is the treadle moved by men, such impediments are generally observed before the rope breaks, and may be made less disturbing when attended to in proper time; but if a steam-engine or other power is at work, it will tear the rope or rod, and cause the spindle to be tightly wedged. In order to prevent the breaking of the rope, that part of the lifter where the rod is suspended must be made so weak, that, when the cam lifts it, and it is heavier than the weight of rope, spindle, and bit, it will break and prevent by its rupture the breaking of the rope. Is the latter not injured, there is generally not much difficulty in getting the spindle out. At the top of the bore-hole must be always a certain mark, which indicates exactly the depth of the well by the length of the rope; if the spindle is in any way raised above the bottom, we may know it by this mark, or by the position of the treadle. In this case, gentle up and down motions at the rope will generally loosen the spindle so as to make it play; its going down to the bottom, however, ought to be prevented, for which reason the end of the rope is laid on the windlass, and the rope so far stretched as to prevent its sinking to the bottom. By means of the treadle or by hand, the apparatus is now kept in motion and gently raised by the windlass. If these means will not succeed, force at the windlass is tried, but never beyond the strength of the rope so as to break it. If this also fails to lift the spindle, an iron rod, with a blunt end, which cannot penetrate between the spindle and the walls of the hole, is let down by means of the pump-rope, and gentle blows are imparted on the head of the spindle; this will either start the spindle, or will crush the pebbles which hold it. Is the rope or rod broken, these operations must be performed with more caution, so as to prevent forcible lifting; for when the tongs have hold of the broken end of the belt, that is never so firm as the rope or belt itself.

Most of the accidents are caused by loose stones, gravel or pebbles, crystals or pieces of slate, from cavities above. Most of the rocks contain caves, or nests of crystalline loose matter, which is thrown down by the motion of the water and the vibrations of the boring instruments. In these cases, pipes of sheet iron, of copper, or of other metals, have been inserted in such places;

which operation, however, is expensive, tedious, and not quite safe; much ingenuity has been expended on inserting such pipes. In all cases of boring, the mouth of the well, or upper part, ought to be well secured by the bore-log; it should reach down into the solid rock, and prevent any dropping of gravel from above. When, in the course of the descent, cavities are penetrated which prove to be filled with loose matter, threatening to obstruct the progress of the operation, the best plan is to cut through such a cavern, if possible, and reach the solid rock again. If this cannot be accomplished, the chisel is driven down as far as possible, and the cavity filled by cement, which is closely rammed in by a plunger. The cement for this purpose is mortar cement, also called Roman cement, which is made of impure limestone, such as is found in the coal regions and marl beds, in the form of lumps imbedded in marl, clay, or shale. This kind of limestone, when burned, does not slack; it must be ground fine, and is then mixed with water to a stiff mortar. If no such impure limestone can be obtained, common lime is mixed with burnt and finely-ground iron ore, burnt marl, or burnt ferruginous shale, pumice-stone, or any kind of volcanic porous rock. The whole, lime and admixture, of which latter about 40 per cent. of the lime is used, is ground together and mixed with water so as to form a stiff mortar. Cement mortar will harden in the course of a few days under water; but it is advisable to make a trial of it before it is put down into the well. This mortar is filled in canvas or muslin bags, of such a size as to sink gently down to the bottom of the well. A number of filled bags is let down, and then the plunger,—which may be the spindle,—is pressed upon them to break the bags, and drive the mortar into the cavity. This is gradually filled entirely with mortar, and then left at rest for some days. Part of the mortar is, in the meantime, immersed in water, above ground, in order to observe its progress of hardening. When the mortar is hardened below, it is penetrated by the bit, and a round hole bored through it, which forms now a pipe of cement, which will effectually prevent sand or gravel from running down and causing disturbances in the operations.

In all cases of sinking a well or a bore-hole, the progress of the work should be recorded in a journal from day to day; and each day, or at each pumping, a part of the bore-meal, or the coarsest *débris*, saved for future examination. The latter operation is simple, and causes no loss of time. When the pump is raised, the contents of it are cast into a fine wire sieve, or into a bag of fine wire gauze, which is made to contain all the contents of the pump. The water and the fine parts of rocky matter will pass through the meshes of the sieve and float off, while the coarser parts remain. A part of the sediment is saved in a paper, or in a small box, and it is marked with the time and depth, when and where obtained, for future reference. These evidences, when put together, form the elements of a section of the rock strata penetrated by the well, in that particular spot, and are suitable objects for publication. Any geologist can form, by these means, a profile of the rock, or general formation. Many hundreds of *artesian wells* are now sunk, and have been sunk in times past in our country; these would furnish means for obtaining a correct insight of the geology of those places where the operations are performed. For the want of such records, the information arising from the labour of boring, at a particular spot, is lost to the community and the science of geology.

Any size of hole will answer the purpose of the miner; and if 2 in. in diameter could be sunk, it would be sufficiently wide; but this cannot be done; the form of the tools, pump, and rope, require at least 2.5 in. All complicated tools, such as cross-chisels, rasps for widening, and similar instruments, are to be avoided. They are expensive, both in first cost, repair, and cause loss of time. The simple flat chisel will form a perfectly round hole; when attended to in turning the rope, it will make the hole wide enough all the way down; if frequently changed and sharpened, it works easy and fast. A chisel and a good pump, a safe rope, and good tongs, are all the implements requisite for sinking a hole of 2000 ft. deep.

We give an example of boring for minerals, from the 'Transactions of the North of England Institute of Mining Engineers,' vol. vii. The paper which furnishes this example was read by the justly-celebrated Nicholas Wood; we give it and the discussion thereon, without any material alterations, to show the baseless fabric upon which the so-called science of geology is made to rest.

Nicholas Wood, President of the Institute of Mining Engineers, on the Deposit of Magnetic Ironstone in Rosedale.—In John Marley's very elaborate and very able account (says Wood) of the Cleveland Ironstone District, communicated to this Institute at its meeting of June, 1857, and published in vol. v. of the 'Transactions,' he states:—"The only special district to which I think necessary now to allude is the Rosedale Abbey district, the ironstone from which has attracted a large amount of attention, on account of its large percentage, immense deposit, and magnetic properties."

Marley then gives a history of the discovery of this bed of ironstone, its position in the series, as well as in the district generally, and adds all the information which had then been elicited with regard to the particular features and character of such deposit, which he illustrates by a diagram, showing the explorations which had been made by drifts and pits towards such elucidation; and he then concludes by saying:—"I have no doubt that this seam is the same as the seam at the point A, Fig. 1087, as also the same as that found on the east side of Rosedale, in Captain Vardon's property, of varied thickness, as well as the same seam as that at Grosmont, Fryupdale, Swainby, and Boltby, known as the *top seam* of Cleveland—the nine inches of coal in the pit sunk agreeing with *Beckhole*, near Grosmont, in particular; so that the only doubtful point is as to the portion from the outcrop at A to the so-called magnetic quarry; the most feasible solution being that it is a disjointed patch of the regular seam, known as the *top seam*, and not a vein, as has been said; and, with all deference to the parties who have had more opportunity for examining this district than I have, I propose leaving the extent of the magnetic and extra percentage tract as an *unsolved problem*, as it may vary from one or two acres to any indefinite extent, not being at all proved to the south."

This is a very clear and correct account (says Wood) of the information then existing on this

deposit, Marley's opinion being that it represented the top seam, as developed at Grosmont, Fryupdale, Swainby, and Boltby.

Reference:—O, Shale and ironstone ramble. P, Brown and grey sandstone. 9, Coal and shale. S, Shale and sandstone. T, Sandstone; top bed, of iron and lias respectively, not proved by the bore-hole.

A Section of the Strata at Grosmont is given by Marley as follows:—

	Ft.	In.		Ft.	In.
Sandstone	25	0	Ironstone band and shale	29	0
Ironstone, top seam	12	0	"Pecten" band, part of the Cleve-	5	10
Lias shale	92	0	land thick seam	17	4
Various strata, not identified	51	0	"Avicula" band, Cleveland seam ..	6	4
Lias shale	55	0			
	198	0			

Another section near Grosmont gives the top seam 11 ft. 6 in., then 187 ft. of shale and ironstone, and then the Cleveland band.

The Section at Fryupdale is as follows:—

	Ft.	In.		Ft.	In.
Freestone	55	0	"Pecten" band, Cleveland main seam	6	0
Top seam	12	0	Shale	132	6
Jet, cement, and alum rocks ..	202	0	"Avicula" band, Cleveland main seam	4	4
Shale	60	0			

The Section at Swainby is as follows:—

	Ft.	In.		Ft.	In.
Shale	13	0	Shale	132	6
Top seam	23	0	Cleveland main bed	9	3

And at Felix Kirk, near Boltby, the Section is:—

	Ft.	In.		Ft.	In.
Brown, yellow, &c., gritstone ..	0	0			
Boltby and Rosedale iron rock ..	7	0			
Alum shale, or upper lias shale ..	116	0			
Upper band of nodular ironstone ..	0	7			
Thin seam of soft shale	3	0			
Lower band of nodular ironstone ..	0	6			

Section of Strata in the Hills at Swainby Mines.

The main features of the sections given by Marley as assimilating to the Rosedale bed, are,

- 1st. The top seam, varying from 12 to 23 ft. in thickness.
- 2nd. Lias shale and other strata, 132 ft. to 220 ft.
- 3rd. The Cleveland main band, 9 to 12 ft.

But in all these sections there are no beds of ironstone between the top seam and the Cleveland main band.

Bewick, in a paper presented (says Wood) to the Institute, and printed in vol. vi. of the 'Transactions,' gives drawings, and an account of the deposit of Rosedale, and concludes with these remarks,—“My object in thus troubling the members of this Institution with the foregoing remarks is twofold. First, to show that the iron ore of Rosedale, instead of being a large mineral field, as was first asserted, and still believed to be so by many, is nothing more than a volcanic dyke; and secondly, that the ironstone lately opened out in this locality is not, as it is reputed to be, the main seam now being worked in the Cleveland and Grosmont districts, but it is my opinion, if Marley will permit me to say so, the top seam.”

I shall now (observes Wood) give an account of the operations concluded by Professor Phillips and myself towards the investigation and development of this bed of ironstone.

The first discovery of this deposit of ironstone was at a quarry on the south-west side of the valley of Rosedale, about a mile south from Rosedale Abbey, and shown, Fig. 1088. When this

1088.

quarry was opened out it was found to consist of apparently a confused mass of ironstone boulders of an ellipsoidal structure, and of gigantic size, often 3 or 4 ft. in diameter; the central part of these boulders being generally blue, and consisting of a solid dark oolitic magnetic iron ore, with, in many cases, sandy and solid ironstone crusts around it; and, in receding from the centre, the iron ore becomes paler, alternating with dark brown purplish layers; the layer then becomes pale brown, and the magnetic quality is lost. In most cases, however, the nodules are quite solid, and a slight stratification exists, though very obscure; and in several cases, likewise, the oolitic structure is merged into compact brown iron ore. In some parts also, where exposed to the water and to the weather, the iron ore is partly washed away, and a gritty ferruginous crust remains. These great variations do not occur where the ironstone is under cover, or covered by other strata, but appears to assume those different phases in consequence of its extreme susceptibility to change by exposure to air and water; and it is somewhat remarkable that the magnetic property is

Datum Line 200 above Sea Level

strongest where the mass is thickest, and scarcely shows any magnetism in places where it is thin, or where it has little cover, and, consequently, more exposed to decomposition or change.

The great characteristic difference of composition between this ironstone and the top and main band of Cleveland is, the entire absence of shells, the structure being entirely of an oolitic character, being entirely composed of small round concretions of iron ore, cemented together with extremely thin siliceous or arenaceous films, and in its magnetic properties exhibiting polarity, and likewise in its greater richness than the ordinary ironstone of Cleveland.

This quarry has been excavated so as to form a face of 60 ft. in thickness; to which must be added 11 ft. of blue magnetic stone, 2½ ft. red ironstone, slightly magnetic, bored down below the bottom in magnetic stone, and 3 ft. of shale.

Soon after the quarry was discovered, it was thought advisable to drive a drift into the side of the hill, to ascertain the extent of this deposit, the quarry being about 600 ft. from the bottom of the valley, and about 300 ft. below the utmost level range, or plateau of moors, lying on the south-west side of the valley. This drift, together with a pit sunk upon it, is shown by a drawing in Marley's paper. Since then, it has been driven to a much greater distance, and three bore-holes have been put down from the surface to the Rosedale bed of ironstone.

Fig. 1088 shows the position of this drift, the distance and direction in which it has been driven into the hill, and also the position of the three bore-holes and the quarry. And Fig. 1089 also shows the section of the same drifts, and the section of the borings, together with their depths from the surface, and the beds of ironstone which they have proved. I have carried such section across the valley, for the purpose of showing the position of the ironstone band on the opposite side of the valley.

Fig. 1090 shows, on a larger scale, the strata bored through in the three bore-holes above alluded to, and the ironstone beds which they have proved; Figs. 1091 to 1093, bore-holes, Fig. 1094, facing drift, and Fig. 1095, side drift—show the thickness of the lower bed of ironstone in the several bore-holes in the face of the drift, and also in the side of the drift.

It is necessary to remark that, where the drift was first set away in the side of the hill, it met with shale, and it continued in shale for a distance of about 80 yds., when the ironstone was found. The drift continued in the ironstone for a distance of 180 yds. farther, making a total distance of 260 yds. from the face of the hill. Fig. 1089 is a section of the ironstone at the face or farthest extremity of the drift, showing an entire thickness of 32 ft. of ironstone, namely, 6 ft. 2 in. of drift, 11 ft. 9 in. above the drift, and 14 ft. below it. And, what is important to mention, the ironstone was here distinctly stratified, as shown by the lines across the section, Fig. 1094.

400 yds. in advance of the extreme end of the drift, and 660 yds. from the side of the hill, a bore-hole, No. 2, Fig. 1089, was put down; and at right angles to the line of this bore-hole from the drift two other bore-holes were put down from the surface, as shown, Figs. 1089, 1090, each 200 yds. distant from No. 2 bore-hole, or 400 yds. separate; and the following are sections of the strata passed through in these bore-holes.

These borings and sections show two distinct beds of ironstone, stratified with great regularity; and they prove most conclusively that neither of them is at all like what Bewick terms “nothing more than a volcanic dyke.”

It will be seen by the map of the district, Fig. 1088, that a border is traced around the edge of the valley; this is undoubtedly the outcrop of what is called the “top seam” of ironstone, as it can be traced south and east into Eskdale, and towards Grosmont and Fryupdale; and also north towards Swainby and Boltby, in which localities Marley has given sections of the top seam, and also of the Cleveland main band. Supposing this outcrop in the Rosedale valley to be the top seam, then the upper bed in the sections, Figs. 1089, 1090, is unquestionably the top seam likewise; and we there have a bed of ironstone upwards of 30 ft. thick, lying parallel to and strictly conformable with the “top seam” (and separated therefrom only by a thin bed of shale), of an entirely different character from either such top seam or the main band of Cleveland.

I have (says Wood) laid down on plan, Fig. 1089, a section of the strata given by Marley, at Grosmont to the south-east, and at the Swainby mines to the north; and I have added the section at Eston Nab. It should be observed, also, in corroboration of the upper bed of ironstone, Fig. 1089, being the top seam, that a bed, or rather three or four beds, of ironstone intermixed with shale occur in the brook of Rosedale and crops out in the bank, which is generally believed to be the representative of the Cleveland main band, though the ironstone is very inferior, and not workable. I have laid down on the section, Fig. 1089, the position of this bed of ironstone, which agrees pretty well with its position in the other sections, making allowance for the variation in the thickness of the lias shale as found in the several localities.

I have (observed Wood) likewise, in Figs. 1088, 1089, shown the position of the quarry, which

appears to have slipped down below the level of the beds, as shown by the drift and borings. This appears to have been occasioned by a slip-dyke which crosses the drift near the pit, as shown on the plan, Fig. 1088. It will be seen by this plan that the drift passed through alluvial soil and shale up to near the pit, when this dyke was crossed and the ironstone cut, as shown on the plan. This dyke is supposed to run in the direction shown on the plan, crossing the drift near the pit, and throwing the strata down on the south-west side, and, consequently, the strata comprising the quarry; and it appears that the quarry itself is much broken, and has very much the appearance of a disjointed slip, the elliptical nodules being in a mass of confusion, as shown on the plan.

It has been supposed by some parties that this dyke has given the magnetic character to the ironstone; but it is well known that the character of the ore must be changed from a peroxide to a protoxide to become magnetic, which the crossing of the dyke through the strata could scarcely accomplish; and then we have the entire absence of shells in the lower bed, while the matrix of the upper bed or top seam is entirely calcareous and filled with shells. The concretionary nature of the stone, and the much greater percentage of iron produced by this deposit over that of either the top seam or the Cleveland main band, are also characteristic of this bed of ironstone; the analysis given by Marley of the Rosedale stone being upwards of 50 per cent. of metallic iron, while the top seam and main band are about 32 to 35 per cent.; and the produce of a large quantity smelted at Cousett gave 55 per cent. from the calcined ore, and 45 per cent. from the raw stone.

Whatever opinion may, therefore, be formed of the cause of this deposit, we certainly have the fact that, for a width of 400 yds. and a length of 580 yds., we have a bed of ironstone highly magnetic, of an almost entirely uniform thickness, totally different in its mineralogical character from the ordinary stone of the district, and yielding in produce nearly 20 per cent. more iron in the furnace. To what extent this bed may exist beyond the extent already proved will be the subject of further investigation; but it will be a very extraordinary anomaly in geology if a bed of such uniform thickness should not extend to considerable distances. It has been stated that a similar bed has been discovered in other and distant localities; not being myself cognizant of the facts, and my information not being very precise, I abstain (says Wood) from giving such information at present. The importance of such discoveries are of too great interest in the district, and too valuable in a commercial point of view, to remain long unexplored, and therefore we may hope that at some future period the Institute will be favoured with an account of such deposits.

The President's paper on the Rosedale Ironstone having been read, a discussion thereon was taken.

Bewick said the magnetic ore in the quarry was a casual deposit in the shape of a dyke or vein.

Marley.—I understand, since I was at Rosedale Abbey, that which the President stated to be the top seam had been discovered in a regular stratified state on the south side of the magnetic quarry. At the last discussion we had on the subject, I admitted if that bed of ironstone had been discovered keeping on its uniform rise and dip, from the north side of the quarry to the south, I had been mistaken in supposing the magnetic seam to be the same as that of the seam then discovered on the north side of the quarry. Then, as to whether it was a vein or a bed, or whether, what I supposed at the last meeting, it was an overflowing between soft strata, similar to "flats" in lead veins, I had not an opportunity of forming an opinion, for want of the *three bore-holes*, which have now been given.

The President.—What you stated was quite correct. The top seam had not then been found on the south side of the quarry. It is now found on the south side as well as the north side; but I do not think we have yet discovered the magnetic stone on the south side of the quarry, except in the drifting and borings.

Marley.—When I made my examination, preparatory to reading my paper, the top seam at the point A on Fig. 1087, therein referred to, was lost, and no continuation was found south of the magnetic quarry; but, by competent witnesses, I have been informed it is now found south of the said magnetic quarry. But, if the magnetic stone is a bed, it is extraordinary so large an extent of country should give no trace of it, as at Grosmont and other places we have not the slightest trace of it. At Ingleby they are putting three bore-holes down, with a view of proving the existence or otherwise of the magnetic ironstone there. They are now, I believe, past the top-seam position, but have got nothing but shale yet. These borings will prove about 100 fathoms of strata. I have hitherto been of opinion that the round particles, in the specimens of magnetic ore, are oolitic shells.

The President, N. Wood.—No. I believe they are iron, with a siliceous matrix.

Marley.—Has one of those globules ever been analyzed by itself, and found to be pure iron?

Wood.—I do not know; but I believe there is no calcareous matter in those particles which there would be if it were shells.

Marley.—Unless it is some peculiar formation.

Wood.—Then the shell is gone, and the iron left.

Boyd.—The chemical part of the shell remains in the Cleveland stone.

Marley.—The magnetic stone is not in analogy with the Cleveland.

Wood.—It has changed its character from a peroxide to a protoxide.

Marley.—I acknowledge the magnetic stone is free from "pectens."

Bewick.—After hearing what has been stated by our President, I am bound to say our opinions are as much opposed as ever; and I shall endeavour to show you that the ironstone beds they have bored through at Rosedale Abbey are not the same as the magnetic ore and top bed found by the side of the valley, that, in fact, the borings have not reached those deposits by several feet, and that, therefore, they have not as yet proved anything more respecting them. The strata they have bored through are quite above them, and you will find on looking at the table of the borings,

published with the July discussion, that an important member of the series, which immediately overlies the top bed is wanting. I allude to the great sandstone rock, which is seldom under 50, and sometimes met with 100 ft. thick. This rock does not appear in the borings at all.

Wood.—Yes, it does, namely:—

					Fms.	Ft.	In.	
Brown freestone	..	No. 1 bore-hole	..	..	12	5	6	} with other beds of post, mixed with shale.
Brown and grey post	..	" 2 "	..	..	12	1	0	
Brown post	..	" 3 "	..	..	11	5	0	

Bewick.—That is not the sandstone I allude to. That rock is found higher in the series, and belongs to the coal measures, which your *bore-holes* have gone through; but, as I have just said, they have not yet reached the other sandstone, and cannot, therefore, have touched the top bed. In this section, Fig. 1096, you have, in my opinion, a type of the ironstone you have gone through in your borings. The seams here are thin and divided, and the shale between them is interspersed with iron nodules; and, as you admit the seams are split in the last *bore-hole*, it but serves to confirm my opinion that they are one and the same. They occupy the same geological position in the series—that is, they intervene the great sandstone rock and the coal measures in the oolitic series.

Wood.—Do you purpose giving the sections for publication?

Bewick.—Yes; I intend leaving the whole of the sections with you for that purpose. The thickness of every stratum, in the diagram representing a cross-section of the vale of Rosedale, is taken from the table of the borings before referred to, in which I may here observe there is an error of 3 fathoms 2 ft. The total ought to be 48 fathoms 2 ft. instead of 51 fathoms 4 ft.; and if you take from this 1 fathom 1 ft. for the grey shale they have left off in, below the ironstone, it leaves 47 fathoms 1 ft. from the top of the bore-hole to the bottom of the ironstone. I am thus particular because I have taken a line of levels, commencing at the south drift, by the side of the hill, and terminating at the south *bore-hole*; and I find there is a difference in the height of the level, and the depth of No. 2 *bore-hole*, Fig. 1090, of 64 ft., fully corroborating what I have before stated, namely,

—That the *bore-holes* have not yet reached the sandstone which overlies the top bed; and if you will allow me to explain my sections, I think they will prove to you that the ironstone they have cut through belongs to that which we call the oolitic beds, and which are found in different localities in the Grosmont district, not so thick, it is true, neither are they magnetic; but they are found, as I before stated, occupying the same geological position, and accompanied by the same description of strata. Section, Fig. 1096, is taken between Goathland Mill and Beckhole, near Grosmont, which, you will observe, contains the same alternating strata of sandstone, shale, coal, and ironstone, as you see in section, Fig. 1087, which is a transverse section of the vale of Rosedale, representing the strata they have bored through there. The ironstone beds *a* and *c*, in section, Fig. 1096, are, in my opinion, the same as those marked *a* and *c* in section, Fig. 1087. The bed *c* is very irregularly diffused throughout this portion of the oolitic district. It is found in the nodular form. In some places you find it of considerable thickness, and then, again, entirely wanting. Sometimes of good quality, but more frequently coarse and inferior, and gradually alternating with the sandstones. The bed *a* is more regular, but thinner, and of very good quality: its upper portion consists of a nodular bed averaging from 3 to 6 in.; and the lower portion a bed averaging from 12 to 18 in. in thickness. Wherever I have met with those beds, however, I have always found them so variable, both in extent and thickness,

Reference:—1, 2, 3, Sandstone, shale, and coal.
4, Sandstone. 5, Upper lias. *a*, *b*, *c*, Ironstone.

as to afford no reasonable prospect of their paying for working. They may certainly be found different at Rosedale; but I would just observe that I consider *boring a most fallacious mode of proving ironstone deposits in strata* such as that which these borings have gone through, you are so liable to mistake a nodule for a bed, or a portion of a bed. I shall be much surprised if you do

not find the section of your shaft, should you sink one, very different from the section of your bore-hole.

Wood.—Then it is a question of policy, in Bewick's view of the case, commercially considered, whether the borings should not be continued. With regard to the identity of the position in the series of the bed of ironstone ranging around the Rosedale valley, as shown in Fig. 1097, and also in Fig. 1087, it appears to be undoubtedly the top bed of Cleveland. All parties admit this. Then the question is, Is the bed of ironstone proved at the pit No. 1, Fig. 1089, and the bed corresponding therewith and proved in the bore-holes Nos. 1, 2, and 3, and therein designated by me as the top seam, the same bed of ironstone? Bewick thinks not, and that the borings have not yet reached this bed. I can, of course, only refer to the borings, driftings, and the section of pit No. 1, and I must add that there appears to me no doubt whatever on the subject; and the fact that, according to Bewick's plan, Fig. 1097, we have the top bed on both sides of the magnetic quarry, ranging as accurately as can be conceived with this bed in the borings, confirms this supposition, in my opinion. It is true that this bed is at a lower level at the south or left-hand drift than on the north side, but this is clearly the effect of the dyke shown in Fig. 1087, which throws down the strata in that direction. With regard to the supposed want of what Bewick calls the thick sandstone strata immediately above the top bed of ironstone, and shown on the section, Fig. 1096, to be 100 ft. thick, I have looked carefully over the sections given in Marley's paper, and I do not find in any one of them, except at Eston Nab, the extreme northern point of the district, any bed of sandstone approaching to that thickness, and there the section given is

	Ft.	In.
Freestone	60	0
Shivery post, patches of jet, and fire-clay	54	0
Top seam, exclusive of shale bands	1	3

At Rosedale Cliffs, between Staiths and Runswick Bay, we have

Freestone	26	0
Fire-clay	4	6
Freestone shale	5	5
Blue shale	0	10
Top seam, exclusive of shale bands	4	7

Still farther south, the sandstone at Wreck Hill is only 10 ft., with 2 ft. 6 in. of shale covering the top seam; and at Grosmont, Marley gives 25 ft. of sandstone, and another section at 58 ft. 6 in., which he says varies in thickness and quality. At Fryupdale, the thickness of sandstone is given at 55 ft., and at another place, namely, Swainby, the following is the section:—

	Ft.	In.
Soil, &c.	3	0
Freestone	24	0
Slaty coal	0	9
Shale	1	0
Sandstone	4	0
Slaty coal	0	9
	6	6
Shale	5	0
Coarse freestone	3	6
Shale, with occasional nodules of ironstone	13	0
Top seam	28	0

Considering, therefore, that in the borings there is about 60 ft. of sandstone, there does not appear to me any substantial difference between the shale in those borings and in the other parts of the district to justify the supposition that the upper bed of ironstone is not the top seam. Bewick thinks the bore-holes have not reached the sandstone he describes. If so, he should like to ask Bewick what seam of ironstone that is in the district which has been bored to?

Bewick.—It is, in my opinion, as I have previously stated, the ironstone found in the colitic series.

Wood.—Where does it occur in the other districts? Where do you find another similar deposit in Mr. Marley's sections?

Marley.—Dr. Verity gives a variety of ironstone seams. If you refer to my paper, you will find there are several ironstone seams lying over the seam, which we agree to be the top seam of Cleveland. Professor Phillips said that, with the exception of the classification of names, this section was practically correct.

Wood.—Do you think the ironstone which crops out all around the valley of Rosedale is the top seam?

Bewick.—I think so; I have no doubt about it.

Wood.—If we are agreed about the deposit of ironstone found cropping out around the valley of Rosedale, as shown in the different plans, then there can be no difficulty in tracing the sandstone overlying that bed to the sandstone first of all sunk through at the pit, Fig. 1089, and thence to the borings Nos. 1, 2, and 3; and these borings having passed through the upper bed of ironstone, below such sandstone, and then through the magnetic bed, there cannot be the least doubt of the geological position of these beds. With reference to the levels, there is no discrepancy whatever

in that respect; there is a rise in beds in the line of the drift, and in the extension of that line to the borings, and the direction of the line between the borings seems to be nearly water-level at that part. There is not, therefore, the least discrepancy on this point. I have taken the Ordnance maps as my guide as regards the levels, and have no doubt they are correct. Whatever opinion may, therefore, be arrived at with respect to the comparison of the beds proved in the borings and in the pit, with the beds at Grosmont, &c., there appears no doubt in my mind that the mass of ironstone of the quarry is a detached portion of the thick or lower bed of ironstone, and that such bed exists *in situ* for a considerable, and, of course, at present, for an unknown extent in the locality of Rosedale.

Bewick.—If our President means by pit Fig. 1089 the air-shaft sunk on the main drift, I quite agree with him that the sandstone found in that shaft is the same as that which overlies the top seam; but, I beg to say, I entirely differ from him in supposing it to be the same as that they have gone through in the borings. I am also opposed to his opinion with reference to the direction of the dip and rise of the strata. There can be no doubt, I think, but the strata on the west side of Rosedale, and to the south of the crown—that is, the point from whence the strata dip in contrary directions—are dipping in a south-westerly direction, as shown in my section, Fig. 1097, and still more clearly proved by the drift commenced on the south side of the magnetic dyke, and driven in a line with the south bore-hole, running nearly west, but which has been discontinued, owing to the top seam, in which the drift was commenced, dipping so much in that direction, instead of rising, as our President supposes, as, at the distance of not many yards, to be completely under water-level. With reference to the slip-dyke or fault mentioned by that gentleman, I can only state that I have never yet been able to discover any dislocation or disturbance of the strata, other than what has been occasioned by the dyke of magnetic ore in its immediate vicinity. Then, as to the extent of the magnetic ore, all I can say is, I have paid several visits to Rosedale solely for the purpose of examining the strata in that neighbourhood, the many deep ravines which abound there affording ample opportunity for doing so, but I have never been able to trace the magnetic ore beyond the vicinity of the quarry, and every visit only serves to convince me that it is a casual deposit, in the shape of a dyke or vein. A bed, however, of 560 yds. in length, and from 30 to 32 ft. thick, cannot be identified with a casual deposit; nevertheless, I think, very probably there may be a mistake in supposing you have a solid mass of ironstone 32 ft. thick. This may have occurred from the borers having cut through nodules or irregular patches of ironstone, and also from the shale in which it is found being very hard, and of the same colour as the ironstone. From these circumstances it is an easy matter to be misled by borings.

Wood.—Whatever may have been the result of investigations on the surface, I do not think I can add any further information to that already given and shown on the plans, to prove that a thick bed of ironstone of about 32 ft. exists over a space of upwards of 560 yds. in length, and 200 yds. in width, with not the least indication of any change or termination of such deposit. It would, indeed, be a most extraordinary occurrence in the annals of boring, to suppose that occasional nodules, or irregular patches of ironstone, should have produced the result recorded in these borings. The boring through the ironstone beds was performed under the immediate inspection of *Stott*, a well-known experienced borer, who kept the specimens brought up the bore-hole; and I can add, that I examined a great many of the specimens myself with a magnet, and found them magnetic. There is not the least pretence for supposing that shale could be mistaken for ironstone. Have you seen any nodular magnetic ironstone in the Grosmont district?

Bewick.—Never. You must remember (addressing the President) that you stated at the October discussion in 1857, that Professor Phillips and yourself had discovered the magnetic ore in “two localities two miles apart,” namely, at Sheriffs drift and at the Quarry; and, again, in the July discussion of last year, you stated the stone in the drift south of the dyke was magnetic, but on examining it I found this not to be the case as regards both the drifts. I believe the reason why there are so many conflicting opinions with reference to the nature and extent of the magnetic ore is owing to the difficulty there is in distinguishing the ore from the top bed—that is, in separating the igneous portions from the sedimentary; for, although they are both frequently magnetic in the immediate vicinity of the dyke, there is yet a vast difference between them. The igneous portion is harder, heavier, and more compact than the sedimentary; and the former appears to have acted upon the latter whilst in a heated condition, much in the same way as a magnet acts upon a piece of common iron, imparting to it a portion of its peculiar magnetic properties. I may here be permitted to add, that whilst I believe this ore to have been subject to a heat sufficient to evolve the different gases it contained, I yet do not think the heat has been of that intensity so as *entirely* to expel it. We need not, therefore, be surprised at *traces* of carbonic acid being found in the chemical analysis of this ore. Here is a specimen of the igneous portion, which I took from the bottom of the quarry, and, after examining it, no one can doubt, I think, of its having been subjected to heat.

Wood.—There is no doubt, as stated by Mr. Bewick, that portions of the top bed in Rosedale are occasionally magnetic, and it was this property which led to the mistake, if there are mistakes, in supposing the magnetic bed to have been discovered at Sheriffs drift, and at the drift south of the magnetic quarry. The explorations at that time had not been sufficiently extended, nor have they yet been prosecuted to such an extent as to ascertain if the magnetic bed exists in those localities. Finding part of the ironstone partaking of magnetic influence led to a supposition that this bed did exist in those localities, and the subsequent explorations have not been prosecuted to an extent to ascertain the fact either one way or the other. To *Bewick.*—From what part of the quarry did you take this specimen?

Bewick.—It is from the floor of the quarry. This (showing another specimen) is a sample of the top bed which appears to have been partially burnt, and you will at once be able to detect the difference between them. These (showing other specimens) are samples of the ironstone found in the oolitic rocks, in the neighbourhood of Grosmont, some of the nodules of which are amongst

the richest of the clay or calcareous ironstones. I omitted to state that, with the exception of the first 60 ft., where the ground was so steep that I could not fix my instrument, and from which there may be some slight inaccuracies, I took my levels with a good and safe instrument, and the operation was performed in the ordinary way of back and fore sights. I find the difference between my levels and what I suppose the correct position of the top bed of ironstone, and that shown by the bore-holes, to be 64 ft.

Wood.—The question of the difference of the levels rests entirely upon the assumed inclination of the beds; a difference of level of 64 ft. in a distance of 400 yds., accords, in my opinion, with what may be supposed to be the regular inclination of the beds.

Bewick.—Yes; but in your section you connect two sandstones which have nothing to do with each other, namely, the sandstone found in the air-shaft immediately overlying the top bed, and the sandstone found in the bore-hole, between which there are several feet of *alternating strata*; and to do which you must of necessity raise your level line, and show the strata to be rising in that direction; but the drift you have driven some distance into the side of the hill, and at the same point as my line of levels, shows the strata to be *dipping in that direction*. I may mention, too, that had another bed of 32 ft. thick really been met with in the bore-hole, it must have been found along the sides of the valley, which are intersected in so many places with mountain streams, all of which have been searched by persons having a fair knowledge of the geology of the immediate neighbourhood, but without the least trace of it having been met with.

Wood.—I cannot think that there is the least doubt that the sandstone in the pit, No. 1, Fig. 1089, is the same sandstone as that proved in the borings; all the appearances on the surface, as well as the general rise and dip of the strata, prove this. Extending the line of section across the valley, it is clear there is a general rise of strata along the line of section. No doubt the strata in the drift dip towards the west, but that is no doubt influenced by the slip-dyke which crosses it. I would observe that, taking the line of section along the face of the valley in Fig. 1087, in the direction of the dotted line *a b*, and applying the inclination of the top bed of ironstone, shown Fig. 1097, to that line, and not to the curved or projecting line along the face of the hill, the position of the bed would be rising from *a* towards *b*, and it would require a slip-dyke, shown Fig. 1087, to throw the bed into its proper position along the face of the valley to the west of the magnetic quarry. On examining Fig. 1087 it will be seen that the magnetic quarry and the top bed of ironstone, as shown in Fig. 1097, project considerably to the east of the general line of the side of the valley, which, being towards the dip of the strata, shows the top bed at a lower level than if the section had been continued in a more direct line, or in the direction *a b*. Whatever conclusion, therefore, may be arrived at after all the explanations given, we have the fact of an almost horizontal bed of ironstone, and of nearly a uniform thickness, distinct in character from the ordinary beds of the district, extending over a length of 568 yds. and a width of 200 yds., which clearly proves that it is not a vein. How much greater distance it extends, must be left to future explorations to prove; but it would certainly be an extraordinary anomaly in geology for such a thickness of strata to disappear altogether in a short distance. If it extends across the valley, as shown in *Bewick's* plan, Fig. 1096, then there is no reason to suppose that it may not extend to the same distance to the north; and if, according to *Bewick*, the borings have not yet reached to the top bed of ironstone, then the deposit of ironstone, in the valley of Rosedale, is richer in ore than either Professor Phillips or myself has set forth. The correct extent must, however, be left to future explorers to discover. Enough has been proved to show a most extraordinary deposit of a very peculiar and rich ironstone, and well worth further investigation.

Bewick.—There is a section of the cross drift, shown in Fig. 1089, driven at right angles from the main drift to prove the breadth of the dyke, and which, at the distance of 16 yds., cuts the shale, and apparently touches the top seam at the same time. At the distance of 6 yds. the stone in this drift ceases to be magnetic. It is, therefore, incomprehensible to me how it can again become so at the distance of 200 yds. from this point. Of course, you have a right to infer from the information that reached you that such is the case. Still I would strongly recommend that the borings should be continued to prove whether the sandstone be below you or not, to ascertain which could not fail to give great satisfaction to all concerned; the cost would not be great, as the bottom of your borings must be near the top of that rock.

Wood.—The cross drift was not sufficiently extended to the west to prove the dyke, but, as there was a considerable rise of the strata in that direction, no doubt such an inclination has been occasioned by the proximity of the dyke, shown on the plans, Figs. 1087, 1088. All the facts show that the slip-dyke has been a dislocation subsequent to the formation and consolidation of the various beds affected by it; and consequently such dyke could not, we can scarcely conceive, have any influence on the character of the ironstone bed itself, especially as it is not contended, I believe, that such dykes are either of a basaltic or mineral character, there being no appearance, in my judgment, to justify such a conclusion.

Tubing Bore-holes.—P. S. Reid being consulted as to the chance of finding coal in the Cleveland district, at Kirklevington, near Yarm, and finally he was requested to superintend a boring then pursued to the depth of 582½ ft., but which, owing to circumstances which were difficult to determine, had become very expensive, and made slow progress.

The 582½ ft. had been done entirely by manual labour; but Reid recommended the erection of a horse-gin, in which the power was applied to a 40-in. drum placed upon a vertical axle, the arms of which admitted of applying two horses, and men at pleasure, the power gained being in the proportion of one to ten at the starting-point for the horses.

Upon the upright drum a double-ended chain was attached, which worked over sheer-legs erected immediately over the hole, so as to attain an offtake for the rods of 10 fathoms, and so as that, in the act of raising or lowering, there might always be one end of the chain in the bottom, ready to be attached, and expedite the work as much as possible.

These arrangements being made, it was soon found that there was a defect in the tubing which was inserted to the depth of 109 ft., and the defect was so serious, in permitting the sand to descend and be again brought up with the boring-tools, as to render it very difficult to tell in what strata they really were; this increased to such an extent as to cause the silting up of the hole in a single night to the extent of 30 fathoms, and occupied nearly a fortnight in clearing the hole out again.

On carefully examining into this defect, it appeared that the water rose in the hole to the depth of A, Fig. 1098, 74 ft. from the surface; and that at this point it was about level with the high-water mark on the Tees, about two miles distant, which it was no doubt connected with, by means of permeable gravel beds, extending from the arenaceous strata at B, Fig. 1098.

On commencing to bore, the motion of the rods in the hole caused the vibration of the water between A and C at the bottom of the tubing, and so disturbed the quiescent sand as to cause it to run down through the faults in the lower end of the tubing at the latter point.

This tubing was made of galvanized iron plates, riveted together and soldered so as to attempt to make it a water-tight casing; at the top of the hole it was in three concentric circles, which had been screwed and forced down successively until an obstacle was met with at each different place shown by the letters D, E, C. So soon as the outer circle reached the depth of D, all hope appears to have vanished, from those who bored the earlier part of the work, of getting the tube farther; a second tube was, therefore, inserted, which seems to have advanced as far as the point marked E, where it, in its turn, was abandoned; and a third one advanced until it rested in the strata at C, which is, no doubt, the lower part of the lias freestone of a blue nature, as found on the rocks at Seaton Carew, and in the bed of the Leven, near Hutton Rudby. The diameter of the first tubing was $3\frac{1}{2}$ in. external and $3\frac{1}{4}$ in. internal; the second tube was $3\frac{1}{2}$ in. external and 3 in. internal diameter; and the third tube was $2\frac{3}{4}$ in. external and $2\frac{1}{2}$ in. internal diameter.

Such being the account gathered from the workmen who superintended the earlier part of the boring, it became necessary to decide upon the best course to remedy the evil. At first sight it would have appeared easy enough to have caught the lower end of the tubes by means of a fish-head properly contrived, and thus to have lifted them out of the hole, and replaced them with a perfect tube, such as a gas-tube, with faucet screw-joints; but, on attempting this, it soon became evident that, however perfect the description of tubing which might have been adopted, it would be a work of the greatest difficulty to extract when once it was regularly fixed and jammed into its place by the tenacious clayey strata surrounding it; and that the difficulty of extracting, in the present case, was even enhanced by the inferior quality and make of the tubing: in short, that, unless by crumpling it up in such a manner as to destroy the hole, it was impossible to extract this tubing by main force.

There was, therefore, no other choice left, but to attempt cutting it out, inch by inch; though before doing so, I may add, says Reid, that we did attempt main force, to the extent of upwards of 30 tons, applied to the bottom of the tubing, in which the only success we attained was, the losing of several pieces of steel down the hole, which we were compelled to fish up with a powerful magnet.

After much mature consideration and contrivance, it was determined to order such a perfect tubing as would at the same time present as little obstacle as possible to the clay to be passed through on the outside, as well as surround the largest of the three tubes then in the hole, and present no obstacle to their being withdrawn through its interior.

These tubes were made 12 ft. in length, flush outside and in, the lower portion being steeled for 6 in. from the bottom end, so as to cut its way and follow down the space, and cover that exposed by the old tubes when cut and drawn, as shown in Fig. 1099.

In order to commence operations, and avoid too much clay going down to the bottom of the hole, a straw-plug was firmly fixed in the lias portion of the hole at F, Fig. 1098. The lower portion of the new tubes was then screwed on to the top of the old ones by means of powerful clamps, attached to the exterior in such a manner as to avoid injuring the surface; and so soon as it was evident that they could be screwed no farther, the knife or cutter, Figs. 1099 to 1101, was introduced inside the old tubing. Some force, it will be evident, was needed to get this knife down into the tubing, but the spring *a* giving so as to accommodate itself to the hole, permitted its descent to the distance required; this being effected, it was turned round so that the steel cutter, shown at *b*, being forced against the sides of the tube, cut it through in the course of ten minutes or a quarter of an hour's turning. See section at *b*, *c*, Fig. 1101.

The old tubes being three-ply, three of these knives or cutters were required to cut out the three tubes, the inner one being detached first, and then the two exterior ones; and so soon as these latter were cut out as far as they had been forced into the clay, the work became simplified into following down the interior tubing by the new tubes, as shown by the dotted lines from *d* to *e*, until we arrived at the lower end, where it was evident that the old inner tube had been so damaged or torn, either by the putting in or hammering it down, as to leave a vent or fissure for the sand to descend, and thus spoil the whole of the work for all future success in the boring, to say nothing of the very great cost of lifting the sand out, and subsequent most arduous labour to put the hole right.

We (says Reid) finally recommenced the boring after about a month's labour in taking out the old tubings, leaving the new ones firmly bedded into the lias formation at G, Fig. 1098, 112 ft. from the surface, and subsequently bored to a depth of 710 ft. in the new red sandstone formation, proceeding at the rate of about 3 ft. in the 12 hours, and leaving the hole so as, if requisite, it may be widened out to 4 in. diameter; and, possibly, should more sand be met with on reaching the magnesian limestone, or sands connected with it, it may again be retubed and the work continued to such depth as may be desirable.

Reid observed, in his paper published in the 'Transactions of the North of England I. M. E.,' "To the care of G. B. Lloyd in the manufacture I attribute a good deal of my success in renewing these tubes. At the same time, the experience so gained in their construction convinces me that if adopted in many places where air-holes are required in mines, and which will not justify the

still rising only to A, and flowing always from that point when passed down the hole. Fig. 1099 shows the action of the knife and spring-cutter, when forced down into the tubing, ready to commence cutting. It also shows the lower end of the new tubing enclosing the others at the commencement of the work; the junction of the tubes, by means of the half-lap screw, being shown at j. Fig. 1100 shows a front view, with knife or cutter b. Fig. 1101 shows the action of the spring and cutter when the requisite length is cut through and ready for lifting; the position of the tube being maintained perpendicular, or nearly so, by the ball or thickening on the rods at K, and the lower end of the tube being supported by the projecting steel cutter at b, the dotted lines from d to e showing the position of the new steel-ended tube when screwed down ready for another operation. In boring deeper after the tubes were removed, three wooden blocks were used round the rods in the new tube to keep them plumb.

"In examining the nature of the strata thus passed through, as described, it will be evident that, to ensure success, the tubing, of whatever it is made, should be as truly cylindrical as possible, straight, and flush surface, both outside and in. It will also be evident that in thus joining pieces of tubing together in this manner, the thickness ought to have a due proportion to the work required, and the force likely to be used in screwing them down; and also that the only correct way of getting such tubes effectively into the ground is by screwing and not hammering, as in the case of pile-driving, or similarly to forcing a nail in. The author has seen this attempted on several occasions, but invariably with failure to the success of the work, and is convinced that no successful practical borer will adopt such measures.

"In some cases we had to widen out holes below the sharp edge of tubing, so as to permit its descent. This is an operation requiring great care and attention." P. S. Reid, in concluding, observed, "That no branch of mine-engineering is qualified to bring out more thoroughly the abilities of a young engineer than a perfect knowledge of the science of boring, requiring, as it does, the best mechanical skill, as well as the best knowledge of assaying rocks by chemical analysis. He is aware of more than one deep boring in important districts, which were finished many years ago, and cost large sums of money, but which, in the then knowledge of chemistry, were not critically examined, and hence, so far as their results are concerned, are utterly useless; the fact being that, beyond the colour of the material bored through, it is unknown whether it was a limestone, or what it was, to this day."

Rock-boring Machinery.—In driving a tunnel or quarrying in hard rock, the only method whereby the rock can be worked is by blasting; and the Rock-boring Machine, which we will presently describe, was constructed by George Low for the purpose of boring the blasting holes, with a view to facilitate and expedite the work by superseding the very slow and laborious mode of performing this operation by hand. The machine is driven by compressed air, and works a boring tool or jumper for boring the holes; and the boring-tool works in a direct line, with a self-acting reciprocating motion at a very high velocity, and is continuously turned round during its working, being made to rotate slightly between each blow.

The boring-tool is fixed direct upon the end of the piston-rod of a working cylinder; and this working cylinder moves within another exterior cylinder, in which it is made to rotate for the purpose of giving the rotating motion to the tool. The working cylinder has also a longitudinal forward motion within the exterior cylinder for giving the advancing feed to the tool, the working cylinder being propelled forwards by the compressed air that works the tool, thereby dispensing with the necessity for employing propelling gear, which is liable to break or get out of order, and is subject to rapid wear. The exterior cylinder is carried by a spherical trunnion in a movable radial arm or jib mounted on a travelling carriage, which gives the means of adjusting the boring-tool to any desired direction and position, so that the holes may be bored in the most suitable directions, according to the strata of the rock, for the blasting to take the best effect in breaking up the rock.

This rock-boring machine, which is the invention of G. Low, is shown in Figs. 1102 to 1112. Figs. 1102 to 1106 are sectional plans and longitudinal sections, showing the boring-tool and working cylinder in different positions during the working of the machine; and Figs. 1107 to 1112 are transverse sections at successive points.

The machine is only 4 ft. 6 in. total length, being made as short as possible in order that it may be moved in any direction in the tunnel, so as to enable it to be set to bore at any angle and in any position and direction that may be desired. The working cylinder A, Fig. 1104, constructed of brass, is placed inside an exterior cylinder B of cast iron, which is fitted with a spherical trunnion C to support it in the radial jib or arm of the travelling carriage, as shown in Figs. 1122, 1123. The inner cylinder A is free to move longitudinally within the exterior cylinder from end to end as it advances during the process of boring, as shown in Figs. 1104 and 1106; and it is also free to rotate within the outer cylinder, for giving the rotating motion to the boring-tool D. The back end of the working cylinder A is packed with a cupped leather, shown black in Fig. 1106, so as to be air-tight when moving within the exterior cylinder B. The front end of the working cylinder A fits into a wrought-iron cross-head E, in which it is free to revolve; this cross-head is bored out on each side to slide upon the two screwed guide-bars F, which are bolted to the exterior cylinder B, Figs. 1106, 1110, and 1111, and are carried forwards to the end bearing G of the machine. The guide-bars F have a double thread of $1\frac{1}{2}$ -in. pitch chased upon them from end to end, but the thread is planed off on the inner side of each screw down to the body of the guide-bar, for the purpose of obtaining greater compactness in the construction of the machine, as seen in the transverse sections, Figs. 1110 to 1112.

At the back end of the working cylinder A is the air-valve N, Figs. 1106 to 1108, which is a circular disc valve with six inlet-ports and six exhaust-ports, as seen in Figs. 1107, 1108. This valve is turned by a double spiral cam O, which is carried forwards into the end of the piston and piston-rod K, and is acted upon by the four rollers P P, Figs. 1106, 1109, bearing on both sides of the spiral wings of the cam. The spiral wings are so sloped that as the piston moves backwards

and forwards the cam is gently turned or twisted, carrying with it the air-valve N fixed upon the spindle of the cam. The slopes of the cam are so arranged that the valve N opens the inlet-ports for admitting the compressed air to act upon the large area of the piston, in order to make the forward stroke of the tool; and the valve is then turned so as to allow the air to exhaust again after the piston has struck the blow. The return stroke of the piston is produced by a constant pressure of the compressed air upon the small annular area of the front of the piston, the pressure for this purpose being maintained through the two ports shown in Figs. 1106 to 1110, which are always open. The exhaust air is discharged at the front end of the exterior cylinder B, being carried along grooves in the circumference of the working cylinder A, as seen in the plan, Fig. 1104, and the transverse sections, Figs. 1107 to 1110.

The boring-tool is caused to rotate by rotating the working cylinder A, the piston being prevented from turning in the cylinder by means of two flats planed on opposite sides of the piston-rod K, which fit into corresponding flats in the stuffing-box of the cylinder, as seen in Figs. 1106, 1110, and 1115. The rotating of the working cylinder A, with the piston and boring-tool, is effected by hand by the worm Q, Fig. 1110, which is turned by the handle R, Figs. 1110, 1111, and gears into a worm-wheel fixed on the square shaft S. The brass pinion T, Figs. 1103, 1105, and 1111, slides upon the shaft S, and gears into the teeth U round the circumference of the working cylinder A, Figs. 1104, 1111; so that by turning the handle R the working cylinder is caused to rotate; and as the cylinder advances at each turn of the nuts H, the pinion T slides forwards with it along the square shaft S, as seen in Fig. 1105. In an earlier construction of the boring machine, having a pair of cylindrical trunnions instead of the present spherical bearing C, a self-acting rotating motion was obtained from the spiral cam O that works the disc air-valve N, by prolonging the spindle of the cam through the back end of the exterior cylinder B; and a couple of pawls on the end of the spindle worked into a ratchet-wheel on the end of the square shaft S, which was also prolonged backwards for the purpose in the absence of the spherical bearing C. In practice, however, it has been found preferable to rotate the working cylinder by hand, by means of the handle R, as above described, because the very rapid reciprocation was very severe upon the self-acting rotating motion, making it liable to derangement; and the hand arrangement, besides having the advantage of simplicity, avoids the necessity of prolonging the shaft S backwards, and thus allows of adopting the spherical trunnion C, which gives increased facility for turning the machine into any position desired for boring the holes.

The cross-head E slides forwards along the two screwed bars F as the working cylinder A is advanced inside the exterior cylinder B during the process of boring; and in front of the cross-head the nuts H are fitted on the screwed bars F, against which the cross-head and with it the working cylinder are pressed by the pressure of the compressed air behind the working cylinder A. The nuts H are held from turning, and thereby prevented from going forwards, by four projecting stops upon their circumference, Fig. 1112, which are caught by the catches I below; these catches are kept pressed up by springs against the under-side of the nuts; and between the two

catches is placed a tappet J, so curved that it may be struck by the end of the piston-rod when the latter has reached the outer extremity of its stroke, as shown in Fig. 1105.

The mode of action of this advance motion is as follows:—The compressed air is admitted by the flexible pipe L into the exterior cylinder B behind the back end of the working cylinder A, which is thus kept pressed outwards against the cross-head E, while the cross-head is kept in its place and prevented from going forwards by the nuts H, and these are prevented from turning by the catches I. But when the boring-tool D has advanced $\frac{3}{4}$ in., the distance due to one quarter turn of the nuts H, the outer end of the piston-rod K, which is allowed a range of $\frac{3}{4}$ in. variation in the length of its stroke, strikes against the tappet J, as shown in Fig. 1105, and depresses it sufficiently to make the catches I release the projections on the nuts H; the forward pressure of the working cylinder and cross-head against the nuts then causes them to slip past the catches and advance one quarter turn, thereby moving forwards $\frac{3}{4}$ in. upon the screwed bars F, when the next projections on the circumference of the nuts are caught by the catches I. This process is repeated for every $\frac{3}{4}$ in. bored by the tool, until the nuts reach the front end of the screwed bars F.

By this arrangement the boring-tool is allowed to advance at whatever rate it may be cutting in the rock. When the rock is comparatively easy to bore and the tool is cutting rapidly, the projections on the nuts slip past the catches from one to another rapidly, and consequently allow each successive $\frac{3}{4}$ -in. advance to occur more quickly; whilst when the rock is harder and the tool is cutting slowly, there is so much longer an interval between each release of the catches, and the advance of the nuts is less frequent, thus admitting of a greater number of strokes being made by the boring-tool for each $\frac{3}{4}$ -in. length of hole bored.

For winding back the working cylinder A by hand, when required for the purpose of changing the boring-tool, the two worms M M, Fig. 1112, turned by a hand-wheel, are geared into the nuts H, as shown in Figs. 1102 to 1106. The friction of the worms also acts as a break to prevent the nuts from turning too suddenly, as it causes them to move gently when the projections on the nuts are released by the catches I at each $\frac{3}{4}$ -in. advance of the boring-tool.

As the working cylinder A and cross-head E only press loosely forwards against the nuts H, neither the nuts nor the screwed bars F receive the slightest portion of the concussion from the blows of the tool; but the shock of each blow is conveyed direct to the air-cushion behind the working cylinder A, in the back end of the exterior cylinder B. This effectually prevents crystallization of the portions that are exposed to the direct concussion of the blow, and prevents any loosening of the several parts of the machine; it also relieves the carriage-frame from the full shock of the blow, and steadies the boring cylinder.

At the outer end of the two guide-bars F are two screwed caps V V with steel points, Figs. 1102, 1104, for the purpose of steadying the end of the machine against the rock. The outer end of the boring-tool D is steadied in the front bearing G, across the end of the two guide-bars F, in order to compel the tool to bore straight when it meets with extra hard rock or quartz veins inclined to the direction of the hole; and by turning the handle W, the top bearing or step can be readily lifted out when the boring-tool requires taking out for changing. During the working of the tool a jet of water is kept constantly playing into the hole; and this, aided by the reciprocation of the tool, effectually clears out all the loose material as fast as it is detached by the tool, without ever requiring the tool to be withdrawn, as in hand-labour, for the purpose of clearing out the hole. In one of these boring machines, worked in the Roundwood Tunnel of the Dublin Corporation Water-works, the water was obtained from the top of the tunnel shaft, being a

portion of that raised by the pumping engine which drained the tunnel, and the jet was thrown into the bore-hole under a pressure of about 80 lbs. per sq. in.

The mode of fixing the boring-tool D in the piston-rod K is shown in Figs. 1113 to 1115. The fixing of the tool is a very important point in the working of the machine, in order to ensure a thoroughly secure fixing and at the same time the means of readily and quickly changing the tool. The tool D is dropped into a socket in the end of the piston-rod K, and the parallel cotter X being then passed through is fixed by the screwed gland Y, which presses the tool home to the bottom of the socket, and secures the cotter endways by entering into the two notches in the front edge. The gland Y is prevented from turning back by a ratchet and spring Z; and for releasing the tool the spring is held back by a stud while the gland is unscrewed.

Several different forms of boring-tools have been tried with the machine, but the results of experience have led to the adoption of the two forms only that are shown in Figs. 1113 to 1119. The rose-tool, Figs. 1113, 1117, having two chisel-edges at right angles to one another, is found the best form for commencing the hole and boring the first 9 or 10 in. length. The shape of this tool, in conjunction with the continuous rotary motion given to it between each stroke, prevents

1120.

it from being led away sideways when it meets with a vein of quartz harder than the rest of the rock and lying much inclined to the direction of the hole. The second tool, Figs. 1116, 1118, used for completing the hole, is a chisel formed with the cutting-edge in three bevels a little inclined to one another in both directions. The chisel shown in Figs. 1114, 1119, was found the best for boring straight, but it could not be made to stand well, and was consequently abandoned. A hollow tool has also been tried, into which was inserted a water-jet; and the exhaust air from the cylinder was also turned into it, which blew the water out from the point of the tool into the hole with considerable force. This was found a most excellent plan for keeping the hole clean; but in consequence of its complication and the liability of the jet-orifice to become choked up with deposit from the water employed, it was abandoned, and the separate water-jet already described was substituted.

The frame and carriage for this boring machine are shown in Figs. 1120, 1121. The traversing carriage A is made very low, in order to allow of readily removing the debris from blasting; and upon it is mounted the upright pillar B, capable of swivelling round upon the carriage and having means for clamping it securely between the top and the bottom of the tunnel. The working cylinder C with the boring-tool D is carried by the transverse frame or rest E upon the

1121.

extremity of the horizontal jib F projecting from the centre pillar B. The arm G carrying the boring cylinder C can be traversed into any position in the frame E by means of a screw-motion worked by the hand-wheel H; while the frame E can itself be turned round upon the axis of the horizontal jib F by the hand-wheel I working the worm-wheel J, and the jib F can be lengthened or shortened by the hand-wheel K. By this means the boring cylinder C can be adjusted to any part of the face of the tunnel; and the spherical trunnion by which the boring cylinder is carried in the arm G allows of its being placed to bore in any position and direction. These several adjusting movements enable the tool to bore the holes in the exact line the miners may wish to place the shot, as the boring cylinder can work either upwards, downwards, sideways, or at any inclination; and all the movements are at all times central and within easy reach of the attendant, whatever may be the direction or position of working.

The transverse frame or rest E is provided at each end with a pair of projecting steel points L L, which can be lengthened or shortened so as to clamp the rest securely against the rock, thereby relieving the horizontal jib F and the pillar B from the shocks produced by the blows of the boring-tool. The steel points L L are attached to pistons inside the columns of the rest E; and, by admitting the compressed air between the pistons, the points are caused to strike out against the sides of the tunnel, and are then secured by self-locking catches. It is generally found sufficient, however, simply to wedge the hind wheels of the carriage in order to render the whole perfectly steady, without any necessity for clamping the carriage and rest against the rock.

The compressed air for working the boring machine is supplied by an Air-compressing Engine at the top of the shaft, driven by a small portable steam-engine. The air-compressing engine is shown in Figs. 1122 to 1126, and consists of two horizontal compressing cylinders A A, Fig. 1122, fitted with air-tight pistons packed with brass rings or cupped leathers, Fig. 1124. On each end of the cylinder A are upright chambers C C, and on the top of each chamber are a pair of inlet and delivery air-valves, so that there are two inlet-valves D D and two delivery-valves E E to each compressing cylinder; these valves are circular, and fit air-tight upon conical faces, as seen in Figs. 1124, 1125. The four inlet-valves D D are each suspended from a lever F, and in the original construction there was simply a weight on the outer end of the lever to cause the valve to shut when the piston B had drawn in sufficient air to fill the chamber C; it was found, however, that the valves did not work very steadily with the levers and weights, and they also shut before the piston reached the end of the stroke, so that part of the stroke was wasted in uselessly expanding the air in the chamber C. A cam G, Fig. 1125, worked from the crank-shaft H, was therefore added to each of the valve-levers F; and the cam opens the inlet-valve at the commencement of each forward or suction stroke of the piston, and keeps it open till the commencement of the return or compressing stroke, when the valve is shut suddenly by the weight; and this arrangement has proved quite satisfactory. The delivery-valves E E are shut by the back-pressure, as soon as the compressed air is all forced out of the chambers C; they deliver the air into the air-vessels J, which are for the purpose of equalizing the pressure of the air under the varying pressure of the stroke. A pipe K from each of the two air-vessels conveys the compressed air to a large wrought-iron receiver, from which it is supplied for working the boring machine.

The two air-compressing cylinders A A, Figs. 1122, 1124, are each 14 in. diameter with 18 in. length of stroke, and are placed at each end of a cast-iron bed-plate; the pistons are worked by connecting-rods from the double cranks H at right angles to each other, which receive motion from the countershaft L driven by the steam-engine. By employing two cylinders of half area each for compressing the air, worked by cranks at right angles to each other, instead of a single larger cylinder, an advantage is gained in delivering the compressed air to the receiver more uniformly, and also the strain on the working parts is more evenly divided. The cylinders A are filled with water, which rises at each stroke to the top of the upright chambers C C, and the surplus water is forced through the delivery-valves E, the object being to fill up every space with water at the end of the stroke, and so ensure every particle of air being forced through the delivery-valves. To allow for leakage and waste of water, a supply is kept constantly flowing into the inlet-valves D from the small pipe M, regulated by a tap; and the water forced through the delivery-valves at each stroke keeps the air-vessels J J constantly filled with water up to the mouth of the pipe K, so that the compressed air is kept quite cool. The surplus water passing into the pipe K slowly accumulates in the large air-receiver, out of which it is discharged occasionally.

1122.

The crank-shaft H is driven at 22 revolutions a minute, and at each stroke the piston draws in the air through the inlet-valve at one end of the cylinder, and compresses the air to six atmospheres, or 90 lbs. the sq. in., at the other end of the cylinder, discharging the compressed air through the delivery-valve to the receiver. The minimum pressure maintained in the air-receiver is 75 lbs. the sq. in., and the maximum 125 lbs., the average being about 85 lbs. the sq. in. From the receiver the compressed air is conveyed, by cast-iron pipes with india-rubber joints, up to within 50 ft. of the boring machine. It is then conveyed to the machine through an india-rubber pipe made with six-ply canvas, and about 100 ft. long, which allows the boring machine to be advanced or drawn back without undoing a single joint.

This boring machine, of which a longitudinal and transverse section are shown in Figs. 1120, 1121, was employed in the construction of the Roundwood Tunnel for the Dublin Corporation Water-works, where it bored the holes for blasting at one of the working faces. The tunnel is rectangular, 5 ft. wide and 6 ft. high, and is carried through Cambrian rock of a remarkably hard and difficult character, interspersed with quartz veins. Six shot holes of 20 in. depth were usually fired at each blast, and these six holes of $1\frac{3}{4}$ in. diameter were all bored by the machine in about $3\frac{1}{2}$ hours; two chisels were used for each hole, which required fresh grinding before being again used. With hand-work, however, each of the same holes takes $2\frac{1}{2}$ to 3 hours for drilling, and requires usually about fifteen fresh tools before it can be completed. The practical value of this remarkable saving of time that is effected by the use of the machine is specially experienced in such work as tunnelling or other rock-blasting, where saving of time is of such great importance both in expediting and economizing the work. The average rate at which the very hard rock was bored by the machine at the Roundwood Tunnel was about 1 in. a minute: and it has been found as the result of experience with the machine that it bores quicker and keeps the edge on the tool better by striking with less force of blow but with greater rapidity. The number of blows has been increased from 250 to 500 or 600 blows a minute, and the result is that one hole is now bored with two tools without re-sharpening, instead of using five or six tools, as formerly; and with one tool a hole of 26 in. depth was bored in the Dalkey granite without re-sharpening.

The following are the results of working in the Dalkey granite:—

1st hole, $24\frac{1}{2}$ inches deep, in 11 minutes 10 seconds.	
2nd " $19\frac{1}{2}$ " " " 14 " " "	
3rd " 9 " " " 5 " " 55 "	
4th " $4\frac{1}{2}$ " " " 2 " " 10 "	
5th " 9 " " " 7 " " 35 "	
6th " 9 " " " 5 " " 25 "	

The following are the results of working in the remarkably hard rock of the tunnel at Roundwood, Wicklow:—

1st hole .. { $8\frac{1}{2}$ inches depth, in $3\frac{1}{2}$ minutes.	4th hole .. { 10 inches depth, in 6 minutes.
6 " " " 8 " "	9 " " " 3 " "
9 " " " 3 " "	
Total .. $23\frac{1}{2}$ " " " $14\frac{1}{2}$ "	Total .. 19 " " " 9 "
2nd hole .. { 12 " " " 8 " "	5th hole .. { $10\frac{1}{2}$ " " " 4 " "
9 " " " 4 " "	8 " " " $4\frac{1}{2}$ "
Total .. 21 " " " 12 "	Total .. $18\frac{1}{2}$ " " " $8\frac{1}{2}$ "
3rd hole .. { 6 " " " 5 " "	6th hole .. 14 " " " 10 "
9 " " " 10 " "	
Total .. 15 " " " 15 "	

The average at which the machine continued to bore was, for the first portion of the hole, 10 and 11 in. depth in $4\frac{1}{2}$ to 8 minutes; and for the second portion, 9 and $9\frac{1}{2}$ in. depth in 3 to $3\frac{1}{2}$ minutes.

The following special points of advantage have been experienced in this boring machine; and these may be considered as essential conditions to be fulfilled in a good machine for the purpose of boring in hard descriptions of rock, and for standing satisfactorily the special wear and tear to which such machines are necessarily subjected.

The boring part of the machine with the tool is made very short, so as to allow it to work in any direction and position in the tunnel, in order that the blast of the hole bored may displace the largest amount of rock. The carriage-frame carrying the working cylinder is also very compact, occupying little space, and allowing the cylinder to be quickly adjusted into any desired position.

The reciprocating parts are very few in number, and are in the direct line of the blow; these are only the piston and rod in one piece of steel, and the tool secured in the piston-rod so as to allow no play. Moreover, in order to prevent crystallization of the parts exposed to the direct concussion, a cushion of air is provided at the back of the working cylinder, which also relieves the carriage-frame from the shocks of the blows. Also, the tool being made to reciprocate with the piston, the hole is more easily kept free from the *débris* than when the tool is stationary and receives blows from a detached piston, as in other descriptions of boring machines; and the strong water-jet playing into the hole is found to keep it quite clear during the process of boring.

The advance of the tool is self-acting, and exactly at the same rate that the tool is cutting, however variable may be the nature of the rock; and whether the tool is cutting at the rate of

3 in. a minute in one part of the hole, or only 1 in. a minute in another part, the advance given to the tool is exactly at the same rate that the boring progresses in each case; so that there is no risk of the piston at any time working beyond its proper range of stroke, and striking the cylinder-cover. The advance motion for the tool is obtained from the pressure that drives the piston, without the use of propelling gear, the absence of which greatly increases the durability of the machine. The turning motion for the tool also, being connected to the stationary outer cylinder, is freed from the source of derangement that would arise from the rapidity of the blows of the tool if the turning motion were connected to the reciprocating part. The motion for working the valve is gradual and easy in its action, so that a very rapid action is obtained without any destructive shocks. The outer end of the tool is guided in a bearing, to prevent it from working to one side, and getting jammed when meeting with an oblique vein of harder material.

The machine is arranged so that it can be brought to work again immediately after a set of holes have been blasted and before the *débris* is removed, which can be done whilst the machine is at work, the material being carried or thrown through the clear space left by the carriage-frame; and a jet of air being left open near the face at the time of explosion soon dilutes and clears off the gases resulting from the explosion of the powder. This saves much of the loss of time which occurs with other machines in removing the *débris* before the machine can be set to work again. The compressed air, on being discharged from the boring cylinder, also serves effectively to ventilate the workings, and supplies fresh air to the miners.

Bergström's Boring Machine.—This boring machine, Figs. 1127 to 1132, which is now being used at the Perseberg mines, near the town of Philipstad, in Sweden, is a modification of that constructed by Schumann, of Freiberg.

The machine consists of a cast-iron cylinder A, Fig. 1127, $4\frac{1}{2}$ in. in diameter, in which the piston B, and at the same time the borer fixed in the socket C, is moved by compressed air. The length of the stroke is 7 in. The compressed air enters by a pipe at D, and then passes through one of the ports E into the cylinder, and moves the piston backwards and forwards. F and F are two single-acting cylinders, in which the pistons O L, and their common piston-rod, are moved by air. K is the slide-valve, which is pushed backwards and forwards by bosses on the piston-rod, in order to make the air act sometimes on one side of the piston and sometimes on the other. By means of the nuts at L, the position of the slide-valve on the valve-face is determined, and con-

sequently at the same time the entry of the air. M is a guide for the slide-valve. On the valve-rod the cross-head N is keyed, which, by means of two connecting-rods O, sets in motion the fly-wheel P, its axle, and the worm Q, which has been formed on it. The screw takes into the worm-wheel R, which thus causes the spindle S to rotate. The spindle S has on each side a groove, in which feathers, dovetailed into the hollow piston-rod C, can readily move, and thus when the spindle turns it causes the rotation of the piston and consequently also of the borer.

The machine hangs from, or may be supported by, a bar T having a thread cut on it. In order to prevent the machine from turning on the bar T, the thread is cut away, as shown on the cross-section and plan. By means of the screws U and U, the rod is firmly forced against the rock. The advance of the machine is effected by hand, by working a winch-handle X, which actuates a mitre-wheel Y, which gears into another mitre-wheel on the nut W. This nut W is held between two lugs cast on the cylinder, and therefore as the nut is caused to rotate the machine advances or retires. The machine gives 200 to 300 and even 350 blows a minute, and the borer makes one entire turn for 22 blows.

Strut.—In order to furnish a point of support for the screws U, a wooden strut, Fig. 1130, provided with an iron at its upper end, and at its lower with an adjustable screw and tripod, is firmly fixed across the level.

It will now be readily understood that the machine can be fixed in any position, and consequently holes can be bored in all directions. It takes two men to put up the machine, and one to attend to it. The other man can be boring by hand in the meantime.

Air-compressor.—At the Perseberg mines the machine is worked by compressed air. The air-compressor, Figs. 1131, 1132, was designed by Professor Angström. It consists of two vertical iron barrels, 15½ in. in diameter and about 8 ft. high, communicating with one another at the bottom by a chamber.

The upper end of each barrel is provided with a valve-box having two valves, one opening inwards, for the admission of air, and the other outwards into the delivery-box, for the eduction of air. In one barrel a piston is made to work up and down, and in order to deliver every particle of air at each stroke, and to keep the barrels cool, a quantity of water is placed inside the pump, which at each stroke entirely fills up the valve-box, and thus expels the whole of the air from the pump. The other barrel has no piston working in it, but is also filled with water, which is caused to rise and fall as the piston goes down and up. This water also forces out all the air from the barrel and valve-box at each stroke. The piston-rod is connected to the main rod of the pumping engine, and is provided with a cross-head, from which a weight is suspended by rods. The stroke is 7 ft. Four strokes a minute furnish enough air for one boring machine. The air must be compressed to 15 lbs. or 20 lbs. a sq. in., which corresponds to an excess pressure of 1 or 1½ atmospheres. If such a pressure cannot be had, no good results are obtained.

This air-compressor is specially constructed for places where the power is derived from the main rod of the pumps. It is considered that 5 or 6 horse-power would be required to drive an air-compressor. In the Perseberg adit the air-compressor is from 60 to 70 fathoms from the end; there is no regulator.

Pipes.—The air is conducted from the compressor along the level by cast-iron flange-pipes, 4 in. in diameter and 9 ft. long, with a small spigot and socket, the joints being made with tar, mixed with finely-powdered brick and lime.

These pipes conduct the air very nearly to the end, and the air is finally brought into the machine by some 30 ft. of india-rubber pipe, 3 in. in diameter and $\frac{1}{8}$ in. thick.

F. B. Doering's rock-boring machine, Figs. 1133 to 1138, has an effective means of regulating

the forward movement of the main cylinder in which the piston carrying the tool works, as the work progresses. A piston-valve *a* regulates the supply of water or other fluid to and its outlet from a pair of cylinders *b b*, attached to the main cylinder *c*, the valve *a* being worked by a piston in a cylinder by motive fluid distributed from the main cylinder to the small cylinder *d*, the piston of which is connected to the valve. Instead of attaching the adjacent cylinders to the boring

cylinder, the pistons of these cylinders may be attached to the working or boring cylinder, the adjacent cylinder in this case being fixed. The adjacent cylinders *b b* have each a fixed piston *c*, and a supply of compressed air may be maintained at the front. So much of each of the cylinders as is behind the piston or pistons is filled with water. A tube connected at *f* leads from the piston-valve *a* to a reservoir containing this water or fluid.

The action of the engine is as follows:—Supposing the main cylinder *c* and adjacent cylin-

ders *b b* are at the back end of their travel; whenever the tool, as it continues to work, has cut to a sufficient depth to allow the main piston to uncover a port in the main cylinder communicating with the cylinder of the piston-valve *a*, this valve moves and allows part of the water in the adjacent cylinders *b b* to escape under the pressure of the compressed air on the other side of the fixed pistons *e e*, or under the pressure due to the weight of the machine if the same is working downwards. The adjacent cylinders and main cylinders are thus caused to advance, and this advance takes place intermittently, according to the quantity of water which escapes from the valve, until they reach the forward end of their travel. A cock at the front part of the adjacent cylinders is then opened to let out the compressed air, and pressure is exerted on the water in the reservoir to force the water through the valve into the adjacent cylinders, the small cylinder *d* exhausting into the main cylinder to allow the valve *a* to be moved by the pressure of the water, the piston of the main cylinder being put into the required position. The pressure of the water in the adjacent cylinders causes them and the main cylinder *c* to run back on their supporting-bars to recommence their forward travel; the valve *a* is then closed, the cock at the front end of the adjacent cylinders reversed, and the pressure in the water reservoir removed.

When the engine is working vertically or nearly so, the employment of compressed air in the adjacent cylinders may be dispensed with, as the weight of the engine will be sufficient to effect the feed as the tool cuts. Again, instead of compressed air in the adjacent cylinders, a vacuum may be created in the water reservoir connected with the valve. This application of water to regulate the advance of a boring engine may be applied directly to the advance of the boring-tool, as shown in Fig. 1137, the cylinder *a* being stationary, and the piston-rod *b* forming a cylinder in which a piston *c* attached to the boring-tool moves. Water is placed in the front portion of the piston-rod at *f*, and a pressure of the motive fluid acting on the back of the piston being constantly supplied through *h* to keep it pressed against the water so as to advance when the water or a portion of it is discharged through *k*. In this case, the valve for the discharge is formed by the piston. This discharge can only take place when the tool has penetrated to such a depth as to allow the port *h* to communicate with *m*. A circular groove is cut in the piston at *k* to regulate or adjust the engine for working in materials of different hardness or softness.

The ports *g g g*, Fig. 1133, in the main cylinder are formed at various distances from the cylinder end, and communicate with the passage leading to the advance cylinder *d* through a cock common to all these ports. According to whether the material operated upon necessitates a short or long stroke, the cock is turned to open the way between the advance cylinder and one or other of the ports, to produce the advance of the engine when the main piston has passed this port in its stroke. Instead of employing a cock common to all these ports, the inventor has provided plugs by which he can close all the ports except the one required for work. It is also sometimes desirable to alter the position of the ports in the main cylinder for working the valve; this may be effected by a cock *h* arranged similarly to that before described, or the communication between the cylinder and its valve-piston may be throttled or *wire-drawn*.

For the purpose of securing the tool in the end of the piston-rod, Doering threads the end of the piston-rod to receive a nut *a*, Fig. 1135, and makes the position of the ordinary key *b* adjustable. The nut *a* is screwed up and the key driven in, thus enabling him to dispense with the washers usually employed. In some cases grooves *c*, Fig. 1136, are formed in the nut to keep it from turning. A nut is also employed on the inner end of the tool-head, Fig. 1138, and the main piston-rod formed hollow so as to pass the tool down it and secure it by a nut and key, as in Fig. 1135.

Mather and Platt's Boring Machine.—The construction of the boring-head and shell-pump, and the mode of acquiring the percussive motion, constitute the chief novelties of the system and machine, shown in Figs. 1139 to 1142. The couple-cylinder engine, with the reversing or link motion, is used for winding and lowering the apparatus; but an ordinary winding engine, similar to those used in collieries, may be applied.

The boring-head consists of a wrought-iron bar, about 8 ft. long, on the lower part of which is fitted a block of cast iron, in which the chisels or cutters are firmly secured. Above the chisels an iron casting is fixed to the bar, by which the boring-head is kept steady and perpendicular in the hole. A mechanical arrangement is provided, by which the boring-head is compelled to move round a part of a revolution at each stroke. The loop or link by which the boring apparatus is attached to the flat wire rope is secured to a loose casting on the wrought-iron bar, with liberty to move up and down about 6 in. A part of this casting is of square section, but twisted about one-fourth of the circumference. This twisted part moves through a socket of corresponding form on the upper part of a box, in which is placed a series of ratchets and catches, by which the rotary motion is produced. Two objects are here accomplished—one the rotary motion given to the boring-head, the other a facility for the rope to descend after the boring-head has struck, and so prevent any slack taking place, which would cause the rope to dangle against the side of the hole, and become seriously injured by chafing.

The shell-pump, Fig. 1141, is a cylinder of cast iron, to the top of which is attached a wrought-iron guide. The cylinder is fitted with a bucket similar to that of a common lifting pump, with an india-rubber valve. At the bottom of the cylinder is a clack, which also acts on the same principle as that in a common lifting pump, but it is slightly modified to suit the particular purpose to which it is here applied. The bottom clack is not fastened to the cylinder, but works in a frame attached to a rod which passes through the bucket, and through a wrought-iron guide at the top of the cylinder, and is kept in its place by a cotter, which passes through a proper slot at the top of the rod. The pump-rod, or that by which the bucket is worked, is made of a forked form, for the twofold purpose of allowing the rod to which the bottom clack is attached to pass through the bucket, and also to serve as the link or loop by which the whole is suspended.

The wrought-iron guide is secured to the top of the cylinder, and prevents the bucket from

being drawn out when the whole is so suspended. The bottom clack also is so arranged that it is at liberty to rise about 6 in. from its seating, so as to allow large fragments of rock, or other material, to have free access to the interior of the cylinder when a partial vacuum is formed there by the up-stroke of the pump.

The percussive motion is produced by means of a steam-cylinder, which is fitted with a piston of 15 in. diameter, having a rod of cast iron 7 in. square, branching off to a fork, in which is a pulley of about 3 ft. in diameter, of sufficient breadth for the rope to pass over, and with flanges to keep it in its place. As the boring-head and piston will both fall by their own weight when the steam is shut off and the exhaust-valve opened, the steam is admitted only at the bottom of the cylinder; the exhaust-port is a few inches higher than the steam-port, so that there is always an elastic cushion of steam of that thickness for the piston to fall upon.

The valves are opened and shut by a self-acting motion derived from the action of the piston itself; and as it is of course necessary that motion should be given to it before such a result can ensue, a small jet of steam is allowed to be constantly blowing into the bottom of the cylinder; this causes the piston to move slowly at first, so as to take up the rope, and allow it to receive the weight of the boring-rod by degrees, and without a jerk. An arm which is attached to the piston-rod then comes in contact with a clam, which opens the steam-valve, and the piston moves quickly to the top of the stroke. Another clam, worked by the same arm, then shuts off the steam, and the exhaust-valve is opened by a corresponding arrangement on the other side of the piston-rod. By moving the clams, the length of the stroke can be varied at the will of the operator, according to the material to be bored through. The fall of the boring-head and piston can also be regulated by a weighted valve on the exhaust-pipe, so as to descend slowly or quickly, as may be required.

The general arrangement of the new machine may be described as follows:—The winding-drum is 10 ft. in diameter, and is capable of holding 3000 ft. of flat wire rope, $4\frac{1}{2}$ in. broad and $\frac{1}{2}$ in. thick; from the drum the rope passes under a guide-pulley, through a clam, and over the pulley which is supported on the fork end of the piston-rod, and so to the end which receives the boring-head, which being hooked on and lowered to the bottom, the rope is gripped by the clam. A

small jet of steam is then turned on, causing the piston to rise slowly until the arm moves the clam, and gives the full charge of steam; an accelerated motion is then given to the piston, raising the boring-head the required height, when the steam is shut off, and the exhaust-valve opened in the way described, thus effecting one stroke of the boring-head as regulated by a back-pressure valve in the exhaust-pipe. The exhaust-port is 6 in. from the bottom of the cylinder; when the piston descends to this point it rests on a cushion of steam, which prevents any concussion. To increase the lift of the boring-head, or compensate for the elasticity of the rope, which is found to be 1 in. in 100 ft., it is simply necessary to raise the clams on the clam-shaft whilst the percussive motion is in operation. The clam which grips the rope is fixed to a slide and screw, by which means the rope can be given out as required. When this operation is completed, and the strata cut up by a succession of strokes thus effected, the steam is shut off from the percussive cylinder, the rope unclamped, the winding engine put in motion, and the boring-head brought up and slung from an overhead suspension-bar by a hook fitted with a roller to traverse the bar. The shell-pump, Fig. 1141, is then lowered, and the *débris* pumped into it, by lowering and raising the bucket about three times, which the reversing motion of the winding engine readily admits of; it is then brought to surface and emptied by the following very simple arrangement. At a point in the suspension-bar a hook is fixed perpendicularly over a small table in the waste tank, which table is raised and lowered by a screw. The pump being suspended from the hook hangs directly over the table, which is then raised by the screw till it receives the weight of the pump. A *cotter*, which keeps the clack in its place, is then knocked out, and the table screwed down. The bottom clack and the frame descending with it, the contents of the pump are washed out by the rush of water contained in the pump-cylinder. The table is again raised by the screw, and the clack resumes its proper position; the *cotter* is then driven into the *slot*, and the pump is again ready to be lowered into the hole as before. It is generally necessary for the pump to descend three times, in order to remove all the *débris* broken up by the boring-head at one operation.

The following facts obtained from the use of the machine in boring in the new red sandstone at Manchester, will show its actual performance, and enable us to compare it with the other systems. The boring-head is lowered at the rate of 500 ft. a minute; the percussive motion is performed at the rate of 24 blows a minute, and being continued for ten minutes, the cutters in that time penetrate from 5 to 6 in.; it is then wound up at 300 ft. a minute. The shell-pump is then lowered at the rate of 500 ft. a minute, the pumping continued for one minute and a half, and being charged, the pump is wound up at 300 ft. a minute. It is then emptied and the operation repeated, which can be accomplished three times in ten minutes, at a depth of 200 ft. The whole of one operation, resulting in the deepening of the hole 5 to 6 in., and cleansing it of *débris* ready for the cutters or boring-head being again introduced, is seen to occupy an interval of 20 minutes only.

Blasting.—Gunpowder is the most valuable agent for excavation; it is, however, of more service in the work of extraction than in that of preparation, because in removing the minerals those regular forms of the walls are not required which distinguish the shaft and the drift from the gallery. Blasting-powder is employed in different quantities and in various forms, according to circumstances. In slaty open rock, in rotten brittle shale, and in loose gravel, it is of no use; but in hard rock, in sandstone, limestone, and similar substances, blasting is extremely serviceable, and often reduces the prices of working hard rock to that of soft material. Gunpowder is of most service where the vein has a seam of soft mineral, or a succession of cavities on one side, so that a blast applied at the opposite termination of the vein may remove the whole thickness of it. If the soft matter or the cavities are in the middle of the vein, it requires always two blasts, and of course the drilling of two holes, as well as two charges of gunpowder, to remove the vein. The amount of gunpowder used is often calculated to be proportionate to the amount of rock removed, but this is not so in practice; where the amount of matter removed is limited, the consumption of powder increases more rapidly than the quantity of rock removed. In mines which have a large quantity of shattered rocks, the application of powder is limited by the consideration that injury may be caused to other parts of the mine. The removal of thick veins, or masses, of heavy rock, also veins of pyrites, is often conducted with considerable difficulty, because heavy blasts cannot conveniently be applied. In all such cases it is, however, the cheapest way of working masses; and if holes for blasting cannot well be drilled, they can be formed by acids. Pyrites may be penetrated by nitric or muriatic acid; also native metals, such as copper, limestone, and magnetic iron ore, may be dissolved by any acid—the muriatic is, however, the most generally used. In this case we cannot sink any other form of hole than a vertical one. The manipulation is easily performed by setting a glass tube vertically upon the rock, and providing its top with a funnel and apparatus, so as to let in the acid drop by drop. If the pipe is close fitting to the rock, and the acid poured in very slowly, the hole will not be much larger than the glass-pipe. The tube must descend with the bottom of the hole, and be always close to it. This operation works very slowly; but in pyrites, or compact magnetic iron ore which cannot be penetrated by steel tools, it is a useful method of preparing a hole for blasting. When heavy masses are to be detached by one charge, the hole may be made wider in the bottom by letting down the acid more rapidly, which will spread over a larger surface and dissolve a greater width. See GUNPOWDER.

We will now give one example of firing charges of gunpowder by means of a fuze, and another by a voltaic battery.

Demolition of a Fort at Furruckabad, in January, 1858: by P. H. Scratchley, R.E.—The fort ordered to be destroyed was a front built of good sound brick masonry, consisting of two solid towers, the left one being 54 ft. in height and the other 36 ft. high, and both being 54 ft. in diameter, connected by a revetted curtain 130 ft. long and 34 ft. in height; two portions of revetment, 30 ft. in length, running at right angles to the curtain, from the towers on each side, and of nearly the same height as the curtain; and also a wall 160 ft. long, 11 ft. high, and 2 ft. thick, forming part of an enclosed court-yard. L is put = the length of the line of least resistance in feet.

The project for the demolition of the front was as follows:—Two charges, with lines of least resistance 18 ft. long, to be placed in each of the towers, 3 ft. in advance of their centres, and at one-lined intervals, Figs. 1143 to 1148. Two charges, with $L = 12$ ft., to be placed in each tower

in rear of the angles formed by the tower and the revetment. The remaining portion of the connecting-curtain to be destroyed by charges, with $L = 10$ ft., placed at $2\frac{1}{2}$ -lined intervals, which required 6 more, as shown in Fig. 1143.

In the towers, galleries with returns were to be driven at nearly equal levels, which the nature of the ground favoured. The mines in the revetment were to be formed by sinking 5 shafts, each 15 ft. deep, with galleries running out right and left from them to the requisite distances.

The charges were calculated according to the formula for strong masonry revetments without counterforts, placed at two-lined intervals, or $\frac{3}{20} L^3$. As native powder was to be used, there was allowed $\frac{1}{2}$ of $\frac{3}{20} L^3$, or $\frac{3}{40} L^3$, in addition to the proper charges of English powder, making the formula $\frac{3}{20} L^3 + \frac{3}{40} L^3 = \frac{3}{10} L^3$.

Scratchley was also directed to prepare the towers at the entrance gateway for demolition, and he carried out the following plan. These towers were 28 ft. in diameter, and from 22 ft. to 29 ft. high on the outside: they were built of softer masonry than the others, and were solid only to a height of 15 ft. from the bottom. A shaft was to be sunk in the centre of each tower, at the level of the ground inside (15 ft. from the bottom), 12 ft. deep; and small galleries were to be driven right and left, 5 and 6 ft. long respectively. The charges were calculated, as above, by the formula $\frac{3}{10} L^3$, and were to be placed so that their lines of least resistance were respectively 8 and 9 ft. long.

The following journal gives the particulars of the work executed.

A detail of officers and men of the Engineer Brigade left the camp at Futtchghur at 3 P.M., 5th January, 1858:—

Corps.	Officers.	Native Officers.	Sergeants.	Corporals.	Privates.	Bugler.	Total.	Remarks.
Royal Engineers	3	..	2	5	52	1	63	Lieut. Scratchley, R.E.
Bengal Engineers	2	..	..	..	..	..	2	" Wynne, R.E.
Bengal Sappers	..	2	4	..	33	..	39	" Keith, R.E.
and Miners .. }								" Lang, B.E.
.. }								" Forbes, B.E.
Total	5	2	6	5	85	1	104	

This detail was divided into 3 reliefs, namely:—

1st relief—20 rank and file,	European.
12	Native.
2nd relief—19	European.
12	Native.
3rd relief—18	European.
12	Native.

The 1st relief commenced work at 8 p.m. on the evening of January 5th.

January 5th, 1st Relief, 8 till 12 p.m., Wynne.—4 galleries, marked B, C, G, H, Fig. 1143, were commenced in the towers, at the respective levels of 26 ft. 6 in., 27 ft. 6 in., 29 ft. 6 in., and 29 ft. 6 in., below the terreplein of the fort, and driven towards the centre of each tower. 4 shafts, A, D, E, F, were also commenced at a distance of 10 ft. from the curtain wall.

January 6th, 2nd Relief, 12 till 4 a.m., Keith.—Shafts A, D, E, F, were completed to the depth of 15 ft. each, and were made 4 ft. by 3 ft. Galleries running parallel to the wall were commenced right and left of each shaft. Soil very easy, being made earth. Galleries B, C, G, progressed slowly through very tough pukka masonry. That at H was softer.

3rd Relief, 4 till 8 a.m., Lang.—The 8 galleries of A, D, E, F, progressed rapidly through made earth. The galleries B, C, G, advanced through tough masonry, and H through soft masonry. The tools were in bad order and were not adapted to mining.

1st Relief, 8 till 12 a.m., Forbes.—The 8 galleries progressed rapidly. The gallery H was cut through pukka masonry, 7 ft., and reached rubble. The progress at B, C, G, was slower.

2nd Relief, 12 till 4 p.m., Wynne.—The 8 galleries were nearly finished:—

		Ft.	In.	
That at B had advanced		9	0	through pukka masonry.
" C	"	8	6	"
" G	"	3	0	"
" H	"	12	0	through made earth.

3rd Relief, 4 to 8 p.m., Keith.—The galleries of A, D, E, F, were finished to the following lengths:—

		Ft.	In.			Ft.	In.
A c (Fig. 1143)	..	12	0	E c' (Fig. 1143)	..	12	6
A b	"	13	6	E c	"	12	6
D b ¹	"	14	0	F c	"	12	6
D c	"	12	6	F b ¹	"	20	0

Hardly any progress was made at G.

1st Relief, 8 till 12 p.m., Lang.—Another shaft I, Fig. 1143, was commenced at a distance of 10 ft. from the wall. A party was also employed in lodging charges in the wall to be destroyed, described in accompanying memorandum.

January 7th, 2nd Relief, 12 p.m. till 4 a.m., Forbes.—

B gallery was 24 ft. long.
 O " 24
 H " 17 ft. 10 in., and return commenced.
 G had not extended through pukka masonry.

3rd Relief, 4 till 8 a.m., Wynne.—Shaft I was completed to a depth of 15 ft., and 2 galleries were commenced from it, running right and left parallel to the wall.

1st Relief, Keith.—The galleries of shaft I were completed to the required lengths, namely, b², 14 ft., and c, 12 ft. Chambers were formed in all the shaft-galleries.

B gallery was completed, with a return 5 ft. 8 in. long.
 C " 7 ft. long.
 At G the work was continued by blasting.
 H gallery was completed, with a return 6 ft. long.

2nd Relief, 12 till 4 p.m., Lang.—The chambers in all the galleries except G were completed. G was 8 ft. 5 in. long, pukka masonry 7 ft. thick having been cut through. More experiments were made on the wall of the court-yard.

3rd Relief, 4 till 8 p.m., Forbes.—More charges were tried on the wall, and a party was employed destroying it by hand.

1st Relief, 8 till 12 p.m., Wynne.—Shafts A and B were sunk 12 ft. deep in the entrance towers.

January 8th, 2nd Relief, 12 till 4 a.m., Keith.—Galleries were driven from shafts A and B, right and left, 7 ft. and 9 ft. long respectively.

3rd Relief, 4 till 8 a.m., Lang.—A party of men was employed in demolishing the wall. Chambers were prepared and bamboos laid (as in all the other mines) for the entrance-tower mines. The whole of the mines were now ready for loading, but the powder had not yet arrived.

9th January.—At 3 p.m. this afternoon the party of Engineers, after carefully closing all the openings of the shafts and galleries, was marched back to Futtehghur camp.

Remarks.—The whole of the work had thus been carried on without interruption, the soil being very easily worked, and being evidently all made earth. No sheeting had been required, excepting in the left gallery at the right entrance tower, where the earth fell in. The whole of the mines were ready for charging in forty-eight hours, with the exception of that in gallery G, where the pukka masonry gave great trouble. The dimensions of all the galleries were 3 ft. 6 in. by 2 ft. 6 in.

13th January.—A detail of the Engineer Brigade left camp at 5.30 a.m. to load the mines at the Fort, namely, 2 officers, 2 sergeants, and 82 rank and file; and 1 officer, and 24 native sappers. 12 of the sappers were, however, afterwards withdrawn to be employed elsewhere.

The charges were placed as follows:—

In B gallery at a ¹	..	..	1050	lbs. of Native powder.
C	"	a	..	{ 800 " English "
G	"	a	..	{ 99 " Native "
H	"	a ¹	..	{ 874 " English "
			..	{ 1050 " Native "

A shaft at	$\left\{ \begin{array}{l} c \\ b \end{array} \right.$	$\left\{ \begin{array}{l} \dots \\ \dots \end{array} \right.$	180 lbs. of Native powder.
D "	$\left\{ \begin{array}{l} b^1 \\ c \end{array} \right.$	$\left\{ \begin{array}{l} \dots \\ \dots \end{array} \right.$	310 " " "
E "	$\left\{ \begin{array}{l} c' \\ c \end{array} \right.$	$\left\{ \begin{array}{l} \dots \\ \dots \end{array} \right.$	180 " " "
F "	$\left\{ \begin{array}{l} c \\ b^1 \end{array} \right.$	$\left\{ \begin{array}{l} \dots \\ \dots \end{array} \right.$	180 " " "
I "	$\left\{ \begin{array}{l} b^2 \\ c \end{array} \right.$	$\left\{ \begin{array}{l} \dots \\ \dots \end{array} \right.$	180 " " "

Approximation.—For English powder and length of 16 ft. of least resistance, we have 16 cubed = 4096, and $\frac{1}{100}$ of 4096 = 614 lbs. of gunpowder, which may be put = 620, the half of which is 310 lbs.

The charges were placed in boxes where practicable, the hose was laid in bamboos, and the whole was carefully tamped.

The galleries took most time in loading and tamping, and were not ready till 7 p.m., whilst the shafts were finished by 4 p.m.

The firing was put off till the next morning, when the hoses of all the shafts were brought to one focus R. There was one focus for each tower, the length of hose for each being 5 ft. less than that for the upper focus, to allow, if possible, a few seconds elapsing between the two explosions. The hose was lighted at the three foci at the same time, at the sound of the bugle, and the explosions were very nearly simultaneous, with the exception of that of one mine, marked X, Fig. 1143, which did not take place till 30 seconds after the others.

The demolition was complete, and the object desired was attained, which was to leave a pretty practicable ramp from the outside into the interior.

There is no doubt that if more time had been allowed, or more men had been procurable, the demolition might have been effected by the expenditure of one-half of the quantity of powder used; but it must be borne in mind that Scratchley's instructions were to have everything ready in forty-eight hours, and native powder was to be had in abundance.

The mines at the entrance gateway were not loaded, but remained ready to be charged at some future time.

Statement of the Expenditure of Powder, Hose, &c.

2 charges of 1050 lbs. each, total 2100 lbs., Native powder.

1	"	$\left\{ \begin{array}{l} 874 \\ 800 \end{array} \right.$	"	"	1674 lbs., English	"
1	"	99	"	"	99 lbs., Native	"
6	"	180	"	"	1080 lbs., "	"
2	"	310	"	"	620 lbs., "	"
2	"	258	"	"	516 lbs., English	"
Total, 2190 lbs. of English powder.						
" 3899 lbs. of Native "						
" 848 feet of $\frac{1}{2}$ -inch hose.						
" 2 port-fires.						

Taking the line of least resistance = 18 ft., then 18 cubed = 5832, and $\frac{1}{100}$ of 5832 = 1050 lbs. of powder nearly. The other charges were calculated in a similar manner.

Memorandum.—*Partial Destruction of a Wall by means of Small Charges.*—This wall was 11 ft. high, 2 ft. thick, and about 160 ft. long. There were two piers, 6 ft. square, one on each side of an entrance at the centre of the wall; these were built much better than the remainder of the wall, which had been constructed with bricks and a little mud, mortar being found only in the foundation.

Ten charges, of 5 lbs. each, were placed along the wall, at intervals of 10 ft., and were lodged as nearly as possible 2 ft. below the surface of the ground, and under the centre line of the wall. One charge of 10 lbs. was placed in each pier, 2 ft. 6 in. below the level of the ground, and under its centre.

The piers were completely thrown down, without violence: all the other charges, with the exception of three, failed; some blowing out the tamping and making a small breach in the wall, others throwing out the foundation and earth on the other side, but failing to bring down the wall, or any part of it. Four more charges, of 5 lbs. each, were placed equidistant between the former, which completely destroyed the part where they were lodged.

The remainder of the wall was picked and thrown down by about twelve men in a very short time, and other portions of the walls around were thrown down in the same manner.

The powder made use of was native, and undoubtedly of inferior strength to that of European manufacture.

Blasting was not tried, as the nature of the wall did not admit of it. Had Scratchley known that it was so very rotten, he would have had the whole of it picked down.—*Papers of the Corps of Royal Engineers*, vol. viii.

Bickford's fuze is generally employed in blasting operations. See FUZE-MAKING MACHINE.

Blasting with Large Charges of Gunpowder at Holyhead, 1860: by Col. Hamilton, R.E.—The quarries, opened and worked for the harbour-works, were situated on the declivity of the Holyhead Mountain, at about 1500 yds. distance from and in rear of the land end of the breakwater; the portion thereof, 120 ft. by 40 ft., and 90 ft. in height, on this occasion operated on, was formed of quartzose schist, extremely hard, and weighing about $1\frac{1}{2}$ cwt. to the cubic foot, stratified in lines extending from N.E. to S.W., a little overhanging to S.E., but nearly vertical, with numerous joints in that and other directions throughout the whole mass.

An entrance gallery, Figs. 1149, 1150, 5 ft. 6 in. by 3 ft. 6 in., was driven from the face of the rock, commencing at a height of 12 ft. above its base, with a view to gain an efficient line of tamping resistance, a favourable joint in the line of strata having been taken advantage of to the extent of 34 ft., where a shaft, 3 ft. 6 in. by 3 ft. 6 in., was sunk to the depth of 14 ft. 6 in.; from this, level galleries, 5 ft. 6 in. by 3 ft. 6 in., were driven right and left, the former to the extent of 49 ft. 9 in., and the latter 56 ft. 6 in., with a length of 43 ft. 6 in. of headings and chambers of similar dimensions, as illustrated in the accompanying plan and elevation. The galleries, shafts, and so on, were worked out by blasting, necessitated by the hard nature of the rock; and the increased size given to these communications above that generally adopted was with a view to enable the miners to strike with more freedom and effect, the extra excavation being more than compensated by the facility of working. The chambers were formed by slightly enlarging the short return-headings, and were placed from 2 to 3 ft. below the level of the ground or rail line in front of the quarries, to ensure the bottoms of the face acted upon being well lifted, as want of attention to this particular before a former explosion led to considerable subsequent labour in removing a portion of stone left standing.

1149.

1150.

The gunpowder used was similar to the fine grain Government powder, its strength having been previously tested by projecting with a 1½-oz. charge a 68-lb. shot, from a mortar at an angle of 45°, to the distance of 480 ft.; the charges were placed in canvas bags well coated with tar, 2000 or 3000 lbs. in one bag, and the remainder in smaller bags, and so respectively lodged in each chamber.

The tamping was executed throughout with a sort of stiff red clay obtained in the vicinity, used in a slightly moist state, well rammed up to the entrances of the chambers, and close to the bags of gunpowder, merely leaving a small air space round the latter, and was continued

to the mouth of the gallery in the face of the rock : it apparently answered its intended purpose admirably.

The battery employed to fire the charges was that known as Grove's. It had 32 cells, and platinum plates, 8 in. by 6 in., in nitric acid, in porous cells surrounded by diluted (6 to 1) sulphuric acid ; it was placed on the top of the cliff, and directly in rear of the line of chambers, 300 ft. distant from the upper edge of the former ; two copper wires connected the battery with each charge, extending from the latter through the galleries directly up the face of the cliff and on to the cells, where the four positive were united, as well as the four negative. To the extremities of the copper wires at the charges were attached platinum wire about $\frac{1}{2}$ in. in length, protected by a wooden block, round which block a small bag of fine or sporting powder was tied and introduced into the large bags of powder before mentioned.

The total quantity of powder used in the explosion was 12,000 lbs., placed in four charges, amounting respectively to 4000, 3000, 2300, and 2700 lbs., with lines of least resistance 29 ft., 32 ft., 22 ft., and 24 ft. 6 in., as shown in Figs. 1149, 1150 ; these respective charges were not calculated by any specific formula founded on the lengths of the lines of least resistance, but a certain number of pounds of gunpowder a ton of rock to be removed was allowed, according to the particular features and tenacity of the portion to be acted on (in the present instance 1 lb. of gunpowder to 3 tons of rock) ; this calculation was based upon the experience gained from numerous previous explosions of a similar character carried out at different parts of the quarries. In some cases, 1 lb. of gunpowder was found sufficient to remove only 2 tons, in other cases it has proved adequate to displace 4 tons of stone.

Shortly after the hour appointed (twelve o'clock), the mines were fired on a signal with most successful results ; the rock a little above its base was seen to bulge slightly outwards, and then tumble to pieces, emitting much smoke, and the superincumbent mass gently sliding down, separated into various sized blocks ; a perfect volley of small stuff, mostly the tamping, shot horizontally along, close to the ground, directly in front of the face of rock, to a distance of about 250 ft., covering the surface with a coating of fine damp clay, separated into small particles like sand ; no stones of any magnitude were thrown out beyond the general *débris*, which was confined to a width of 125 ft. from the original face of the quarry.

The total quantity of rock removed was about 40,000 tons, which gives $3\frac{1}{2}$ tons to the pound of gunpowder used. The report on the effect of a similar explosion in January, 1857, shows that $7\frac{1}{2}$ tons the pound of gunpowder were then brought down, or nearly double the quantity removed by each pound on this occasion ; and on reference to the accompanying plan it will be observed that if, instead of the charge of 4000 lbs., a smaller one had been employed, the effect would probably still have extended as far as the joint at that end, and also that a slight addition to the charge of 2700 lbs. at the other end would have caused the fall of all the portion as far as the recess, which is described as much shaken. It may also be remarked that the cliff brought down in January, 1857, was 25 ft. higher than that here described ; also that the strata of the former were horizontal, whilst those of the latter were vertical ; and, on the other hand, that the blocks forming the *débris* of the latter were smaller, and more suitable for building, than those of the former ; it is evidently, therefore, difficult to fix any rules for determining the quantity of powder required, especially where hidden joints exist which limit its effects.

The miners were but little impeded by wet or damp ; the gallery was driven with a slight inclination upwards to allow any water met with to find its way out. Whenever damp holes had to be fired, pitched bags or cases, capable of holding 3 to 5 oz. charges, were used ; the smoke from the firing of the blasts and foul air were removed by a rotatory blower worked by a boy at the mouth of the heading, and a canvas pipe conveyed the fresh air to the chambers.

The powder was brought to the mouth of the gallery in casks (containing from 50 to 100 lbs.), and there emptied into canvas bags capable of holding 50 lbs. ; these bags were then passed from hand to hand by men placed at intervals in the galleries, to the respective chambers, where they were discharged into larger bags previously lodged there, to the extent required, after which some old powder-cask sackings were thrown round and over them.

The clay for tamping was brought to the mouth of the main gallery in wagons, and wheeled through it on planks to the shaft, where it was thrown down, and conveyed from the bottom thereof in a similar manner to the headings. This method was found to require less time and labour than any other known to the engineer. The whole of the tamping was performed in 42 hours by 25 labourers.

The copper wires leading from each charge were, throughout their course in the tamping, lapped round with calico and tar-bands, great care having been taken when tamping about them. This method was preferred to that of using wooden casings, and gave much freedom and ease in turnings at the angles and bends in the headings.

Grove's Battery.—32 porous cells ; 32 zinc plates ; 32 platinum plates ; 32 gutta-percha troughs ; mahogany case for box, quicksilver, and poles ; $2\frac{1}{2}$ gallons nitric acid to fill the cells ; $\frac{1}{2}$ gallon sulphuric acid.

Wires.—8 copper wires from the battery to the charges, including calico lapping and tar-bands :—8 × 500 ft. = 4000 ft., and 800 ft. of wire weighing 28 lbs., 4000 ft. = 140 lbs.

The time occupied in driving the galleries, shafts, and so on, was about 9 months, the rate of progress averaging 1 foot the day of 24 hours, and 8 miners working. Powder used in blasting (3 lbs. a foot), $210 \times 3 = 630$; 1 in. of fuze a foot = 210 ft. ; 6 lbs. of candles a week, $36 \times 6 = 216$; 30 bags or tarred cases.

Thus it would appear that 40,000 tons of stone were procured at an expense of 669*l.* 10*s.* 6*d.*, or about 4*d.* per ton.

At a point 150 yards in front of the cliff, the report was not loud, it resembled the sound of very distant thunder.

Application of the Galvanic Battery to Military Purposes. Taken from H. Ward's paper, 'Profes-

sional Papers, R.E., 1855.—The inquiry, whether the explosion of charges of powder by voltaic agency could be made generally applicable to engineering purposes in the field, seems naturally to divide itself into the following heads:—An inquiry

1st. Into the motive power.

2nd. Into the conducting medium, or the means by which that power could be conveyed to a distance.

3rd. The construction of bursting charges to produce the desired explosion.

4th. How the power obtainable could be best applied to the explosion of a number of mines simultaneously.

Motive Power.—The inquiry into the motive power arranges itself under the following subdivisions:—

1st. The determination of the principle by which voltaic action could, on the whole, be most effectually produced; that is, the determination of that combination of metals and acids which, while it comprises such as are generally procurable at a moderate expense and are safe to handle, would exhibit the greatest power.

2nd. The most economical arrangement of these, as to size and numbers; so that the power required should be produced out of the smallest bulk, and at the least cost.

3rd. The general simplification of the arrangement of cells and plates, so as to admit of their easy repair or replacement; the arrangement to combine portability and facility in charging and dismantling; the whole to admit of being readily packed and put together; to be durable, having as few parts as possible liable to deterioration by keep or use, and those such as to admit of many spare ones being carried with the apparatus, and easily procurable anywhere.

4th. To reduce the manipulation to a mere mechanical process, requiring in the application no chemical or scientific knowledge to work it effectually.

Conducting Medium.—The inquiry respecting the conducting medium naturally embraces the best metal for the purpose and the most desirable thickness under every circumstance; a ready mode of ascertaining the conducting power of any description that might be procured on the spot in an emergency; the degree of isolation required to preserve the strength of the circulating current, the best covering to effect this perfectly, and the cost of the most approved.

Bursting Charges.—The most approved bursting charge to be ascertained; whether that formerly made with a thin platinum or iron wire, or that discovered by Brunton, where an inflammable compound is obtained seemingly by a combination of copper, sulphur, carbon, and gutta-percha.

In the former, the best length and thickness of platinum or iron wire, and the most desirable construction for bursting charges under such circumstances; in the latter, the most approved compound, and the readiest method of making it.

Simultaneous Firing.—How far the power obtainable by voltaic agency can be applied to the explosion of a number of charges simultaneously by each description of bursting charge, and the best arrangements for this purpose; the rules deduced from scientific inquiry that should be the guide in considering such arrangements, and how far they must be modified in practice.

As the whole of the investigation is based on the theory of voltaic circuits, propounded by Professor Ohm, of Nuremberg, of which a translation is to be found in Taylor's 'Scientific Memoirs,' June, 1840, we cannot expect to be generally intelligible, unless we preface the experimental results with a notice of the principles established by him, and the conclusions deducible therefrom.

In considering a voltaic arrangement of one pair, say zinc, platinum, and dilute sulphuric acid with the circuit closed, Ohm has shown that the force of the current in circulation is directly as the sum of the electro-motive forces, and inversely as the sum of the resistance to its circulation.

By the sum of the *electro-motive forces* is meant the excess of affinity of the zinc for one of the elements of the solution, as, for example, the oxygen of the water in the above case, over all other counteracting agencies: this force therefore being *entirely independent of the size of the plate*, and subject solely to the nature of the metals and liquids in voltaic combination.

By the term excess of affinity it is understood that if zinc is put in sulphuric acid and water, the zinc decomposing the latter, the cause of the decomposition must be that the affinity of the zinc for oxygen is in excess of that of the hydrogen for the oxygen, with which it is in the first place combined. It is this excess that in this particular case is called the sum. In many combinations of metals and liquids, as in a Daniell or Grove, this excess is the result of more complicated forces, but in all cases the sum of the electro-motive forces is intended to express this excess.

By *resistance* is intended the obstacle opposed to the passage of the electric current by the substances through which it has to pass. It is the inverse of what is termed conducting power. We are in the habit of talking of conducting instead of resisting power, but it will be acknowledged an equally accurate conception, to view all conducting media in the light of resistances opposed to the passage of electricity, as to consider them conductors aiding its circulation. No substances in nature are perfect conductors, consequently some electric excitement is lost in each step of the transmission from particle to particle; and it seems as rational therefore to ascribe the loss experienced to a resisting agency, as to attribute the quantity obtained to a favouring one.

Let F then represent the force of the current in circulation, which it must be remembered, from what has been before stated in the first part of this paper, is equal in all parts of the circuit. Let E = the sum of the electro-motive forces, and R = the sum of the resistances. Then

$$F = \frac{E}{R}. \quad [1]$$

The resistance R in an ordinary voltaic pair is made up of two principal and some inconsiderable portions. The former include the resistance of the wire completing the circuit, and that of the liquid intervening between the plates.

The resistance of the conducting wire which we call w , varies directly as its length (l), and its specific resistance (s); and inversely as the area of its section (a). Or,

$$w = \frac{s l}{a}. \quad [2]$$

The resistance of the intervening liquid, which we will call L , varies directly as its specific resistance (S), and the thickness of the stratum (T); and inversely as the surface of the plate in contact with it (A). Or,

$$L = \frac{S T}{A}. \quad [3]$$

By specific resistance is meant the resistance due to the nature of the liquid employed, and the term is used in the same sense as we speak of specific gravity.

In fact, Ohm assumes that every atom, whether of liquid or wire, is capable of receiving excitement from the one before it in the circuit, and parting with it to the next in succession; that a loss occurs in the transmission depending on the differences of the electric forces existing in the two adjacent atoms; just as in the theory of heat the transmission of caloric between two particles is regarded as proportional to the difference of their temperatures. From this the laws in equations [2] and [3] seem obviously deducible.

There are other resistances in an ordinary voltaic circuit, namely, that of the plates themselves, and of the metallic connections between each pair, when a number are combined in series; but the great sectional area and short length of them make their absolute resistance, when compared with the rest of the circuit, insignificant. They do not require a separate consideration.

The resistance R then consists of L and w , or

$$F = \frac{E}{R} = \frac{E}{L + w}. \quad [4]$$

Now, instead of completing the circuit by a wire, let the plates of a pair be connected by a medium whose resistance is insignificant, and equation [4] becomes

$$F = \frac{E}{L}, \quad [5]$$

representing the free circulation in a voltaic pair, when $w = 0$.

If n such pairs are arranged in series, the first zinc and the last platinum being brought in contact by a substance whose resistance is insignificant, we shall then have n electro-motive forces, but also n resistances; so the value of F will remain unchanged, for

$$F = \frac{n E}{n L} = \frac{E}{L}; \quad [6]$$

but there can now be added n times as much resistance of wire as could be borne in equation [4], without diminishing the value of the force F below that which it represented there, for

$$F = \frac{E}{L + w} = \frac{n E}{n L + n w}. \quad [7]$$

When the galvanic circuit is divided and circulates at the same time through two or more branches, the force of the current through each will be in the inverse ratio of its resistance; thus, if r and r' be the resistances of the two portions or branches of a conducting medium through which the current passes, $\frac{1}{r}$ and $\frac{1}{r'}$ will be the proportional force of the current in each, and

their sum $\frac{r + r'}{r r'}$ will be that of the current passing through both; therefore $\frac{r r'}{r + r'}$ will represent the resistance of a medium that could be substituted for both, and not diminish the amount of circulating force.

It is very important to bear in mind the law relative to divided currents, as it particularly concerns arrangements for simultaneous firing. We are too ready to assume that electricity selects for itself the readiest path, utterly rejecting inferior means of conduction; but with respect to the circulation of voltaic currents, this idea is decidedly erroneous, and the converse is capable of easy practical demonstration.

These are the points of Ohm's theory that most immediately concern us; let us now see what conclusions are deducible from it.

Referring to equation [1], $F = \frac{E}{R}$, it is evident that in a voltaic arrangement, the nature of whose metals and liquids has been decided on, the force F is entirely dependent on the magnitude of R , or the resistance offered to the circulation of the current; as when R decreases, F increases, and when $R = 0$, $F = \infty$, which implies that whatever arrangement of plates and acids may be made, if the resistance can be reduced to 0, the power obtainable is infinite. That this is true may be explained in this way. It will be remembered that it was shown (see BATTERY) to be essential to the flow of a continuous current, in an arrangement, for example, of zinc, copper, and dilute sulphuric acid, that the zinc should be oxidized, the sulphuric acid should combine with the oxide to form a sulphate, and the salt should be removed by dissolution in water, leaving all things *in statu quo* for a new set of actions. Now, though these are described as subsequent operations, where no restraint is offered, they all take place at the same instant.

Now when $R = 0$, the initial force F is dependent on the value of E , which represents the excess of affinity of the positive metal for one of the elements of the solution over all counteracting

agencies, and is therefore limited; but if such an arrangement were made that the limited force should be developed again and again, independent of time, the resultant power, of course, would be infinite. At first view it seems as if the combination of zinc, platinum, and dilute acid, above described, is such an arrangement; and as far as the chemical action is concerned (if we leave out of consideration the adherence of the hydrogen to the negative plate) it certainly is, but there is one great check to the development, which can be diminished, but not got rid of altogether, namely, the resistance of the liquid to the passage of electricity from plate to plate. As there must necessarily be some liquid to produce excitement, so must there be a resistance R ; let this but assume a value, and F becomes limited.

The development of an unlimited force F would seem, then, to be prevented by the resistance offered to the circulation of the current. It may be considered that the zinc, for instance, on being continually attacked, and finding a difficulty in getting rid of its excitement, becomes so charged that it resists a further disengagement of electricity, or, which is equivalent, resists further destruction, that is, loses its affinity for oxygen, till it can be restored to a certain state of quiescence. We have a case analogous to this in electricity produced by friction in an electrical machine, where, in order to obtain an unlimited supply of positive excitement from the glass cylinder, to charge Leyden jars, or for other purposes, it is necessary to connect the negative prime conductor with the ground, to carry off a portion of the high negative excitement produced in it by the friction; it being well known that if this was not so connected it would become so highly charged as to resist further disengagement of excitement. I have here given, says Ward, this theoretical view of the varying value of F , to bring before the mind the fact that the force of the current circulating is controlled only by the value of R , and that I conceive it to be true that, *without any limitation*, so long as R is decreased F will increase.

The value of R is, as has been stated, composed of two parts, namely, the resistance of the exciting liquid and of the metallic wire closing the circuit; and how these can be diminished in a simple voltaic pair we shall find by referring to equations [2] and [3].

From equation [3] we can diminish the resistance of the liquid stratum, by bringing the plates nearer together, by substituting an exciting solution whose specific resistance is less, or by increasing the size of the plates in each cell.

From equation [2] the resistance of the conducting wire in a simple voltaic pair can be diminished, by substituting a metal whose specific resistance is less, by shortening the length of the wire, or by increasing the area of its section.

Diminishing the distance between the plates in each cell by one-half or one-third will permit us to diminish the size of each plate, and therefore their weight, by one-half or one-third, without a loss of power.

Increasing the section of the conducting wire, or, which is the same thing, increasing its weight per yard, will permit its length to be similarly increased, without diminishing the value of F .

In the equation $F = \frac{E}{L + w}$, taken as representing the condition of a circulating force F in a determined combination of metal and acid, we have seen that F can only be increased by the diminution of L or w , or both.

We have just seen the means by which L can be diminished, and supposing that by one of these it has been reduced to $\frac{1}{n}$ its value, the equation of the voltaic pair becomes

$$F' = \frac{E}{\frac{L}{n} + w} = \frac{nE}{L + nw}$$

With respect to w , every mode of diminishing its value, which has been before mentioned, is adopted in practice; that is, a metal (copper) is employed, the specific resistance of which is the smallest known; such a size of wire is used as can with a due regard to economy be employed, and no longer length than is actually required would, of course, ever be placed in the circuit. But there is yet another mode of reducing the resistance.

For instance, if it is desired to reduce w to $\frac{1}{n}$ th its present value, it is readily done by combining n voltaic pairs in series, and applying them to circulate the current through w ; the equation then stands,

$$F'' = \frac{nE}{nL + w} = \frac{E}{L + \frac{w}{n}}$$

There are here, then, two modes of increasing the force F , and the question is, which is the greater, F' or F'' , that is,

$$\frac{E}{\frac{L}{n} + w} \quad \text{or} \quad \frac{E}{L + \frac{w}{n}}$$

Their comparative values evidently depend on the respective values of L and w ; for if L is greater than w , F' is greater than F'' ; if equal, equal; and if less, less. From this we have the following rule:—

When the resistance of the liquid stratum is greater than that of the wire, it is more advantageous to increase the size of the plates of a voltaic pair than to arrange a number in series. When the two resistances are equal, it matters not which is done; and if the resistance of the wire is greater than that of the liquid, the development of the force F is most economically obtained by placing several pairs in series.

This is a most important principle to bear in mind (as will be hereafter shown) when making an arrangement for the explosion of a series of charges; for by a simple alteration of the disposition of cells, effects can be produced which without the knowledge of this principle would be unaccountable.

The rule above made evident is supported by practice. In electro-plating, where the metallic portion of the circuit is short and ample in size, experience has taught that it is more profitable to increase the size of the pair in action. But in the explosion of charges of powder at long distances, where the metallic resistance is usually extensive, it is found more economical to arrange plates in series.

The explanation usually given for the necessity of different arrangements for the two purposes is, that in electro-plating a quantity of electricity is required, while in exploding charges intensity is essential. Intensity of heat (for this is one of the forms in which electricity can be made apparent) is a property partly dependent on the quantity of heat, and partly on the space it occupies. An increase of intensity can be obtained by putting the same quantity into less space. The same quantity of caloric applied to a 12 and 24 lb. shot would produce heat of various degrees of intensity. Intensity, therefore, is directly and entirely dependent on the space into which a given quantity of heat is compressed, not upon an arrangement of cells in series. It would be equally correct to say that increasing the size of a voltaic pair would increase the intensity, as to ascribe that power to the accumulation of cells in series. In fact, both these arrangements have that power, as we can imagine the same force F being made to circulate by each mode in the same combination of metals and acid—though in one case by an arrangement in series, and in the other by having one large voltaic pair—and through two wire circuits identical in their size, length, and conductibility. In the former, assuming n cells to be placed in series, $F = \frac{n E}{n L + w}$;

and in the latter, w and E being of the same value as above, $F = \frac{E}{L' + w}$. And for both these values to be equal it is only necessary that L' should equal $L - \frac{n-1}{n} w$, which value is obtainable by a proportional increase of one pair of plates, as long as $\frac{n-1}{n} w$ is less than L .

The same force F , then, whether caused to circulate by the conditions expressed by $\frac{E}{L' + w}$ or $\frac{n E}{n L + w}$, will exhibit the same intensity on similar parts of two identical wire circuits, and the property of producing intensity is thus shown not to be confined especially to either arrangement.

To produce any required intensity it is necessary to get the requisite quantity into the given space, and this can only be done by overcoming the obstacles to its transmission. There are two descriptions of resistance to overcome, namely, that of the connecting wire and that of the liquid, and it depends on their comparative power which it is most desirable to diminish; the former can be lessened most readily by accumulating cells in series, and the latter by increasing the size of the plates.

It is practically true that in the explosion of charges at long distances the required intensity can only be obtained by accumulating cells in series; but the reason of this is evident, namely, that in equation $F = \frac{E}{L' + w}$, even if the resistance L by the increase of the size of the plate be reduced to an insignificant value, that of w may still be too great to admit of the required quantity circulating through all parts, and then plates in series are essential to reduce the value of w , as by that means only can F now be increased.

The converse, however, is equally true, and deserves consideration. Imagine a combination of n cells arranged to overcome a resistance w , and that the number is so great that the opposition of w has been practically reduced to nothing, or the equation representing the value F standing thus—

$$F = \frac{n E}{n L + w} = \frac{E}{L + \frac{w}{n}},$$

in which $\frac{w}{n}$ is so insignificant as to admit of its being left out of the consideration, then practically

$F = \frac{E}{L}$. Now, if L is so great that its resistance alone will not permit of a sufficient quantity of force circulating, then if 1000 or 10,000 cells were placed in series, we could not sensibly increase the value of F , for it could only approach, but never could equal $\frac{E}{L}$; to obtain sufficient intensity in this case it would then be essential to increase the size of each plate in the series, for by that means only could F now be augmented. These considerations are important, for they show clearly that there is a limit in each case, beyond which we can get no appreciable increase of power: in the one no further increase of the size of the plates will increase the force, unless we at the same time increase the number; in the other we may diminish the size so much as to render a large number placed in series of no value.

Returning again to equation $F = \frac{n E}{n L + w}$. It has been shown that, whatever the value of n , F cannot equal $\frac{E}{L}$, that is, the electro-motive force of one pair restrained by the resistance of the inter-

vening liquid; at the same time the combination $\frac{nE}{nL}$ has the power of circulating the force F through n times the metallic circuit which $\frac{E}{L}$ could, for $F = \frac{E}{L+w} = \frac{nE}{nL+nw}$. These two theoretical conclusions admit of the popular explanation, that in a series of cells, with plates, say of zinc and copper, each copper, while receiving excitement from the zinc of its own cell, restores to equilibrium the zinc in the next, or that to which it is metallically connected; that is, the first copper in the series tranquillizes the second zinc, the second copper the third zinc, and so on; and then there remains only the first zinc and last copper, which require to be connected to permit each to return to a state of quiescence; of course, then, any connection uniting these two, however small its resistance, cannot have so great an amount of electric fluid traversing it as that which one voltaic pair is able to produce, or that expressed by $\frac{E}{L}$.

At the same time, as Ohm has shown that the quantity of electric fluid travelling by two paths to the same destination will proceed by each in quantities varying in the inverse ratio of their powers of resistance, let us imagine the quantity at the last copper plate in the series desirous to return to the first zinc, and that the zinc and copper is metallically connected, bearing also in mind that this zinc and copper are connected by another means, that is, by the alternation of metals and acid solutions, both conductors intervening between them, so that there are here two paths by which equilibrium can be restored; and now if we suppose, first, the metallic resistance insuperable, the whole of the electricity will return by the liquid; if we suppose the liquid resistance to be insuperable, tranquillity will be restored wholly by means of the metallic road. But in reality, as neither resistance is actually insurmountable, the fluid does return by both roads in the inverse ratio of their resisting powers. Conceive, then, one voltaic pair with the circuit closed by a wire of any given length. In this position a certain amount of electric force is proceeding from the copper to the zinc by the wire, the remainder returning by the liquid, the proportion depending on the resisting powers of each; if, then, we increase the resistance of the liquid portion n times, we can proportionally increase that of the metallic portion without altering the absolute quantity proceeding by each path. In a combination of n cells the former is done, and then we are enabled to do the latter. When n cells are used in series, n times the resistance is opposed to the return of the electric fluid at the last plate by the liquid to the first, for it has to traverse n thicknesses of solution and n pairs of metallic plates, and so we can add on n times as much metallic wire resistance without diminishing the quantity, thereby circulating below that which would circulate through the original length, were but one voltaic pair to be employed.

This passage is not perhaps quite clear, as it would imply that an increase of the liquid resistance, taken by itself, would allow an augmentation of the wire resistance also. At page 538 the formula explains it, as it is shown that $F = \frac{E}{L+w} = \frac{nE}{nL+nw}$; $\frac{E}{L+w}$ representing the

conditions of a single pair, and $\frac{nE}{nL+nw}$ that of a series of n pairs, in which L having been increased n times, w has also been increased in the same proportion; but the numerator or electro-motive force has been likewise increased n times.

Proceeding on the principles thus developed by Ohm's theory to inquire into the power of every description of battery, it will, we hope, be clear from what has been said that it was in the first place necessary to ascertain the comparative value of L and w in the equation $F = \frac{E}{L+w}$ before it could be decided whether the force F would be most economically produced; and secondly, the comparative value of E to show the relative electro-motive energies of the several known combinations.

Before proceeding to detail the experimental results which determined the choice of the motive power or description of battery for military purposes, we may enumerate those that have been submitted to examination, namely:—

Wollaston's—Zinc and copper and dilute sulphuric acid, and its modifications of zinc and iron, and copper and iron.

Smee's—Zinc, platinized silver, and dilute sulphuric acid.

Grove's—Zinc and dilute sulphuric acid, platinum with strong nitric acid.

Daniell's—Zinc and copper, with dilute sulphuric acid and sulphate of copper.

Dalgleish's—Zinc, platinum, and nitric acid.

McCallan's batteries, of which there are several varieties.

These several batteries can be classified under two heads—those in which an evolution of gas takes place on completing the circuit, and those in which, for the attainment of constancy, the gas is absorbed by a chemical process. To the former class belong Wollaston's and its modifications, Smee's, and Dalgleish's; and to the latter, Daniell's, Grove's, and McCallan's.

The advantages of the first class consist in the simplicity of the arrangements, the use of but one acid, the necessity for porous cells being thus avoided; while the second has the advantage of producing greater constancy by a chemical arrangement, though at the expense of simplicity.

Wollaston's, Smee's, Daniell's, and Grove's batteries have been for some time before the scientific world, and are well known. McCallan has organized several combinations of metals and acids which require notice. In one, cast iron is simply substituted as the negative metal for the platinum of Grove's; in other forms he uses successively platinized iron, platinized lead, chromed iron, chromed lead. He also varies the exciting solutions. Now he employs concentrated nitric and doubly-rectified sulphuric acid in contact with the iron; then, again, this solution is

modified by mixing four parts of sulphuric acid, two of nitric, and two of a saturated solution of nitre together. If, in this latter mixture, nitric acid is dispensed with, its place must be supplied by an addition of the nitric solution, which, he states, need not be saturated. He also finds that nitrate of soda could be substituted for nitrate of potash, though with a loss of power to be repaid by cheapness of material.

Platinized or chromed cast iron answers as well as platinized lead, and cast iron without being chromed appears to act as well as platinum.

After weighing well the relative qualities of lead and cast iron, McCallan prefers the latter, principally because it does not require platinizing.

From these remarks it seems just to infer that cast iron not platinized—that is, plain—was, on the whole, better than platinized lead, platinized iron, or chromed iron; and if this is the case in the laboratory, it will be much more so in the field, for the platinizing process will, owing to the destruction of the iron, require to be frequently repeated, entailing much expense and trouble, and requiring scientific knowledge and practice. It was only necessary then to test the merit of the substitution of cast iron for the platinum in Grove's, and the use respectively of nitric and sulphuric acid mixed, concentrated nitric and sulphuric acid mixed, and concentrated nitric acid alone, when applied to produce voltaic action. These trials have been made.

The battery made by Dalgleish, of the Ordnance Survey Office, Dublin, deserves particular notice. He employs zinc and platinum for the metals, and strong nitric acid, though it should not be concentrated, for the solution. Platinum cups containing nitric acid have suspended over them, attached to a bar, cylinders of zinc, which are kept from the influence of the acid by strong elastic bands. At the moment the voltaic action is required, a pressure on the bar immerses the zinc, and at the same time, by an ingenious arrangement, completes the connection of the several cells. An action ensues, and the desired effect being produced, the removal of the hand allows the elastic bands to withdraw the zinc cylinders, and yet to keep them suspended over their respective cups from further destruction. See Figs. 1151 to 1153.

Plan.

Reference:—*a a*, Platinum cylinders in metallic communication with the platinum connectors *b b*. *c c*, Zinc rods in communication with the platinum connectors *d d*. When in action *d d* press lightly on *b b*, thus connecting each zinc rod with its corresponding platinum cylinder.

Elevation.

Reference:—The right-hand zinc rods are omitted to show more clearly the mode of closing the cylinders with the lid *x*, when not in use. *f f*, Straps of india-rubber, which are intended to raise the bar *x* when pressure is removed, so as to stop the action.

Though this battery is classed with those in which an evolution of gas occurs, they can by no means compare with it in energy. Its electro-motive force is very great; nor can we by description do justice to the ingenuity of the arrangement by which the zinc cylinders are kept out of the acid till their destruction is necessary; at the proper moment the pressure of the hand immerses them, and simultaneously makes the connection of the several cells.

Section on A B, with portions of the battery in elevation.

Reference:—*e e*, Poles of the battery. *s s*, Screws. *n n*, Pillars on which the bar *x* slides.

With respect to Wollaston's battery of zinc and copper, and the modifications of it before mentioned, we did not submit them to any detailed examination, for we believe it is well known and generally acknowledged that Smee's principle is superior to them in *every* way. Having satisfied himself of the truth of this general opinion, Ward tested more carefully the power of a Smee, and the result will show how inadequate such an arrangement is for the intense and constant heat required for explosions of powder.

The plan pursued in the inquiry into the merits, or productive values, of these several forms of battery, was to ascertain first the most advantageous size and arrangement of plates to cause the circulation of the required amount of force in each, and then to select the one best for use in the field.

The principle on which Ward proceeded to obtain these values was by introducing variable resistances into the circuit, and bringing the force of the current circulating in each case to an equality; then, by equating the two expressions obtained, we can arrive at the electro-motive force or resistance of the liquid, according to the conditions of the experiment.

To apply the principles mentioned, it is necessary to have the means of varying the interposed resistance gradually between any required limits; and the instrument employed was a Rheostat, Fig. 1154.

1154.

The following is a description of it:—*g* is a cylinder of wood with brass termination, and *h* a cylinder of brass, both of the same diameter, and having their axes parallel to each other. On the wood cylinder a spiral groove is cut, and at one of its extremities is attached one end of a long copper wire of small diameter, which, when coiled round the wood cylinder, fills the entire groove, and is fixed at its other end to the extremity of the brass cylinder. The two springs *j* and *k*, pressing one against the brass terminal of the wood cylinder, and the other against the brass cylinder *h*, are connected with two binding screws for the purpose of receiving the wires of the circuit. The movable handle *m* is for turning the cylinders on their axes; when it is attached to the cylinder *h*, and is turned to the right, the wire is uncoiled from the wood cylinder, and coiled on the brass cylinder; but when it is applied to the cylinder *g*, and turned to the left, the reverse is effected. The coils on the wood cylinder being insulated and kept separate from each other by the groove, the current passes through the entire length of wire coiled on that cylinder; but the coils on the brass cylinder not being insulated, the current passes immediately from the point of the wire which is in contact with the cylinder to the spring *k*. The effective part of the length of the wire is therefore the variable portion which is on the wood cylinder.

A scale is fixed to measure the number of coils unwound, and the fractions of a coil are determined by an index which is fixed to the axis of one of the cylinders, and points to the divisions of a graduated scale.

The instrument employed was made on the same principle, though of larger dimensions, as more suitable to the inquiry in view. The cylinders were 10 in. long, and exactly 10 in. in circumference, the wire employed being about .045 in. diameter, and weighing about 53 grains a yard. The wood cylinder when covered held 190 turns of such wire, or 52½ yds.; and it was assumed as the standard measure of resistance, estimating and expressing all other resistances in terms of this wire.

Some mode was requisite by which the force of the current circulating could be measured. A delicate astatic galvanometer first occurred to Ward as suitable for the purpose; but he found that, though well adapted for the measurement of feeble currents in circulation, it was not so suitable for measuring those of such great energy as are required for the purpose of exploding

powder. It seemed that the resistance of the liquid stratum and the electro-motive forces were, in some forms of battery, dependent in a degree on the amount of electric current in circulation, or when the quantity was so minute as to be accurately measured by a galvanometer the value of L was less than when a more energetic current was passing. On the other hand, when a sufficiently strong current was circulating, the deflection of the galvanometer needle was so great, that small variations in the extent of the circuit produced no effect on the variation of the needle. Frequent changes were also apparent in the magnetic intensity of the needle when acted on by strong currents, so that two equal degrees of variation could not be taken as indications of the same amount of circulating force. It was therefore no easy matter to ascertain when a current sufficiently energetic for the object of the inquiry was in circulation.

With an intention, then, of ascertaining the amount of resistance and electro-motive force in every form of battery, when a current of sufficient energy for exploding powder was circulating, and at the same time to have a certain indication that such was the condition under which he was making the experiment, Ward adopted the following plan. In some part of the metallic circuit he placed a thin platinum wire, $\frac{3}{16}$ th of an inch long, weighing 1.65 grain a yard. Gradually varying the metallic resistance, he then ascertained the amount at which the small wire would just melt. As the same degree of heat would always be necessary to fuse the same length and thickness of platinum wire, and as that could only be obtained by the same force of current passing uniformly through all parts of the circuit, and, moreover, as the fusion of this wire would readily ignite surrounding powder, he thus obtained a galvanometer which, at one view, gave all the information required.

It was an easy matter to design an instrument for holding the wire, or any number of wires, if required. Ward had one constructed, which also permitted of two wires being placed in successive parts of the circuit, or, if necessary, of two sets of six, the wires of each set being arranged side by side. (The reason for both these arrangements will afterwards appear.) They were held firmly between parallel brass plates; and by means of screws, clamps, and a graduated scale with a vernier attached, any length, from the smallest imaginable to $1\frac{1}{2}$ in., could be introduced in the circuits for the purpose of experiment. As it is an instrument for measuring energetic currents, it may be called an intensity galvanometer.

Fig. 1155 represents this instrument. ss is a wooden stand, resembling a flat ruler, having two graduated scales vv of inches and tenths of inches corresponding to the verniers on the bent down edges of the brass slides aa . In the figure the right slide is represented as drawn back, and it will be observed that it carries with it a vertical brass transverse plate, provided with slits for the reception of the platinum wires, which are then kept firm by the capping bar bd , here represented open, but which turns on a hinge at b , and is secured firmly to the plate when down by the lever-catch represented at ed . The other ends of the wires are received in slits of a similar upright piece, which forms part of the centre plate m , which is attached permanently by screws to the wooden stand. This upright piece has also a lid pd , which is here represented as

1155.

closed on the wires. The left slide a consists of the same parts, but is here shown as closed in to the central upright piece on that side; the two uprights being covered by the cap C , which keeps up a metallic connection between the left and right slides, just as the platinum wires do on the other side. By removing the cap C the left slide becomes movable to the left, and wires can be inserted between the upright of the slide and that of the central plate, just as is exhibited in respect to the right-hand slide. ff are clamping screws to secure the slides in any required position. ww are screws for receiving the connecting wires of the battery. When it is only intended to use a single wire or a set of wires, from two to six, arranged side by side, the cap C must be down on one side, either the right or the left, as here represented; but when it is wished to use two distinct wires successively in line, or two sets of wires in succession, the cap C must be removed. The instrument may be made to complete the circuit, if necessary, without the platinum wires, by closing up the slide on the right as on the left side, and covering the uprights by another cap similar to C .

As before stated, there were barely 53 yds. of standard wire on the rheostat, but it was generally necessary to introduce much greater resistance than this. The means of doing so were easily obtainable, for having on hand about two miles of thin copper wire, varying from 160 to 250 grains a yard, covered with gutta-percha, in lengths varying from 75 yds. to half-a-mile, it was only necessary to ascertain the resisting power of these in terms of the standard wire, and by Wheatstone's instrument this was readily done. Thus with a piece 75 yds. long, taking a Grove's battery (though any constant battery would do equally well), Ward found that three of its cells were capable of fusing the thin platinum wire before men-

tioned, when $119\frac{1}{2}$ turns of the standard wire coiled on the wood cylinder of the rheostat wire were included in the circuit; and the same three cells fused the same length of wire when a coil of wire of another description 75 yds. long, together with $68\frac{1}{2}$ turns of rheostat wire, composed the circuit. Now, three cells acting in series are expressed by $\frac{3E}{3L}$, that is, three electro-motive forces divided by three liquid resistances, if L represent the resistance of the liquid of one cell. The other resistances are in the first experiment composed of $119\frac{1}{2}$ turns of standard wire, and the platinum wire, the amount of whose resistance we may call p ; in the second, of 75 yds. of coil, $68\frac{1}{2}$ turns of standard wire, and the platinum wire p . Under each condition of experiment the same amount of force was capable of circulating; calling this F , we have

$$F = \frac{3E}{3L + 119\frac{1}{2} + p} = \frac{3E}{3L + 68\frac{1}{2} + 75 \text{ yds.} + p}.$$

By which we obtain 75 yds. = 51 turns; or the resistance opposed by the 75 yds. of coil was equivalent to that of 51 turns of standard wire, and whenever this portion was introduced into the circuit it was considered equivalent to 51 turns of standard wire. Again, with a piece of greater length, eighteen cells of another battery were capable of fusing the platinum wire, the current passing through an equivalent of $868\frac{3}{4}$ turns of standard measure, and when a piece 550 yds. long was introduced, the same result could be produced through but $88\frac{1}{2}$ turns. The 550 yds. piece was then = $868\frac{3}{4} - 88\frac{1}{2} = 780\frac{1}{2}$ turns of standard wire; and to show the degree of accuracy attainable, each result (namely, $868\frac{3}{4}$ and $88\frac{1}{2}$) is the mean of eight observations; the first eight observations differing from the mean $868\frac{3}{4}$ as follows—

$$1, 2\frac{1}{4}, 2\frac{1}{4}, 1\frac{1}{2}, 2\frac{1}{4}, \frac{3}{4}, 3\frac{3}{4}, 4\frac{1}{4};$$

and the second eight from the mean $88\frac{1}{2}$ as under—

$$5\frac{1}{2}, 6\frac{1}{2}, 2\frac{1}{2}, 2\frac{1}{2}, \frac{1}{2}, 4\frac{1}{2}, 2\frac{1}{2}, 1\frac{1}{2}.$$

The probable error of the mean difference resulting from these sixteen observations does not exceed 1·15 turn; that of a single pair of observations being within 3·3 turns. The galvanometer is, however, capable of measuring to a still greater degree of accuracy, if necessary. The above observations were made with a battery not particularly suitable to the purpose, and with less than the usual degree of care, in a period of less than a quarter of an hour; the coil in question not being required for the subsequent experimental inquiry. The instrument admits of a repetition of from 40 to 60 observations an hour with ease, and thus, in a short time, it would be easy to obtain a result free from any but an almost inappreciable error. In a similar manner the resistance of any length of wire could be reduced to a standard measure; and as the wires were covered with gutta-percha, Ward was able to arrange them in coils round the table on which the battery stood, introducing such as were required by the nature of the experiment.

As the thin platinum wire before mentioned necessarily formed part of the circuit in every experiment, it was requisite to ascertain its resistance in terms of standard measure. This was done by first introducing one, and then two such wires, all of the same length, in different portions of the circuit (for which, as has been described, the galvanometer was adopted), and producing a fusion in each case by the same power of battery. The amount of standard resistance or length of standard wire which had to be taken out in the second case to produce fusion, was equivalent to the resistance of one platinum wire. This was found, by the mean of six pairs of observations, to be $60\frac{3}{4}$ turns. The probable error of this result being = 1 turn, and that of one pair of observations = 2·3 turns, is equivalent—as the wire is but ·375 in. long—to ·00618 in. in the former case, and to ·0142 in the latter.

A ready mode of checking the correctness of this result is always at hand: it is as follows:—Find the utmost length in standard measure of the metallic circuit (not including that of the platinum wire) which will admit of any even number of cells in series, say twelve, fusing that wire. Ascertain the same with each half, or six of those cells. The sum of the circuits of the two sixes deducted from that of the twelve will give the standard resistance of platinum wire. This will be a true result, subject of course to corrections for errors of observation, however irregularly the cells may be working *inter se*; and a reference to the formula will easily explain the rule.

It might be supposed that the resistance of these several wires would be ascertainable by the formula $w = \frac{sl}{a}$, when the specific resistance, the length, and the area of the section are known;

or if they are all of copper, the specific resistance being the same, that the length divided by the weight a yard should give the comparative resistance; but an approximate value can only be obtained by such measures. A small variation in the description of copper from which the wire is manufactured would affect the value of s , and the difficulty of obtaining in wires of small diameter a correct value for a , or, what is its equivalent, the difficulty of obtaining a long wire of a uniform weight a yard, would increase the probable error of the true result. For instance, several portions of the same wire weighed 249·5, 233·5, 228·6 grains a yard, as ascertained by a delicate balance turning to $\frac{1}{100}$ of a grain, thus denoting an irregularity due either to the manufacture or to the quality of the copper.

It is therefore fortunate that Wheatstone's rheostat furnishes such a ready, as well as practical, mode of ascertaining the degree of resistance of all descriptions of wire without a knowledge of any of the factors of the equation $w = \frac{sl}{a}$.

The amount of error into which we may be led by determining the resistance from calculation instead of by experiment may be seen from the following Table, in which that practically ascer-

tained and that calculated, each in terms of wire weighing 53 grains a yard, are placed side by side:—

Actual length of Wire, in Yards.	Weight per Yard, in Grains.	Calculated Resistance in turns of Rheostat.	Actual Resistance by Experiment in turns of Rheostat.	Percentage of Error in Calculation.	Percentage of Probable Error in ascertained Resistances.
75	233·22	61·3	51	+ 16·8	0·58
125	228·66	104·3	83½	+ 19·7	0·53
245	233·5	200·2	172½	+ 13·7	0·46
495	249·5	378·5	322½	+ 14·8	0·34
280	166·2	321·4	401½	- 24·9	0·41

Thus the first four lengths (which, as before stated, are portions of one original piece, and were therefore probably manufactured from one description of copper) are tolerably consistent among themselves, though differing on an average by more than 15 per cent. *plus* from the standard, whereas the last piece shows a *minus* error of nearly 25 per cent., making an aggregate error between the two descriptions of copper wire shown in the Table of about 40 per cent.

Here, then, is made apparent one of the probable sources of failure in demolition by voltaic agency. The different diameters of the pieces of 495 yds. and of 280 yds., though apparent on *close* examination, would not strike a casual observer; in fact they were purchased from the Gutta-percha Company as one description of wire, yet the resistance of the *shorter* lengths as compared with the *longer* is as 402 to 323! If, then, calculating on the experimental results obtained from the former, the same length of the latter wire had been used in any proposed demolition, the probable result would have been total failure.

The last column shows the probable error in the ascertained resistance, which averages under one-half per cent. These results are more than sufficiently accurate for the purpose of the inquiry, though by no means so near as it would be easily possible to attain, since it is within the compass of an easy day's work to ascertain the resistance of all these lengths to within $\frac{1}{10}$ th per cent. of probable error, and even to eliminate error altogether.

It was easy now to obtain the value of *L* or the resistance of the liquid stratum in any battery, as well as the proportional value of any electro-motive force. The experimental results with each battery examined now follow, being prefaced with a description of the size and mechanical arrangement of each. Ward had, for the commencement of the investigation, that battery of Grove's construction which was employed in the demolition of Seaford cliff in 1850. It was supplied to the Engineer Department at Portsmouth as the best form and description of voltaic implement known for the purpose, and therefore deserves a description to show how much such an instrument is capable of modification, when required solely for blasting purposes.

The battery consisted of ten cells, in each of which was suspended one plate of platinum, with two of zinc facing it, one on each side, at a distance of $\frac{3}{4}$ of an inch; the exciting solution being dilute sulphuric acid for the zinc in the proportion of 1 of acid to 8 of water, and strong nitric acid for the platinum, the two acids being separated by a porous earthenware diaphragm; the plates in action in each were two 9" x 7" of zinc, and one 6" x 6" of platinum; each cell requiring 2½ pints of dilute sulphuric acid, and $\frac{3}{4}$ of a pint of nitric acid. Its weight when charged was 168 lbs., of which 40 lbs. was due to solution and 44 lbs. to zinc plates.

Each cell then had the power of circulating the standard force required, that is, a force capable of fusing thin wire, through a resistance of 66½ turns standard measure.

It was evident, on first sight of the instrument, that this battery would admit of considerable reduction, if the principles of Ohm's theory were correct; and that if the distance between zinc and platinum was reduced from $\frac{3}{4}$ to $\frac{1}{4}$ of an inch, one-half the weight of zinc (= 22 lbs.) and a corresponding bulk of acid could be dispensed with, without lessening in any degree the power of each cell. With this consideration in view, and also wishing to compare an arrangement on Grove's principle with one of Smee's batteries, Ward had one of the former constructed with twelve cells, two zinc plates 4" x 2" being in action in each cell, one on each side of a platinum plate 4" x 4" and at a distance from it of about $\frac{1}{4}$ of an inch. The experimenter also had the platinum plates platinized, the original object of which was to work this identical battery as a Smee, by dispensing with the porous cells and nitric acid; but thinking afterwards that this might appear to some as hardly a fair trial of Smee's arrangement, Ward abandoned that idea, and used these platinized platina plates in the Grove's arrangement only. It will be seen subsequently that platinized platina opposed to zinc gives a stronger arrangement than platinum only—a fact which was first noticed by McCallan.

The investigation was intended to find the power of the several voltaic combinations when excited by ordinary agents, that is, those which might readily be obtained: our author did not enter into an inquiry, except on special occasions which will be particularly noticed, as to the degree of power attainable by the use of concentrated nitric acid, doubly-rectified sulphuric acid, or such reagents as are difficult or expensive to procure, or dangerous to handle; but confined himself to the task of ascertaining the power attainable from ordinary, or what are termed commercial, acids, which do not emit fumes destructive to health.

The rule for ascertaining the merits of any voltaic combination is this. Arranging any number of cells in series, ascertain the metallic resistance that can be comprised in the circuit which will permit one platinum wire to be fused. With the same number in series, ascertain the extent of circuit which will admit of two platinum wires placed side by side in the galvanometer being fused: and these two experimental results may be obtained in five minutes at any time in the

field as well as in the laboratory, with instruments which should always accompany the battery, by a single observation of each result with a probable error not exceeding two turns; whilst by a repetition of observations, all appreciable error could, of course, be eliminated. In making these trials, it is not necessary that the operator should have any knowledge of the metals or acids of which the voltaic arrangement is constituted. The experiment will show him at once if the battery is to be trusted, and to what extent, and, if any disarrangement has occurred, how many cells to add to overcome the defect: indeed, the constancy and duration of the heat made apparent on the wire is at once an infallible and ready test of the value of the battery for explosive purposes.

The demonstration is as follows:—Taking n cells in a battery whose electro-motive force is E , and resistance of liquid L , suppose a metallic resistance w to be the extreme that can be interposed and yet enable a force to circulate that will cause the platinum wire to be fused; call this force F , then the equation stands $F = \frac{nE}{nL + w}$. Now, if the extreme metallic resistance, which we will call w' , is ascertained which admits two identical wires, placed side by side, to be fused, it is evident that the same force F must be passing along each wire at that moment, or a force of $2F$ along both together; and as the same quantity of electric fluid must be passing through every part of the circuit, the equation representing the conditions under which the battery is working will be expressed by $2F = \frac{nE}{nL + w'}$. Now, as the numerator in both these expressions is the same, for in both experiments the same number of cells are used, the denominator in the last must be one-half of that of the first, or $nL + w' = \frac{1}{2}(nL + w)$. $\therefore L = \frac{w - 2w'}{n}$. Thus the average resistance of n liquid strata, or nL can be obtained. The use of this value of L will be better understood when we come to consider the other numerical values in each case.

Again, suppose we have two separate combinations of battery, say a Smee and a Grove arrangement, of which it is desired to determine the comparative value of the electro-motive forces: let the electro-motive force be E and E' , liquid resistance L and L' , and the quantity of metallic circuit that each will bear when n cells are combined, and yet permit the standard force, which we will in future call a force F , to circulate, be w and w' . Let the amounts w and w' require an increase or diminution = a and a' of metallic resistance when a force F' is required to circulate. We then have in the first case,

$$\frac{\text{SMEE. } nE}{nL + w} = F = \frac{\text{GROVE. } nE'}{nL' + w'}, \text{ and in the second } \frac{\text{SMEE. } nE}{nL + w \pm a} = F' = \frac{\text{GROVE. } nE'}{nL' + w' \pm a};$$

then of course $E : E'$ as the sums of the respective denominators in each case, but they are also as the differences of the denominators of their respective fractions, that is to say, as a to a' , or $E : E' :: a : a'$.

In all these observations the forces F and F' have been in the ratio of 2 to 1, to simplify the calculation; and the equations under the conditions became

$$F = \frac{12E}{12L + w}; \quad F' = 2F = \frac{12E}{12L + w \pm a},$$

which being reduced, for the purpose of determining L or the liquid resistance, gave $12L = w - 2(w \pm a)$: and on these principles Ward took the observations that follow, the number of cells in series in all cases being twelve.

With the Grove's having plates, $4'' \times 4''$, of zinc, and platinum in action in each cell,

1. The metallic resistance interposable for 12 cells, when one wire } or $w = 775\frac{1}{2}$ turns.
was fused
2. With two wires or $w - a = 350\frac{1}{2}$..

$\therefore 12L = 775\frac{1}{2} - 701 = 74\frac{1}{2}$ turns; the probable error in this value of $12L$, as calculated from the nature of the observations, is = 1.7 turn; that of $775\frac{1}{2}$ turns, similarly calculated, is equal to 2 turns.

The electro-motive force of this battery as compared with any other would be the difference of these two observations in each case, that is to say, the difference of the denominators of the equations F and F' , as before stated. In the present case this is $775\frac{1}{2} - 350\frac{1}{2} = 425$, having a probable error of 1.6.

The duration of the power of this battery, or its constancy, as it is called, is deserving of notice. The results just given show its energy about an hour after charging, at which time, the porous cells being well saturated, it may be considered to have been at its maximum. During the day it was experimented with sufficiently to fire 300 charges, and at the end of seven hours the experiments above described were repeated in the same order. No. 1 gave $753\frac{1}{2}$ turns; No. 2, $332\frac{1}{2}$, from which $12L = 88$, and comparative value of $E = 420\frac{1}{2}$. Thus the resistance of the liquid had, as regards itself, increased 18 per cent., and the electro-motive force 1 per cent.; but the two together had reduced the available energy of the battery from $775\frac{1}{2}$ to $753\frac{1}{2}$, or not 3 per cent. This constancy is readily attainable by carefully amalgamating the zinc plates before charging, an operation occupying a few minutes; and it has been found on this as well as on other occasions that the battery will continue sufficiently constant for all practical purposes for a period of twelve hours. The small loss of power noticeable here is probably owing to the fact that it was always Ward's custom in charging the several batteries to mix the sulphuric acid and water immediately before filling the cells; this, as is well known, raises the temperature of the mixture above that previously sensible in either of the liquids, and as the temperature is heightened the conducting power of the

solution is increased; but this power diminishes as the solution cools, which it gradually does. On the present occasion sulphuric acid and water, each at 40° Fahrenheit, when mixed in the proportion of one measure of acid to eight of water, gave a resulting temperature of about 70°.

When this battery is in its full strength, the amount of resistance commanded by 12 cells, that is, the amount of metallic resistance which can be added to the circuit for each cell in series without diminishing the value of the circulating force below the standard necessary for fusion, is = $775\frac{1}{2}$ turns for the 12, or $64\frac{2}{3}$ for one cell; but it will be remembered that the power of one cell in the large Grove did not exceed $66\frac{1}{2}$ turns, so that this small difference is the only loss a cell by reducing the battery. In respect to the gain, the quantity of nitric acid to charge each cell has been diminished from $\frac{3}{8}$ to $\frac{1}{8}$ of a pint, and the dilute sulphuric acid from $2\frac{3}{8}$ to $\frac{1}{8}$ of a pint. These two alone diminish the cost of charging 10 cells from 7s. 9d. to 2s.; but as this acid lasts only 12 hours, while the others are available for 24, the comparative cost should stand as 7s. 9d. to 4s. The weight of 10 cells of this battery when charged was only 27 lbs., while that of the large one was 168 lbs. The cost of construction was less than one-half, and the cubical contents less than $\frac{1}{2}$. So that while but $1\frac{1}{2}$ per cent. of power a cell has been lost, the gain has been 50 per cent. in prime cost, the same in working, 600 per cent. in weight, and 700 per cent. in bulk.

Referring back, let us substitute in the equation $F = \frac{nE}{nL + w}$, the value of $n = 12$, $nL = 74\frac{1}{2}$, and $w = 775\frac{1}{2}$, and we have $F = \frac{12E}{74\frac{1}{2} + 775\frac{1}{2}} = \frac{E}{6\frac{5}{12} + 64\frac{1}{3}} = \frac{E}{70\frac{5}{6}}$, in which $70\frac{5}{6}$ represents the utmost amount of resistance in standard measure that this principle of battery will bear a cell, without reducing the amount of circulating force below the force capable of fusing the thin wire, that is the force F , and in which $\frac{E}{5\frac{5}{12} + 64\frac{1}{3}}$ represents how this total resistance is apportioned between the liquid and metallic circuit, in this particular sized battery. But the same resulting force could be obtained by a battery working under any of the following conditions, namely,—

$$F = \frac{E}{24\frac{5}{6} + 46} = \frac{E}{70\frac{5}{6}}, \quad [1]$$

$$\text{or} \quad = \frac{E}{35\frac{5}{12} + 35\frac{5}{12}} = \frac{E}{70\frac{5}{6}}, \quad [2]$$

$$\text{or} \quad = \frac{E}{70\frac{5}{6} + 0} = \frac{E}{70\frac{5}{6}}. \quad [3]$$

The first of these can be produced by a diminution of the size of the plates from 4" × 4" of surface in action in each cell to 2" × 2"; and as this reduction of size would not diminish the power a cell 30 per cent., or from $64\frac{2}{3}$ to 46, while it might reasonably be expected that the expense of charging, weight, bulk, and cost of battery would be diminished at least 100 per cent., this modified form is evidently preferable.

No. 2 is, theoretically speaking, the most economical form under which any principle of battery can work for the circulation of the force required, which in this case is to fuse the particular platinum wire that we have been using, that is, when the liquid resistance of each cell is equal to its available energy; and in a Grove's combination the expression represents plates about 1.66 in. square in each cell.

The third expression represents a battery working under such conditions that if 1000 cells were placed in series they would not have the power of circulating the force F through a metallic circuit of 1 ft.

Theoretically speaking, No. 2 is the most economical form of battery; but other considerations forbid its adoption. To obtain the power, $35\frac{5}{12}$ the cell indicated by the equation, each compartment must be carefully filled to the top, as failing to do this by a quarter of an inch would sensibly diminish the power a cell. Any deterioration in the strength of acid employed would have the same effect, and the whole quantity employed being so small, it would deteriorate soon after the battery was charged. It will be seen that the acids used in the Grove, of which the zinc surfaces in action were 4" × 4" in each cell, were available for but 12 hours, while that in the larger size was equally so for 24 hours. Reasoning from this, it could then hardly be expected that the small battery represented by equation No. 2 would remain efficient for one hour, or work economically for one quarter of an hour.

One more condition of this equation deserves notice, namely, $F = \frac{E}{0 + 70\frac{5}{6}}$. This cannot practically be attained by any construction, for the liquid resistance must be an absolute quantity; but it shows the important fact that *however large* the plates of a Grove's combination, such as the one we have been considering, are made, the force F could not circulate if in *each* cell was developed resistance equivalent to $70\frac{5}{6}$ turns, while *two* cells 2" × 2" can bear a resistance more than equal to this, and yet circulate the required force with ease; in other words, that for the circulation of the force we require two pairs of plates in series, each 2" × 2" in surface, which are more than equivalent in force to one plate even a mile square.

No. 1 arrangement having then been decided on as the best, a battery exactly similar to the former was made, but having zinc plates 2" × 1" overlapping platinum 2" × 2"; the former facing the latter on each side, and thus giving a surface of each metal 2" × 2" in action in each compartment. This diminution in size permitted the zincs to be brought somewhat nearer; and, instead of being $\frac{3}{8}$ of an in. from the platinum, they were $\frac{1}{4}$ in.

The experiments Nos. 1 and 2 were made with this battery, giving the following results as the mean of eight observations of each: No. 1 = $571\frac{1}{2}$; No. 2 = $162\frac{1}{2}$; from which the comparative

value of $E = 409\frac{1}{2}$, and the resistance of $12 L = 245\frac{1}{2}$: the probable error in each result being 1.5. The diminution of the comparative value of E from 425 to $409\frac{1}{2}$, is attributable to the platinized platinum being used in the former case, while ordinary sheet platinum was employed in this, and not to a diminution of size, which does not influence E . The sum of the resistances of the liquid in twelve cells had increased from 74.5 to $245\frac{1}{2}$.

Now, remembering that the plates had been reduced to $\frac{1}{4}$ the size, but had been brought nearer in the proportion of 5 to 6, calculation from the first result would give the second

$$= \frac{74.5 \times 4 \times 5}{6} = 248\frac{1}{2},$$

whilst experiment gives $245\frac{1}{2}$. Assuming the value of $12 L = 245\frac{1}{2}$ or $L = 20.47$, and that of $w = \frac{571\frac{1}{2}}{12} = 47.65$; the expression $F = \frac{E}{L + w}$ stands $\frac{E}{20.47 + 47.65} = \frac{E}{68.12}$, showing that when the platinum is *not* platinized a Grove will bear a resistance of but 68 turns of standard measure instead of nearly 71, as before, to each cell.

Referring back to the largest Grove, namely, that with zinc plates $9'' \times 7''$ and platinum $6'' \times 6''$, we may consider the area of the mean section of the fluid on each side = $49\frac{1}{2}''$, and the plates being $\frac{3}{4}$ of an in. apart, facing the platinum on each side, the value of $12 L$ in this battery by calculation would be $\frac{74.5 \times 16}{49.5} = 24$ nearly, or about 2 turns a cell; and as the available energy of the

battery is $66\frac{1}{2}$ turns, the condition under which the largest Grove circulates a force F is numerically expressible thus; $F = \frac{E}{2 + 66\frac{1}{2}} = \frac{E}{68\frac{1}{2}}$, which, admitting experimental error, is the same expression as that obtained from plates but $2''$ square; thus showing that increasing the size of plates does not increase the electro-motive energy, that is the value of E , for the superior available energy of $66\frac{1}{2}$ turns in the large Grove is merely due to the diminished resistance.

This principle has been established, both by Ohm's theory and experiments, and required no further demonstration, except to bring the consideration of it to special notice as materially affecting a part of the following inquiry.

The batteries hitherto used, it will be borne in mind, were made with zinc plates *overlapping* the platinum plate, and facing it on each side. Thus the outer surface of the zincs was not directly opposed to any negative metal. To ascertain if this portion did any work, Ward carefully covered with a thick coating of sealing-wax varnish the outer surfaces, so that it was impossible they could be acted on, and then tried on a subsequent day the variation of E for 12 cells, as compared with former experiments, but he found no diminution of power. To make sure that this was not owing to any peculiarly good acid used on that day, he removed the varnish from each plate and reinserted them in the same solutions. The battery was found somewhat diminished in power, but very slightly, not more than 2 per cent., though if the outer surfaces had been acting, it ought to have *increased* in power. This was probably owing to the longer time it had been in action. These trials evidently proved that no sensible power is obtained from the outer side of a plate, or from any other surfaces that do not directly oppose each other; for had there been 3 per cent. of increase it would certainly have made itself apparent. It is not at all surprising that it should be so; for, referring to the principles of the action, the electro-motive force, that is, the affinity of the zinc and liquid for each other, depending on their nature, and not their quantity, cannot be increased; the amount of electric fluid they can supply is unlimited, and controlled solely by the resistance of the liquid to its transmission, this resistance varying directly as the distance between the plates; and hence it seems in due course that the whole of the supply should be obtained from the parts where it can be so done with the greatest facility, namely, from those which are nearest to or directly opposing the platinum.

The result, however, must not be confounded with, or supposed contrary to, those obtained when the zinc, being opposed on each side by a negative metal, the battery is found to exhibit greater energy than when the copper or platinum, or whatever the negative metal may be, is on one side only; for here the zinc is directly opposed by a negative metal on both sides, and, of course, supplies electric fluid from each side, though the negative metal is, in this case, not working to the utmost advantage. The fact however made evident, to whatever cause attributable, was of great importance, as it admitted of the battery being much simplified, of dispensing with many binding-screws and of much unserviceable metal, as well as of an economy of size and weight, and an increase of power, for the plates could now be brought nearer together.

Adhering, then, to the same sized plates, a diminution of which seemed of no practical advantage, a battery was constructed with plates of zinc and platinum welded together in the simple style that zinc and copper used to be arranged in, one of each pair being in a separate cell, and the platinum immersed in nitric acid being, of course, separated from the zinc of another couple immersed in dilute sulphuric acid by the porous cell containing it and the nitric acid. A battery so made permitted the plates to be brought to an average distance of little more than $\frac{3}{16}$ of an in. from each other, and by the simple contrivance of a lid, every pair and every porous cell was kept in its place, and could be thus transmitted as ordinary baggage by rail, without extra packing or precaution. Fig. 1156 represents one of these batteries of six plates, and the connecting metallic straps are so represented as to explain the manner in which several of these batteries may be combined together; Fig. 1157 represents a single pair of plates.

Six pairs of plates so arranged occupied a box not exceeding $7'' \times 4'' \times 4''$, substantially made for use in the field, including binding-screws and porous cells; and the reason for this arrangement of six cells in one box will be afterwards explained. The result of the fusion of one and of two wires by twelve cells, or two box batteries of this arrangement, gave on one occasion, No. 1 = 651, and No. 2 = $240\frac{1}{2}$; from which $12 L = 169\frac{1}{2}$, and the proportional value of $E = 410\frac{1}{2}$.

On another occasion, No. 1 gave 641, and No. 2 gave 230½, showing that the total resistance 12 L was now = 179½, but that the value of E was unchanged; the variation in the resistance being due to the time at which the experiments were made, as the increase was probably owing to a different set of twelve having been used in each case.

If we adopt the mean of these two, or $12L = 174.5$, $L = 14\frac{1}{2}$ may fairly be taken to represent the resistance of the liquid when the battery is in its strongest action, namely, for the first three hours after it is charged. Also the electro-motive force of a Grove battery unplatinized may be represented by the numerical value 410, as on three separate occasions experiments have given it 409½, 410½, and 410½, that of a platinized Grove being 425.

To ascertain how much the power of this battery diminished when left charged, the same experiments were repeated after six hours, and No. 1 was then found = 484½, and No. 2 = 104½; giving $E = 380$, and $12L = 275\frac{1}{2}$. Thus the electro-motive force had diminished 7 per cent., and the liquid resistance had increased 35 per cent. These two circumstances combining, diminished the available energy of the battery a cell from $\frac{646}{12} = 53\frac{1}{2}$ to $\frac{484\frac{1}{2}}{12} = 40\frac{1}{2}$, or about 25 per cent.

For the first two or three hours the conditions under which the force F circulates in the battery is expressed by $F = \frac{E}{14\frac{1}{2} + 54} = \frac{E}{68\frac{1}{2}}$, which expresses that each cell commands a resistance, or has an available energy sufficient to overcome a resistance, equivalent to 54 turns of standard wire. At six hours after charging, this command had decreased to 40½ a cell, for the battery then worked under conditions expressed by $F = \frac{E}{23 + 40\frac{1}{2}} = \frac{E}{63\frac{1}{2}}$. The denominators 68½ and 64½ denoting the comparative strength of the electro-motive force at the two periods.

This, then, is believed to be the most convenient form, size, and arrangement, for a Grove battery intended for the explosion of powder; for though on looking at the numerical value of $L + \frac{w}{n}$ it may seem that the size of the plates could yet be reduced, it must be borne in mind that, though α forces expressed by $\frac{E}{68\frac{1}{2}}$ and $\frac{E}{63\frac{1}{2}}$ are sufficient at their respective periods for fusing the platinum wire when in the galvanometer, a still greater force will be necessary for the same fusion when that wire is surrounded by powder. A small platinum wire, not exceeding .0056 of an in. in diameter, in contact with any substance, must be subject to a great abstraction of heat; but how much this is Ward was not able accurately to determine, though supposing, as he believed to be the case, that about one-third is thus withdrawn, $\frac{E}{45}$ and $\frac{E}{42}$ would more nearly represent the force required to circulate, under such circumstances, to produce fusion, giving $46 - 14\frac{1}{2}$, or $31\frac{1}{2}$, and $42 - 23$, or 19, as the available energy to each cell. Again, if a number of charges in a circuit are to be fired, a still greater amount of circulating force is desirable to ensure success, and overcome small differences in the lengths of the several platinum wires. Sometimes also a thicker platinum wire may be employed, which would require greater power to fuse. For all these reasons any further reduction is inadvisable.

Having thus decided that the size, form, and arrangement just described were the most convenient for a Grove battery, when required for the purposes of exploding powder, Ward proceeded to ascertain what increase of power he could obtain from it by using first concentrated nitric acid, specific gravity 1.500, and then a mixture of concentrated nitric and sulphuric acids, in equal proportions.

With the former, No. 1 experiment gave 701.

" " " No. 2 " " 262.

From which 12 L was found = 177, and the comparative value of $E = 439$; and he therefore concluded that concentrated nitric acid, used in place of the commercial acid, increases the electro-motive energy of the battery about 7 per cent., but has no influence on the resistance of the liquid.

The mixture of concentrated nitric acid with sulphuric acid, in equal proportions, has for its object the strengthening of the former; as the sulphuric acid, from its powerful affinity for water,

withdraws that, which is essential for the preservation of nitric acid in its liquid state. A combination of the sulphuric acid with the small quantity of water it finds disengages also a very great amount of heat, and the mixture gives forth copious fumes of nitric acid, which are destructive to health; the liquid at the same time in any but practised hands being dangerous to handle. It is desirable therefore that such a mixture should never be applied in the field, or be put into unskilful hands. Its effect in giving energy to the battery was however tried, and the result was that at first, while the acid was warm, it had the effect of reducing the resistance of the liquid, but gave no appreciable increase of electro-motive force. When the whole had fallen to the ordinary surrounding temperature, all extra power had vanished. The employment of concentrated nitric acid alone gave an increase of electro-motive energy of but 7 per cent. to each cell above that when common acid was used. The price of the former is about three times that of the latter, and its fumes are deleterious, while the latter hardly emits any. Ward therefore considers it unnecessary to employ these extraordinary reagents in any case, especially when any inferiority of power can be compensated by a proportional addition of cells.

It may be as well, before leaving the Grove principle, to show how much the original battery was susceptible of improvement for our particular object, and to do this our experimenter has arranged, side by side, the expenses of keeping each charged during 24 hours, so as to be able at any time during that period to fire one charge through conducting wires weighing about 250 grains a yard, at the distance of half a mile, assuming what his experiments have shown must be about the truth, namely, that when allowance is made for the cooling effect of the powder, a power represented by $\frac{E}{46}$ will fire instantaneously one charge, with platinum wire $\frac{3}{8}$ " long, and weighing 1.66 grain a yard.

	Large.	Small.
Price of acids (used to charge)	17s. 6d.	7s. 6d.
Weight of apparatus charged	386½ lbs.	36½ lbs.
Size of apparatus	6 cub. ft.	½ cub. ft.
Cost of	46 guineas	under 10l.

The inquiry into the power of Grove's principle of voltaic combination has been given in some detail, to show the mode of proceeding, and the conclusion to be drawn from experiment.

Bearing in mind that the size of the plates has no influence on the electro-motive force, and that any diminution of them makes itself apparent only by an increase of the resistance of the liquid reaction, it will be seen that it was easy to obtain the electro-motive energy of any particular arrangement, by simply altering the metals and exciting solutions. Thus, if cast iron was substituted for platinum, and experimental results 1 and 2 obtained, we have a complete knowledge of the electro-motive energy of one of McCallan's batteries, and also its resistance *when made of that size*. The former numerical result would stand true under any arrangement of cells and plates, and from the latter the liquid resistance of any arrangement could be deduced sufficiently near for all practical purposes.

With Daniell's battery we have but to substitute copper for platinum, and sulphuric acid and copper, in the proportions recommended by Ward, for nitric acid, and we could obtain its power under every condition, and so on with any other combination. First, with respect to Daniell's arrangement, the metals were zinc and copper; and the solutions dilute sulphuric acid, in the proportion of one of acid and eight of water for the zinc, and a saturated solution of sulphate of copper in dilute sulphuric acid, of the same strength, with the copper; the two solutions being kept apart by a porous diaphragm, whilst the temperature and conditions under which the trials were made were similar to those to which Grove's principle had been subjected.

The electro-motive force as compared with Grove's was as 235 to 410, though, as these results were somewhat hastily obtained, we do not submit them as wholly accurate; and the resistance of the liquid of 12 cells 2" x 2" was 242½ turns, Grove's having been found to have 174½ at the first hour, and 275½ at the end of six hours.

Daniell's battery has the advantage of greater constancy, its liquid resistance, while the sulphate of copper is kept saturated, remaining the same at the same temperature. On the other hand, difference of temperature has considerable influence on the success of the battery, owing in a great measure to the variation of the resistance of the liquid; the dilute acid at a high temperature taking up more sulphate, which, as the mixture cools, crystallizes in the pores of the diaphragm, and thus increases the resistance and diminishes the energy of the battery.

Ward did not test what difference is due to changes of temperature, for a Daniell's arrangement being more complicated than Grove's, it was but necessary to compare them under ordinary conditions of temperature to determine their relative merits in the field, where means for raising an artificial heat cannot be generally accessible.

Grove's battery is not so influenced by changes of temperature; that indicated by 50° Fahr. being in all cases sufficient, and superior to this can always be obtained by mixing the sulphuric acid and water just previous to charging the cells.

A trial was made to form an idea what difference of power would result if a saturated solution of sulphate of copper in water was used in preference to the same in dilute sulphuric acid. The electro-motive force showed an increase of power throughout the day from 235 to 242; but the resistance of 12 cells 2" x 2" at the commencement was 605½, or nearly 2½ as much as in the former case. The latter, however, diminished during the day, owing to the more intimate mixture of the two solutions through porous cells, the battery consequently increasing in energy, and at the end of six hours it stood at 402 turns.

The solution, as recommended by Daniell gave the stronger energy, the resistance of the liquid of 12 cells being about 248, and the available energy the cell equal to about 19 turns.

The condition, then, under which a battery having surfaces of zinc and copper 2" x 2"

in action at $\frac{1}{3}$ of an in. apart, stands, is this: $F = \frac{E}{20\frac{1}{2} + 19} = \frac{E}{39\frac{1}{2}}$; and as here the value of L is greater than w , it is evident that such a size of plates is disadvantageous for a Daniell's arrangement.

The amount of negative metal in this battery is that comprised in a hollow cylinder of copper $3\frac{1}{2}$ in. diameter, and varying in height according to the power desired. Suspended in the centre is a zinc rod, that employed at Chatham being $\frac{3}{4}$ of an in. in diameter and 20 in. high. If, then, we take for the area of the mean section of the fluid the surface of a cylinder 20" high and $\frac{1}{4}$ " diameter, being the mean of the diameters of the zinc and copper cylinders, we shall have a total area of nearly 134 in., at a distance of $\frac{1}{4}$ of an in.; but it has been found above that a surface of 4" at a distance of about $\frac{1}{3}$ of an in. opposes a resistance of $20\frac{1}{2}$, and hence a surface of 134 in. at a distance of $\frac{1}{4}$ of an in. would oppose a resistance of $2\frac{1}{2}$, leaving an available energy = $39\frac{1}{2} - 2\frac{1}{2} = 36\frac{1}{2}$ the cell, when porous earthenware is employed as the intervening diaphragm.

Daniell, however, remarks that ox-gullet opposes less resistance than earthenware; and if we assume the resistance to be diminished by this substitution to $1\frac{1}{2}$ turn the cell, it will be giving the battery every advantage; and then the available energy to each cell will be $37\frac{1}{2}$ turns for firing the small platinum wire when placed in the galvanometer; or allowing, as we did before, that one-third greater force is required to fuse it when in contact with powder, the available energy a cell will be reduced to 25 turns.

Supposing, then, that the Daniell's battery, of the arrangement described by its author and the size above specified, is required to be applied to the explosion of a mine, its power the cell, as compared with the small Grove, would be about as 25 to 32, or 3 to 4 nearly. Now, the weight of 10 cylinders of Daniell's battery charged is 137 lbs., whereas 10 cells of Grove's do not weigh 8 lbs.: and further, the Daniell is much more complicated in its arrangement.

McCallan's plan of substituting cast iron for platinum was tried. The electro-motive force seemed to be about the same as in the Grove's; but as it seldom remained constant, owing to the dilution of the nitric acid and destruction of the iron, it was not easy to determine it with accuracy. It oscillated between 408 and 413, that of Grove's being 410. The resistance also of the liquid being at the commencement the same as in the Grove's, it might seem that iron, being cheaper, could be advantageously substituted for platinum; there are, however, some material objections to the substitution. The nitric acid destroys the iron during the whole period that the battery is kept charged, and the more so as the acid gets diluted, forming a solution of nitrate of iron in nitric acid, and thus is every moment deteriorating its own power of absorbing hydrogen, the battery consequently falling in energy. The nitrate of iron also impregnates the porous cells; and in dismantling the battery it is necessary to soak them for some hours in water, to be frequently changed, before permitting them to dry, otherwise the iron salt crystallizing in the cells will crack the earthenware. In addition to this, the action of the nitric acid on the iron is sometimes so great as to cause the acid to boil over, necessitating a rearrangement of cells.

All this trouble and uncertainty is dispensed with by the use of platinum, which is uninfluenced by the acid; and, though the first cost of a platinum battery is much greater, in the end it will be found both cheaper and more efficacious.

The substitution of a saturated solution of nitre and sulphuric acid in equal proportion was tried with the battery of McCallan. This also is a most troublesome arrangement; it is very inconstant, so much so, indeed, as to be quite unsuited for circulating energetic currents; it is continually boiling over, and however well it may answer for experimental researches in a laboratory, it should never be trusted for the explosion of mines. Its electro-motive energy varies according to the amount of force required to circulate; but for the quantity necessary to fuse the platinum wire it never exceeded $\frac{2}{3}$ of Grove's, and only came up to that occasionally. The object of this substitution of nitre for nitric acid is stated by McCallan to be economy; but it has been shown that Grove's battery can be kept charged at a cost of $\frac{1}{18}$ of a penny a cell an hour.

If, however, nitre could have been trusted to excite a battery, even in an inferior degree, its application would have been worthy of further inquiry, as it might sometimes happen in the field that the supply of nitric acid should fail; but so long as gunpowder remained in store there could be no difficulty in obtaining a suitable solution of nitre, by simply boiling up powder and filtering it through blotting paper. The application of this ingredient however, as we have before said, gives very precarious and uncertain results, and should never be resorted to by any but those who have had long practical acquaintance with voltaic phenomena.

We now come to another class of batteries, namely, those in which but one kind of solution is employed, the use and complication of porous cells being thus dispensed with. It was on this principle that the voltaic battery known by the name of Wollaston's battery was constructed. The defects in its mode of action, which have been explained in the first part of this paper, suggested the employment of either cast or wrought iron as a substitute for copper; the rough surface thus presented to the evolving hydrogen favouring its escape. Subsequently Smee substituted platinized silver, that is, silver on which the black powder of platinum had been previously thrown down, thus presenting an infinity of small points to aid the escape of the gas.

Probably for the circulation of currents of inferior energy, such as are suitable for electro-plating, the operation of a Smee may be perfect, and no obstruction occur by the detention of the gas; but when a force necessary for fusing platinum wire is required, the quantity of gas generated is by no means satisfactorily evolved. In fact, the battery, as it were, chokes itself by its own exertions; and if three or four successive demands are made upon it in the course of a few seconds, its power of igniting platinum wire entirely disappears,—nor does it return till the cells have been allowed to rest, and thus set free the hydrogen.

The battery from which these experimental results were obtained was identical in size and construction with the second-sized Grove before described, which was made similar to this for the purpose of ascertaining their comparative merits.

The electro-motive force of Smee's battery, ascertained when it was acting under the most favourable conditions, was, as compared with Grove's, 116 to 410, and the resistance of the liquid stratum of 12 cells = 35; that of a Grove of the same size having been found to be 74½. The available energy of 12 cells of this size = 197 turns. The equation then representing the condition under which this principle of battery circulates a force F would be represented by

$$F = \frac{E}{3 + 16\frac{1}{3}} = \frac{E}{19\frac{1}{3}},$$

that is, each cell has a command over $16\frac{1}{3}$ turns of standard wire when a force sufficient for fusing platinum wire in the galvanometer is required; and as $\frac{1}{3}$ greater force = $\frac{E}{13}$ is necessary for producing the same result when in contact with powder, the command would be diminished to about 10 turns a cell; a Grove of the same size commanding about 40 turns a cell; and a Grove $\frac{1}{4}$ the size about 30 turns a cell, which shows clearly at what expense (even supposing Smee's principle capable of being trusted for energetic action) we obtain simplicity of arrangement, and dispense with the use of a second acid. The size and form of the Smee with which the experiments were made are the most convenient if a Smee must be used for the explosion of powder, namely, a surface of metal = $4'' \times 4''$ in each cell. And yet three pairs of this are but equal to one of a Grove, whose cells are but $\frac{1}{4}$ the size.

As the Smee is superior in every way to the Wollaston and to the zinc and iron battery mentioned above, it was of no use to examine the respective merits of the two latter forms of voltaic apparatus. One form of battery, however, remains to be examined, namely, that of Dalglish. Its principle of action has been before noticed. It consists of an arrangement of 12 platinum cups $\frac{1}{2}$ of an in. diameter and 2'' deep, over which are suspended, attached to a bar, 12 cylinders of zinc $\frac{5}{8}''$ in diameter. The battery is charged very readily by putting into each cup $\frac{1}{2}$ of an ounce of nitric acid. At the moment voltaic action is required, a pressure of the hand on the bar immerses each zinc in its own cup to a depth of $1\frac{1}{8}$ in., and at the same time completes the usual connections, causing an immediate and energetic action. The withdrawal of the hand allows the zinc to be removed from destruction by the elastic bands.

The electro-motive force of this battery as compared with Grove's, using the same nitric acid in each, was as 344 to 410, and the resistance of the liquid stratum of 12 cells = 66 turns, or $5\frac{1}{2}$ turns a cell. The available energy of 12 cells = 622 turns or $51\frac{1}{2}$ a cell. The equation then

representing the circulation of a force F stood $F = \frac{E}{5\frac{1}{2} + 51\frac{1}{2}} = \frac{E}{57\frac{1}{2}}$, from which it will be seen

that while this battery is but little inferior to Grove's in electro-motive energy, it has an advantage over it, in that its liquid stratum opposes much less resistance in proportion to its section, this being due to the absence of Grove's diaphragms.

Also in looking at the value of L as compared with w , it seems as if this battery could be advantageously reduced in size. The mechanical arrangements of the battery, which are somewhat complicated, seem crowded even now into as small a space as they can well be put with safety; and any diminution of cells that could be made would sensibly increase the portability of the battery, as the zinc and platinum comprise but a small part of the actual bulk. The small resistance of liquid in each cell is partly obtained by the extreme contiguity of the zinc cylinders to the inner surface of the platinum cups, the distance being but $\frac{1}{8}$ of an in., and partly to the absence of porous cells. The successive wear and tear of the zinc will tend to increase the value of L , and diminish w . The advantages, then, of the Dalglish principle are the simplicity gained by the use of only one acid, thus dispensing with the necessity for porous cells, and the extreme readiness with which it can be charged for action; it is, however, more complicated than Grove's in its mechanical arrangements, which require skilled labour of a higher degree than could generally be met with in the field to effect repairs. It is also more liable to be damaged by carelessness or accident, as it presents more accessible points.

The power of each battery, taken in conducting wire of 250 grains a yd., which, for reasons presently to be given, we have taken as the best conducting medium for general service, would enable one charge to be fired very readily at a distance of 250 yds., or in a circuit of 500; and if the requirements of a battery were limited to this, we should, where rough handling was not to be expected, prefer Dalglish's battery to Grove's; but on service we presume far greater circuits will occasionally require to be overcome; if, for instance, a mine has to be exploded at a distance of half a mile, about 38 or 40 cells of each would be required to be placed in series, and then the arrangement of elastic bands and of the development of electric excitement by pressure of the hand becomes somewhat troublesome. The Grove is also more perfect in its chemical action, as the hydrogen set free by the decomposition of the water is immediately absorbed by the nitric acid; and the consequence is that as soon as the circuit is completed we obtain the whole power of the battery. In Dalglish's arrangement the power visibly increases after the immersion of the zincs, probably owing in part to the heat occasioned by the intense action of the nitric acid on the zinc. This property of the battery is detrimental to firing a number of charges simultaneously in a circuit, and can only be overcome by immersing the zinc cylinders first, and then making connection with the poles. These points will present themselves with greater force to any one operating with the two batteries than they can be expected to do in any description on paper.

The actual cost of constructing the two descriptions of batteries will depend in a great measure on the price of the platinum, which is by far the heaviest item in each. Grove's battery hitherto, to save expense, has been made with platinum foil. Ward, however, prefers employing sheet platinum, of about 120 to 130 oz. to the superficial ft., for the negative. Whether foil or sheet platinum is used makes no apparent difference in the energy of the combination; but as the former is liable to tear, it would in the end be no economy to use it.

The approximate estimate of the cost of 12 cells of each description of Grove's battery, and that of Dalglish's, is as follows:—

Platinum-foil Battery.— $\frac{3}{4}$ oz. of platinum foil, cells, troughs, zincs, and fittings, 3*l.* 2*s.* 8*d.*

Sheet-platinum Battery.—3·63 oz. platinum, cells, and so on, 7*l.* 2*s.*

Dalglish's Battery.—9·96 oz. platinum, $\frac{1}{4}$ oz. pure gold, zincs, castings, and fittings, 17*l.* 10*s.*

Comparing the two Grove's, though the second is more than twice the cost of the first, it will prove more economical on service, when it is considered that 5*l.* worth nearly of material out of 7*l.* 2*s.* worth, is, with ordinary care, absolutely indestructible. Dalglish's battery cannot cost less than 17*l.* 10*s.* for 12 cells, the arrangements requiring also more than ordinary skilled labour to complete. Assuming, then, the Grove's sheet-platinum battery to be on the whole more economical, its cost a cell, as compared with Dalglish's, is about 1 to 2 $\frac{1}{2}$. The cubical space which they respectively occupy is as follows:—

12 cells of Grove's (in two box batteries) = 14" $\times$ 4" $\times$ 4" = 224 inches.

" Dalglish's = 11 $\frac{1}{2}$ " $\times$ 4" $\times$ 7 $\frac{1}{2}$ " = 345 "

Their comparative weights when empty are, Grove's 8 lbs., Dalglish's 10 $\frac{1}{2}$ lbs.; the latter, however, would not require two-thirds of the weight of acid to be carried with it on service, and that only of one description; and though these differences may appear insignificant, they will not seem so when the quantity of available energy required in the field comes to be considered.

Assuming, as a basis of comparison, that it would be desirable to have always a power available for firing one charge at the distance of half a mile, through the conducting medium and with the bursting charge which has been selected; and also that the same number of spare cells should be kept at hand to replace those fractured or undergoing repair; the following statements will show the approximate cost, weight, bulk, and other particulars in each case:—

	GROVE'S.		DALGLEISH'S.
Cost of construction of batteries ..	51 <i>l.</i>		110 <i>l.</i>
Weight of batteries	54 lbs.		70 lbs.
Bulk of	1400 cub. in.		2300 cub. in.

We call attention to the extreme ingenuity displayed in the arrangements adopted by Dalglish, to carry out his principle for producing voltaic action, as, for example, in the ready method of withdrawing the zinc cylinders from the attack of a most destructive acid, and in the plan of making the connection of the several cells, which is most original, and cannot be done justice to by any description. He combines metals and acids, so as to produce a high degree of voltaic energy by a mode that may be considered perfect; and though, on the whole, his battery, as submitted, is not so perfect in its voltaic action as Grove's, is more sensible to rough usage, and for these as well as the other reasons stated, not so applicable to operations in the field, yet it so surpasses the batteries of every other principle, as to entitle the inventor to special thanks for the successful application of a principle which it has never before been considered possible to turn to account.

To close the inquiry into the motive power, the following, as far as experiments made with some haste tend to prove, are the comparative electro-motive forces of the several principles Ward examined:—

Grove, 410; Daniell, 235; Smee, 116; McCallan, 410; Dalglish, 344.

The zinc, iron, and nitric-acid battery is that intended by McCallan's.

Or, if we take E to represent the absolute electro-motive energy of Smee's,

3·54 E = Grove's; 2 E = Daniell's; 3·54 E = McCallan's; 2·98 E = Dalglish's.

Now, the mechanical equivalent for producing fusion in Smee's was found to be $\frac{E}{19\frac{1}{2}}$, from which the several expressions for the other batteries may be deduced.

Conducting Wires.—With respect to the conducting wires, two factors are concerned in the power of resistance of any one length to the circulation of the current, namely, the metal of which it is composed, and the area of the section; the resistance varying directly as the specific resistance of the metal, and inversely as the sectional area.

Copper, it has long since been decided, is the metal whose specific resistance, where economy is taken into account, is the least; and it only remained to decide the area of the section, or the diameter of wire to be used.

Now, considering that by increasing the number of plates in series we are able to overcome any amount of resistance, it is as well to reduce the diameter of the conducting medium till the value of the copper wire destroyed (some portion must always be expended in an explosion) is reduced to a comparatively insignificant quantity, that is to say, such as would about balance the destruction of zinc and consumption of acid necessary to overcome the resistance consequent on a still further diminution.

The Gutta-percha Company supplied copper wire covered with gutta-percha, at prices from 9*l.* to 21*l.* a mile, the difference being due *solely* to the greater or less quantity of gutta-percha covering, and not at all to the weight of copper furnished. The thickest of these averaged about 250 grains a yard, the smallest about 160 grains. As the former was, of course, the superior conductor, was equally portable, and of no greater expense than the smaller size, it may be the best size for a conducting medium. It is about $\frac{1}{10}$ of an in. diameter.

This sized wire when covered with gutta-percha is very flexible, and can be easily coiled on a reel; two miles in length would easily pack in a cubic yard: its conducting power roughly stated is such that 1 $\frac{1}{2}$ yd. of it would be equivalent in resistance to one turn of the rheostat wire, and making this allowance, the measures before stated can be easily reduced to corresponding lengths in this wire.

The degree of covering required to ensure perfect action depends on the nature of the explosion required; if an explosion is to be made under water, when only one wire is required for completing the circuit, the most perfect covering is desirable, and the cost of the wire so covered would be 21 $\frac{1}{2}$ a mile; but for any explosion on land, where a return wire is always necessary, that sold at 9 $\frac{1}{2}$., 10 $\frac{1}{2}$., and 11 $\frac{1}{2}$ a mile is sufficiently isolated, especially if the wires leading to the mine are not buried under the ground, or, if buried, kept as far apart as possible. In no case would we recommend lapping the wires, leading to and returning from the mine, side by side, as has hitherto generally been done, for whatever advantage the practice may possess, the chances of failure in consequence are many. If, for instance, in burying it the spade by chance should lay bare the surface of one, it would probably also do the same with the other wire; or, again, if from extraordinary heat the gutta-percha should get soft, which it will do at a temperature of about 160° Fahr., a twist in the rope may bring the two wires together, and the covering afterwards hardening would prevent their separation; and, above all, if a fracture should take place it would be very difficult to find on which wire and whereabouts it had occurred.

Gutta-percha is the best covering for the conducting medium, as it is the only means by which perfect isolation can be obtained under every circumstance.

Bursting Charges.—There are two descriptions of bursting charges before the scientific world, one of which has been long in use, and in which a thin platinum wire, forming part of the circuit, is brought to such a heat as to ignite the surrounding powder; and another, the invention of Mr. Brunton. The company with whom this gentleman was connected had been in the habit of what is familiarly called vulcanizing the gutta-percha which covered the wire, to render it pliable even in the coldest temperature, and this led to the discovery of the fuze in question. By the vulcanizing process, sulphur and carbon become incorporated with the gutta-percha in a manner, so to speak, almost chemically perfect. These two act on the enclosed copper wire, and in process of time produce on its surface a species of sulphide, portions of which, when the wire is withdrawn, remain adhering to the inner surface of the gutta-percha covering. This inner surface, which before was simply gutta-percha, and therefore a non-conductor, has now a feeble power of conduction given to it by means of the minute particles of sulphide of copper and carbon. The conducting power is however very feeble, and seemingly in no two portions the same; but whatever the amount of resistance may be, if it can be overcome sufficiently to circulate such a force as will ignite the sulphur and carbon, the desired effect is obtained.

That the degree of heat, or what is generally termed quantity, required for this need not be anything approaching to that for fusing a platinum wire, may be easily conceived, if we compare platinum, which no amount of heat from a smith's forge will melt, and the elements sulphur and carbon, which are combustible at moderate temperatures; yet that the degree of resistance they offer to the passage of the current must be great, may be judged, when it is stated that 48 cells, and even more sometimes, of Grove's reduced battery are required to inflame them close to the battery. These same 48 cells would explode a mine, by means of the platinum fuze, at a distance of $\frac{3}{4}$ of a mile very readily.

In order, however, to cause any sensible current to pass through these sulphides, it is necessary to close all other channels of communication, that is, to break the circuit of the copper wires; then, with a sufficiency of power to overcome the resistance, a combustion with powder in contact will produce the desired explosion; and on this principle the bursting charge is made, a part of the copper circuit being broken and the sulphuret surrounding that part being laid bare and covered with powder.

Here, then, we have two modes of igniting powder at a distance, namely, by the fusion of platinum wire, and by the combustion of a compound which seemingly is a sulphuret of carbon and copper; in the former, the medium being metallic, and, therefore, a good conductor, requires at the same time a high degree of heat to fuse it; while in the latter, the sulphide, though opposing a very great resistance to the flow of the current, ignites even when a considerably less quantity is actually passing.

Now, bearing this in mind, and also Ohm's theory or law regulating the circulation of divided currents, namely, that the quantity flowing by each of two or more portions simultaneously is in the inverse ratio of the resistance of each, the following characteristics of these two descriptions of bursting charges, which have been *practically* ascertained, will be easily understood:—

1. To fire a platinum bursting charge, a return wire, where water cannot be made available, is always necessary, for Ward found that the resistance of $\frac{1}{4}$ of an in. thickness of ordinarily moist earth substituted for it could not be overcome by 48 pairs of Grove's, which would fire the same charge at the distance of $\frac{3}{4}$ of a mile, or through a circuit of 1 $\frac{1}{2}$ mile of copper wire of No. 14 gauge; and this shows that the substitution of earth for metallic wire increases the resistance so much as to diminish the quantity circulating to such an extent that the necessary heating effect is not produced.

2. Whatever number of cells—roughly speaking, for of course it cannot be accurately true—it is found necessary to arrange in series to produce ignition in Brunton's fuze at the distance of 1 ft. will produce the same effect through a copper-wire circuit of 1 mile; and an addition of about one-fourth that number will permit of one-half this copper circuit being replaced by ordinarily moist earth.

These two results show that the absolute resistance of this fuze is so great that the addition of a mile of copper wire or a large quantity of earth effects no material diminution in the quantity actually circulating; that is, if E = the electro-motive force, r the resistance of the fuze, and R

that of the sum of all the other resistances in the circuit, then $\frac{E}{r}$ is very nearly = $\frac{E}{r + R}$.

3. The same number of cells in series of a battery furnished by the Gutta-percha Works Company, that would ignite Brunton's fuze at the distance of 1 mile, did not produce any visible heat in the platinum wire of the other bursting charges at the distance of 1 ft.; and this will be easily under-

stood from what has been said before, for if, by increasing the resistance of the liquid stratum L we make $F = \frac{E}{L}$ represent a force generated by one plate, which is not capable of heating

platinum wire, any number of such cells in series will not heat that wire, as $F = \frac{nE}{nL + w}$ must be less than $\frac{E}{L}$. At the same time if the force required to circulate be less than $F = \frac{E}{L}$ or F' , and L remain constant, the combination of cells in series will have the effect of diminishing w , and ultimately of producing the required force F' .

From this we also learn that the force required to circulate for the ignition of Brunton's fuze is considerably less than that for the platinum bursting charge, and this is still more apparent when we find, as we do, that it does not produce any sensible heat in the platinum wire, much less fuse it.

The battery that gave these results was one that was supplied by the Gutta-percha Company as the best then known for igniting these fuzes. It was a common zinc and copper arrangement, each pair 4" $\times$ 4", and each compartment filled up with sand moistened with acid. 100 plates were required to ignite a fuze with certainty, and even 300 would not produce a sensible heat on platinum wire; and this is due to the amount of resistance offered by the intervening stratum, in this case composed of sand and dilute acid: but as sand is no conductor, the only reason for its use is that it enables the batteries to be carried about without spilling the acid. The average resistance of the stratum of sand, supposing it to have been entirely moistened by dilute acid, when a force F was circulating, was found = about 12.8 turns at the distance at which the plates stood, and the available force a cell = 6.7 turns, making the equation representing its action

$$F = \frac{E}{12.8 + 6.7} = \frac{E}{19.5}. \text{ By the employment of sand, certainly not one-fourth the quantity of}$$

liquid can be used, consequently the resistance L must be increased at least fourfold, or = 51.22, which renders it impossible that the force, which we have called F , can circulate in any such arrangement. The use of sand also prevents the evolution of the hydrogen, and so reacts in controlling the electro-motive force. These figures, however, are not given as strictly correct.

4. It is easy, then, to see that the diameter and description of metallic conducting medium for the platinum charge are matters of material consequence, and its standard resistance should in all cases be known; but with Brunton's fuze it is of no consideration to know it, and in this respect Brunton's fuze presents singular advantages.

5. The isolation of the conducting medium to Brunton's fuze must be *absolutely perfect*, whether the explosion is to take place on land or in water; with the platinum-wire charge it need not be so in either. The abrasion of the covering may be so small as hardly to be discovered by the eye, and yet it will be sufficient, if in contact with the earth, to cut off the circuit almost entirely from the bursting charge. From Ohm's law for divided circuits this is easily accounted for. The resistance of the fuze being by far the most considerable one in the whole circuit, any way by which the current can return to the battery, without passing through the charge, will be taken advantage of for that purpose, by just so much the greater portion of the galvanic excitement generated.

When we consider the chances of a covering like gutta-percha—and this is the only covering that is known, which can be employed in practice, and at the same time give perfect isolation—being cut by a flint or by a workman's spade while being buried, and know that however minute the cut no power of battery will be able to overcome the obstacle it forms, or make up for the loss of fluid it occasions, the necessity for adopting some efficacious protection over the gutta-percha, before the mode of firing by Brunton's fuze can be successfully applied in military operations, will be admitted.

That this perfect isolation is not necessary for the platinum-wire fuze is well known, as, even in water, the loss occasioned by a bare wire can be overcome by extra power of battery. The reason is obvious; the resistance in the bursting charge is metallic, and consequently much less than a liquid resistance. The conducting power of iron, which is certainly not superior to that of platinum, is estimated to be to that of water as 400,000,000 to 1, and, therefore, even supposing the proportion of copper surface exposed, on the wire leading to and returning from the platinum bursting charges, to be in this proportion to the area of platinum wire, if their surfaces were brought to within a distance of $\frac{3}{8}$ of an in. of each other, which they never would be in practice, only one-half the quantity of the electric fluid would be cut off from the bursting charge; and if to the distance of 1 ft. apart, not $\frac{1}{30}$ part of the force would be arrested in its passage through the platinum wire. As anything approaching this amount of abrasion can never occur, with ordinary care, in practice, no fear of a failure from a diversion of the currents need be entertained.

The wire leading to the bursting charge having been attached to the two ends of the secondary coil, a few plates of a Grove's battery circulated a sufficient current through the primary wires. The usual contrivance of a temporary magnet, for making a breaking contact, was employed for obtaining intermittent sparks in the fuze.

With this helix, and four plates of Grove's battery 4" $\times$ 4", it was easy to explode a bursting charge at the distance of 1300 yds. from the operator, *the return circuit being made through the earth*. It was but necessary to leave one of the wires of the bursting charge in contact with the earth, the other being attached to the wire leading to the voltaic arrangement, with which it was connected. A wire from the other end of the secondary coil led to the earth, which, if touched, was sufficient to explode the charge. There is no doubt that this helix arrangement greatly simplifies the apparatus required for the explosion of these charges, for without it about 120 cells are required to produce with certainty the same explosion. The fact that a return wire for completing the circuit may be dispensed with is a great recommendation for the adoption of this fuze; though at the same time it must be remembered that perfectly dry earth will resist the flow of any current.

In a bucket full of dried sand Ward put two plates of copper, 1 ft. square, at a distance of 1 in. apart, and the whole power he could apply could not overcome the resistance interposed.

With respect to firing a number of charges simultaneously with each of these fuzes, the platinum charge, as may be supposed, has the advantage, for on account of the great resistance added to the circuit, where a second gutta-percha fuze is introduced, the force before circulating is materially diminished, and can only be brought up to the original strength by a great addition of power. The practice Ward had with this fuze was not sufficiently extensive to give him confidence in its application to simultaneous firing; but, to state what has been done, 120 plates of the sand battery before mentioned, or 10 batteries of 12 each, fired one charge well through a circuit of five miles of copper conducting medium, about No. 16 gauge; 96 did the same feebly; 72 could not fire it: 216 plates were required, roughly speaking, to fire two placed in the same circuit; 216 fired three in a circuit of one mile; 360 fired six; and 480 fired eight in the same circuit.

These experiments were made in Brunton's presence, the wires being under water in the canal basin; but it should be remembered that the whole of the circuit was not metallic, a few yards of the return portion being through earth and water, which however, when compared with the great extent of wire, may be considered to have no sensible influence on the result. From them it will be seen that these fuzes are capable of being exploded simultaneously when placed in a circuit; but it requires more practice to determine if they can be so trusted, and it is apparent that each additional one requires a large addition of cells. With the platinum-wire fuze, an addition of two plates for every charge inserted is all that is necessary to establish the circulation of the required force. The platinum charge possesses a great advantage over the gutta-percha fuze, in that its resistance being metallic is uniform, while that of the gutta-percha depends upon the degree of action that has taken place on the copper wire, and especially on the extent of sulphuret circuit; for its resistance is so great that an additional length of one-eighth of an inch causes a great diminution of force in circulation. This last circumstance, combined with the degree of action that has taken place, tend to make the resistance so variable, that sometimes 12 plates have been able to ignite a fuze: it is not safe to apply less than 100 plates of the sand battery. With the platinum charge two plates are always sufficient to overcome the resistance. The gutta-percha fuzes are also liable to deteriorate by exposure to the air, sulphate of copper forming where the sulphides were, and the fuze losing in consequence its inflammable properties. Several modes have been tried of making these fuzes; some requiring six months to mature, and others only half an hour; but the respective sorts seemingly present this property, that the sooner they come to maturity the easier they deteriorate. Both descriptions of fuze have their peculiar advantages. The one may be issued ready made, as an article of store, and the other would sometimes turn to account in an emergency in the field, when the store supply had been exhausted. In fact, the range of inquiry with respect to this description of fuze is very extensive, and well worthy of pursuit. It may be apprehended that such enormous distances will not be necessary in the field: as the cost of the return metallic circuit can be made up by a less expenditure of gutta-percha in procuring isolation; as the resistance of any wire employed can be ascertained with sufficient accuracy and hardly any labour in a few minutes; and, as we shall show, the power required for any proposed explosions, simultaneous or otherwise, can be calculated with far more correctness and confidence than, with respect to the gutta-percha fuze, it is as yet possible to do; and, above all, as the casualties that ordinarily attend the laying out and burying of the conducting medium will have no sensible effect on the platinum fuze, while they have a most important one on the other, it seems right to conclude that, as far as our experience goes, the platinum fuze possesses greater recommendations for use in military engineering.

Having thus decided on the most suitable battery, conducting medium, and bursting charge, it remains yet to point out the rule for calculating the number of cells necessary for exploding any arrangement of charges with them, and at any distances that may be required. The length of the platinum wire of the bursting charge will, of course, influence the resistance of that part of the circuit. From practice, it has been found that a wire $\frac{3}{4}$ of an in. long gives sufficient heat, with the least expenditure of power; and it therefore seems desirable to use that length, as it is as well to adopt some one length, whatever it may be. A length of $\frac{3}{4}$ of an in., weighing 1.65 grain a yard, offers a resistance of nearly 61 turns of standard wire, which is equivalent to about 90 yds. of the selected copper conducting medium, weighing 250 grains a yard; and any extra length employed must be allowed for in the same ratio.

Referring back to the equations representing the working of the reduced Grove's battery, it will be seen that $F = \frac{E}{46}$ is assumed as the mechanical expression representing that each cell of the battery, in fair working order, may be subjected to a controlling resistance equal to 46 turns of standard wire, and yet will fuse the platinum wire in the midst of powder; and that $\frac{E}{68\frac{1}{2}}$ represents the conditions of fusion when no powder surrounds the wire; but as it is the rule for the explosion of powder which we have now to consider, the expression $\frac{E}{46}$ most concerns us, and this expression for the power in strong action, that is, during the first two or three hours, is represented by $\frac{E}{14\frac{1}{2} + 31\frac{1}{2}}$ where $14\frac{1}{2}$ is the average liquid resistance a cell, and $31\frac{1}{2}$ is the energy available for overcoming the metallic resistance.

Roughly speaking, $1\frac{1}{2}$ yd. of the established conducting medium of 250 grains a yard is equivalent in resistance to one turn of the rheostat, therefore the available energy to a cell would be equal to about 46 yds. of the conducting medium; and the resistance of a platinum wire $\frac{3}{4}$ of an in. long, and 1.65 grain a yard, being 60 turns, would be equal to, say, 100 yds. of the wire. For firing a mine at any distance when the battery is in good work, we have then this simple

rule:—Take the whole circuit in yards, including distance up and down shafts, add to it 100 yds. for every charge in the circuit, and divide by 46 for the number of cells. This is the rule that theory points out; it will not be advisable to draw it so fine in practice, but our object at present is to show the principle which regulates the calculation.

Again, when the battery has been six hours in action, $\frac{E}{42}$ and $\frac{E}{63\frac{1}{2}}$ are shown to be the mechanical expressions representing the resistance which each cell has the power of bringing under control whilst circulating a force sufficient to fuse the wire in and out of powder. Taking $\frac{E}{42}$, which concerns us most at this moment, we find by referring back that 23 of the 42 turns are consumed by the liquid resistance of each cell, and only 19 a cell are left to overcome metallic resistance, in fact $\frac{E}{42}$ being $= \frac{E}{23 + 19}$. These 19, expressed in turns of the established conducting medium, $= 28\frac{1}{2}$ yds. a cell. Having now therefore but $28\frac{1}{2}$ yds. of available energy a cell, instead of 46, the rule for calculating explosion must be modified as follows:—Take the whole circuit as before in yards, add to it 100 yds. for every charge placed in the circuit, and divide by $28\frac{1}{2}$ for the number of cells, and it will be seen that these two rules give widely different results; as, for instance, if a mine were required to be fired at a distance of half a mile, the former would give 41 cells and the latter 66 cells as requisite.

If at any time an economical use of cells is of consequence, it is desirable to have a ready mode of ascertaining what condition the battery is in; for it matters not what that may be, provided we can ascertain it, and apply the proper rule. Fortunately there is a very ready mode of ascertaining with sufficient exactness the power of any arrangement of cells in series at any moment, and of determining the number of cells necessary at any period between the first charging and six hours after. We have, for instance, seen that when the battery is in good action $\frac{E}{68\frac{1}{2}}$ is the force necessary for firing one platinum wire placed in the galvanometer, that double this force or $\frac{E}{34}$ will be required to fuse two side by side; similarly, a force represented by $\frac{E}{23}$ is required for firing three, $\frac{E}{17}$ for four, $\frac{E}{13\frac{2}{3}}$ for five, $\frac{E}{11\frac{1}{2}}$ for six wires, and so on; these results all depending on the figure $68\frac{1}{2}$, which at this period represents the electro-motive energy of the battery in turns of standard wire.

Whatever may be the number of wires that can be fused side by side, the resistance of the liquid stratum cannot be affected by it; and while the electro-motive force a cell remains at $68\frac{1}{2}$, the fact of being able to fuse any number of wires side by side shows that the resistance of the liquid stratum cannot be so much as the denominator of the fraction representing the force required for such fusion. For instance, if five wires can be fused side by side, the resistance of the liquid cannot $= 13\frac{2}{3}$, for if it did, the force $\frac{E}{13\frac{2}{3}}$ would be exactly balanced by the resistance, and could not circulate; if six, it cannot equal $11\frac{1}{2}$. Having thus ascertained that five wires can be fused, and not six, it would be quite safe to call $L = 13\frac{2}{3}$, and as $\frac{E}{46}$ represents the force necessary for fusion in powder, it is perfectly certain that at that moment the available energy a cell for an explosion, in turns of standard wire, cannot be less than $46 - 13\frac{2}{3} = 32\frac{1}{3}$ turns $= 48$ yds. of selected medium. Similarly, if but four wires can be fused, it will be perfectly safe to allow 44 yds. of selected medium a cell; or if but three, 35 yds. a cell, the resistance of the liquid at this period approaching 23 turns.

At the end of the day of six hours it has been seen that the electro-motive force has fallen in the proportion of $68\frac{1}{2}$ to 63. And the available energy a cell will be reduced as follows: if four wires fuse and not five, to 39 yds.; and further, if three wires fuse and not four, to 32 yds.; and it would not be possible to fuse five wires, with electric energy at 63, at any intervening period, but an allowance of $1\frac{1}{2}$ per cent. an hour for the diminution of the electro-motive force will give the available energy a cell at that time.

This detail has been given to show the principle of the rule and its amount of accuracy, but in practice the whole may be combined into this simple one. Previous to firing a mine, when all the plates are arranged and connected, insert five wires in the slits of the galvanometer, and place the whole series on to fuse it. In all cases it is desirable to put on the whole number of cells you intend applying to the explosion required, as by this means you obtain a practical proof of what that combination, with all the errors the manipulator may have committed in arranging the battery, is able to perform; and you must take care *not to touch the connection* of the battery after you are satisfied as to the power it presents for your use. If a fusion takes place, allow 44 yds. of circuit for every cell; and if the number of cells employed do by calculation cover the range, reckoning the charge as 100 yds., you may feel confident in the explosion taking place as soon as the connection is made—if there are not sufficient cells, add one for every 44 yds. over. If only four wires fuse, allow 39 yds. a cell; if only three, 32 yds.

The trial should be made with all the cells that it is proposed to use, and if any are subsequently added it should be repeated; for the more cells there are in combination, the more accurate is the result. The advantage of the trial is that the result immediately points out any mistake that has been made in charging the cells, or in arranging them, and also if that mistake is of any material consequence; and it may be assumed that the same series of this size of plates that will fuse five wires side by side, will as surely command a circuit of 44 yds. for every cell.

It is customary previous to an explosion to test the wire circuit by a galvanometer needle, to ascertain if the circuit is entire; but it seems to me equally necessary to test the power of the battery. The test explained does not require two minutes to apply, and infallibly points out the available force at that moment.

As the diameter of the conducting medium is of great importance, as well as its specific resistance, it is fortunate that the rheostat, by a mode essentially practical, enables us readily to determine the absolute conducting power of any diameter or description of wire. The mode of doing this has been explained before, and need not now be repeated; it will be sufficient to say that the probable error of a single observation with Grove's battery does not exceed $1\frac{1}{2}$ per cent. (for which an allowance can always be made on the safe side), and that any one accustomed to use the instrument could in an hour ascertain the resistance of any platinum wire that may be obtained on the spot, or of two or three miles of conducting medium, as well as every particular concerning the battery, so as to be able to apply them with certainty to explode any arrangement of charges that may be desired.

However, it is essential that every portion of conducting wire issued on service should be proved first. Let there be one description of wire kept at the dépôt, which should weigh, for the sake of accuracy, somewhere near 250 grains a yd., and be covered with gutta-percha; but beyond that no precaution is necessary, nor is it essential to know the precise diameter or weight of it. A rheostat *rated*, so to speak, from this standard should be supplied to each branch dépôt or headquarters, and batteries and wires similarly rated should be also furnished in quantities sufficient to meet the probable requirements.

Thus if any portion of the supplies for voltaic purposes should fall short, if the expenditure of all the platinum wire should render it requisite to employ fine iron wire, if it should be necessary to use a different conducting medium in the place of the established one, or a different battery of different acids, or, in fact, if any alteration should be rendered imperative from local circumstances, we shall have a ready mode of calculating the allowance to be made in consequence of the substitutions; and, above all, we shall have the power of comparing practice in different parts of the world, and of estimating accurately the merits of any new combinations, by a report of the experiments of half a day.

The task of perfecting the details of these arrangements must necessarily devolve on those who may be directed to continue this inquiry, as the operator merely touches on the advantages that may be attained through careful attention.

Simultaneous Firing.—It may be necessary to say a few words on the simultaneous firing of a number of charges or mines by one battery, and point how theory guides us to a just conclusion as to the number of plates necessary for any number under any arrangement. Reasoning, then, from the results obtained from Grove's battery, we have found,

1st. That a force represented by $\frac{E}{46}$ is required to circulate, in order to produce an explosion of one bursting charge made with platinum wire $\frac{3}{8}$ of an in. long, and weighing about 1·65 grain per yd.

2nd. It is also admitted that when any force circulates in the manner that a voltaic electric force does, the quantity passing at any one time in all parts of the circuit is the same, but that the heat developed at particular parts depends on the quality of the metal, its diameter, and conductivity. If, then, we place in the circuit any number of short platinum wires, identical in weight and length, and cause a force $\frac{E}{46}$ to circulate through it, we are led to expect that they will all

fuse at the same instant, and if they do so, the explosion will also be simultaneous. Now, in order to cause such a force to circulate, it is only necessary that cells should be added capable of overcoming the resistance added by introducing each charge, or cells equivalent to 90 yds. of selected conducting medium; that is, when the battery is strong, two cells a charge, and at other times three cells a charge. This theory, if practically applicable, is productive of great economy both in cells and wire; for supposing twelve charges to be exploded simultaneously at the distance of one-seventh of a mile, or in a circuit of half a mile, by the rule before given, when the battery is in strong condition 44 cells would do the work easily with an expenditure of but half a mile of conducting medium; whereas if each had to be fired by a separate battery, we should require 22 cells and half a mile of wire for *each* charge, making in all six miles of wires and 264 cells.

At the close of the latter day Ward arranged twenty charges in a circuit of 800 yds., and endeavoured to fire them by 48 of Grove's small cells, when only fifteen exploded. Twenty charges, it will be seen by the rule given, were more than the battery of 48 cells could bear; for, allowing one cell for each 46 yds. of circuit (17), and two for every charge (2×20), would give 57 cells as necessary; but, as he had not that number, 48 were tried, and failed. In practice it is always best to be on the safe side of the rule, and even to add a dozen cells to the estimated quantity to make sure.

Such is the imperfect practice which Ward had with the smaller description of platinum wire in the bursting charge. We will presently sketch out the rules for guidance in making future trials; but we first notice the following mode of simultaneous firing, which has been before greatly recommended for its safety.

Supposing B, Fig. 1158, to be the battery, and $C_1 C_2 C_3 C_4 C_5$, five mines to be fired. At a convenient distance from B two mercury cups $M M_2$ should be placed, a wire from each mine leading

to each cup, and a pair of wires from the cups to the battery. This mode of arrangement has the advantage of connecting each mine directly with the battery, and making its explosion independent of any error that may have occurred in any of the other mines. So far it has great advantages, and we also save five pairs of wires, which would have been required to cover the five distances, $B C_1$, $B C_2$, &c., and it only remains to determine, by reference to the preceding investigation, what power of battery is necessary to explode the five simultaneously.

As it is evident that the battery B must, when the distances $C_1 M_1$, $C_2 M_2$, &c., are all equal, circulate the same amount of force through each of the bursting charges $C_1 C_2 C_3 C_4 C_5$, and as each platinum wire must be brought to a state of fusion in surrounding powder, the force to fuse all, or that flowing along $B M$ and $M_2 B$, must be five times that for fusing one. Now $\frac{E}{46}$ in standard

measure is assumed as a representation of the force for fusing one wire in powder, therefore $\frac{E}{46}$, or

say $\frac{E}{9}$, will be that required for fusing all. With the reduced Grove arranged in series no number of cells could circulate this force; because, as before stated, the liquid resistance is more than 9, or = $14\frac{1}{2}$; and it then follows that, unless we can reduce this resistance L , we cannot, with the Grove in question, explode these five charges simultaneously.

There is, however, the following ready mode of reducing the amount of this resistance. Imagine a current of electricity flowing through a circuit of wire $B C D$, the parts of which $B C$, $C D$, and $D B$, Fig. 1159, being identical in all respects, will oppose an equal resistance for equal portions to the circulation of the current. Now let the portion $C D$ be increased to double the size, or, what is the same thing, along that portion of the circuit let another wire identical with $C D$ be placed, carrying the electric fluid from C to D concurrently with $C D$, and the effect will be that the resistance of the length $C D$ of the circuit will be reduced to one-half, or, if a third wire be added, it will be reduced to one-third, and so on.

Now, altering this disposition of the circuit, let us imagine one battery B , Fig. 1160, say of 12 cells, circulating a current $B C D$ as before, having another, identical in all respects, placed alongside of it, the two zincs being connected, as also the two platins, and the current circulating in the direction $Z P D C$. Banishing for a moment from the mind the idea that the electricity is being generated there, which circumstance cannot affect the reasoning, it will be seen that if the resistance of 12 cells before was $12 L$, the resistance by this new arrangement of *this part of the circuit* has been reduced to $6 L$; or imagining the two batteries B and B , each of 12 cells, to be now one battery, the resistance of the 12 cells of this new machine is now but one-half of what it was in the old one; and if a third battery was put alongside, the resistance of the combination would be $4 L$, and so on. We can therefore make a battery, *without any more trouble than that of altering the modes of connection*, which shall give a resistance of liquid of any degree we please; and therefore we can circulate *with economy* any amount of force, or in fact form a battery suitable for any purpose.

In the case we have taken, we require to circulate an amount of force expressed by $\frac{E}{9}$ in standard measure, where $R = L + w = 9$. The most economical mode, theoretically speaking, to circulate this is to make a battery in which $L = 4\frac{1}{2}$, leaving $4\frac{1}{2}$ of standard measure for each cell's available energy; but, on practical considerations before noticed, L should be somewhat less than w .

The resistance of each cell of the Grove battery adopted has been shown to be about $14\frac{1}{2}$. Now, five batteries arranged abreast will reduce this to $\frac{14.5}{5}$, say 3, leaving $9 - 3 = 6$ turns = 9 yds. of adopted conducting medium as the available energy a cell; and if in the case before us we suppose the distance $M B$ to be one quarter of a mile = 440 yds., and the distances $M C_1$, $M C_2$, and so on, each = 100 yds., the mode of calculating the number of cells to produce instantaneous explosion of these five thus arranged would be: circuit $M C_1 M_2$ including platinum fuze = $200 + 90$, then the resistance of five concurrently would be $\frac{290}{5} = 58$; to this add $440 \times 2 (= 880)$, giving 938, and dividing by 9 yds., the available energy a cell, will give 104 cells for the number in combination five *deep* in series, or $104 \times 5 = 520$ cells in all.

Now, by the other mode of simultaneous firing, a much less number of cells will be necessary: any one of these charges could have been fired by an arrangement of 30 cells with ease, and as many more introduced into the circuit at the rate of two or at most three additional cells for each charge.

The reason for this immense difference in the number of cells necessary in the two modes is that, in the case where all the platinum wires are placed in one circuit, it is not necessary to increase the *amount* of circulating force, because the quantity flowing through one charge helps to raise the heat of all; but in the latter arrangement it is necessary to supply heat sufficient to melt five platinum wires, of one thickness, simultaneously; and as they *share* the electric

current established *between them*, five times the amount of force is necessary. If, then, an equation

$\frac{E}{L + w} = F$ represents a battery in which $L + w$ are economically arranged to produce a force F , then $\frac{E}{\frac{L}{5} + \frac{w}{5}} = 5F$ represents a disposition for fusing five such wires. Now $\frac{L}{5}$ it has been shown

can only be produced by placing five cells abreast, and as $\frac{w}{5}$, representing the available energy of a cell, is only *one-fifth* of what it was before, it requires that five times as many should be arranged in series, end on, to overcome any given resistance.

These are the only two principles of firing simultaneously that are practised, for the following arrangement is but a modification of the second mode, as will be apparent, and the same mode of calculation applies to it. We have, by the second arrangement, a mode of exploding any number of charges simultaneously, and from the arrangement itself it is evident that a failure cannot take place, for each charge will be quite independent of the others. At the same time it is very doubtful if any economy is secured by this arrangement. Supposing BMC_1 , in Fig. 1158, to be

540 yds. as before, $\frac{540}{23} + 2$ gives 26 cells as quite sufficient for exploding that one mine, and

therefore $26 \times 5 = 130$ cells would be enough to explode all five simultaneously, if *each charge* had a pair of wires leading to B . Now, to economize four pairs of wires along MB , or to save the trouble of laying out two miles of wire, we are obliged to employ $520 - 150 = 370$ extra cells; and it becomes a matter for consideration whether the extra expenditure of trouble and acid, at the source of supply, does not more than counterbalance the labour of arranging the wires. In fact, the first principle of simultaneous firing, namely, that of placing all charges in one circuit, is the *only* economical mode, and that it requires but a knowledge of the principles which we have endeavoured to make clear, without any finessing in practical details, to ensure success with it on every occasion. The great cause of failures in simultaneous explosion has been the want of sufficient power; and if any one will take the trouble to examine, on the principle of Ohm's theory, the statistics of recorded failures, they will see that they all thus occurred from a manifest want of power; so that instead of disappointment at their want of success, they will wonder how they ever succeeded.

It has generally been the habit, as a matter of precaution, to solder two wires side by side in a bursting charge, in case one should break; would any one unacquainted with Ohm's theory imagine that if a battery, economically constructed for fusing one wire, were used to fuse two side by side, it would not be able to produce even visible heat in either of the two, or, in fact, that it would require four times as many cells (arranged as explained before) to fuse these two wires? yet sometimes three or four have been so placed. Occasionally two charges are placed thus, C_1, C_2 , Fig. 1161, in one powder-box, each (C_1 and C_2) having two platinum wires. If a battery were economically constructed to fuse one such wire, it would require nearly sixteen times as many cells to fuse the four.

Suppose, again, Fig. 1162, that a number of charges are arranged in a circuit thus, each with two precautionary wires, and that while the battery is powerful enough to fuse the double wires all round, one of the two wires in one charge (C_1) is broken by some mishap: it is then rendered *positively certain* that, however strong the battery power may be, this (C_1) will be the only charge which will explode, for the *one* wire left in it will fuse before the other pairs will arrive at any visible heat. Ohm's theory explains the cause, and points to this as the certain result.

Again, the conducting wire hitherto used for explosion has been generally $\frac{1}{8}$ of an in. thick, and the platinum wire in the bursting charge sometimes $1\frac{1}{2}$ in. long; now, can it be supposed that it was generally known that the introduction of one such bursting charge in the above circuit was equivalent to adding 1200 yds. of the thick conducting medium, or that an equivalent to this resistance in cells was ever added to compensate for the diminution of force?

These, and many other extraordinary results depending on the principles regulating the circulation of a voltaic current, have given this agent the character of extreme mutability and uncertainty, which it does not deserve, as they were the consequence of an imperfect knowledge of those principles.

From what, then, has been shown above, as the result of the use of a second platinum wire in the bursting charge, it will be apparent that Ward condemns its application; since in firing charges simultaneously in a circuit it is worse than useless, and is indeed ruinous in its effect. The precaution being resorted to, implies a belief that in case of a single fracture in any one charge, a second wire is at hand to complete the circuit and ensure an explosion of all; but the reverse is the case, as has been shown; and the second wire, the first being fractured, ensures that this charge is the only one which will explode: and yet the usual testing of the circuit by a galvanometer needle, previous to connecting with the battery, will delude one with the hope that all is right; whereas, if only one wire had been used in each charge, the fracture would have been

made apparent at once by the breaking of the circuit, and thus a warning given to repair. In no case should we attempt to place more than one platinum wire in a bursting charge, and that charge should be *only* connected with a pair of conducting wires leading to the surface or end of the tamping: place a second charge, if it is thought desirable; and before finally connecting *either* of them with the wires intended to lead to the battery, test each by the galvanometer to see if the circuit to that point is complete, and then connect only one of them to the main wires leading to the place from which the mine is to be fired.

It will be seen that for whatever purpose voltaic agency may be required, and whatever principle we adopt to circulate the amount of current required, there is a certain size of plates which will do it to the best advantage, depending on the mechanical equivalent representing the value of that force. In the present case the force required was found to be best produced by a Grove's arrangement of the size submitted. When a Smee was tried, though from its simplicity it was preferable to a Grove, it was found that it choked itself, as it were, in its endeavours to circulate the amount required, and consequently its circulation was not constant and not suitable for our purpose; at the same time its electro-motive energy being low, more bulk was necessary for producing any effect. Daniell's battery certainly circulated a constant force of the degree required; but it was inferior in electro-motive energy to Grove's, and, being at the same time more complicated, was rejected, and so with the others.

We have shown that the simultaneous explosion of any number of charges of powder can be obtained, if we can at the required moment establish the flow of such a constant current of electricity as shall produce a fusion heat in every platinum wire placed in the circuit.

It is advantageous, however, that this circulation should be produced with the utmost economy, consistent with certainty; and we have shown that the economical consideration is theoretically satisfied when (E representing the electro-motive energy of the combination, L the resistance of the liquid, w that of the wire, n the number of plates, and F the required amount of current) in the

equation $F = \frac{n E}{n L + w}$, $n L = w$, or $L = \frac{w}{n}$; but that practically, for reasons given, L should be

somewhat less than $\frac{w}{n}$, the expression $\frac{w}{n}$ representing the available energy to each cell of the voltaic combination.

Now, the battery submitted has been constructed to satisfy these conditions, with the platinum wire which Ward recommends. But it will be evident that any alteration in the amount of current required to circulate would require a corresponding modification of the battery. For instance, if a platinum wire double the thickness of that recommended were substituted, more heat would be required to fuse it, and therefore a greater current must be caused to circulate. This

can only be brought about in the equation $F = \frac{n E}{n L + w}$, where E and L are constant, as they are in any *determined* form and principle of battery, by a diminution of w ; and if this diminution reduces w in value below $n L$, the amount of current required is no longer economically circulated. Nor can it be so till the value of L is also reduced, the principal mode of effecting which is by enlarging the size of the plates. The *diameter* of the platinum wire is therefore an *essential* consideration in determining the size of the plates in any voltaic arrangement to produce its fusion, as very small differences in the diameter of the platinum wire will lead to gross errors in calculating the number of cells necessary for an explosion, and uniform success can never be obtained in the field if the platinum wire has not been carefully selected, and tested as hereafter suggested before its issue from store.

The *length* of the platinum wire employed in the bursting charge is not a matter of the same importance, as a battery of the same sized plates can economically circulate the force required through any length of platinum wire. For it must be borne in mind that by adding lengths of wire we do not call on the battery to circulate a *greater amount of force*, but merely to overcome a *greater resistance* to the circulation of the *same* amount, which can readily be done by increasing

the number of plates in series. For if in the equation $F = \frac{n E}{n L + w}$ we increase w to $w + a$, and so diminish the value of F, we can immediately restore the equation to its former value by adding cells = $\frac{n a}{w}$, and the force F will circulate as economically through a resistance $w + a$

by the combination expressed by $\frac{\left(n + \frac{n a}{w}\right) E}{\left(n + \frac{n a}{w}\right) L + w + a}$ as it did in the first case through w by

the combination of n cells.

It is thus quite open to any future operator with the battery submitted, to introduce any lengths of platinum wire into his bursting charge, merely remembering to employ the thickness recommended, namely, 1.65 grain a yard; though $\frac{3}{8}$ of an in. is sufficiently long for all purposes, and possesses the advantage of less liability to fracture than greater lengths.

With respect to the copper conducting medium, that weighing 250 grains a yard, covered with gutta-percha, is recommended; but it is not *essential* that any particular metal should be employed, or that the wire should be of any particular weight, as we have described a ready mode of ascertaining the resistance, in standard measure, of any material of any length.

Mining Operations for Blowing Down the Cliff near Seaford, on the Coast of Sussex, 1850: by Major-General John F. Burgoyne.—Along the coast of Sussex the banks of shingle afford protection to the rich low lands within them from the encroachments of the sea.

The shingle, however, is in a gradual but irregular state of movement from west to east, and

at times a great impression is made on particular parts, that would lead to much damage, if not arrested by projections of timber and planking, between high and low water marks, termed groins. These groins are very expensive, and their useful effects extend but for a short distance.

William Catt, whose family have considerable possessions in the plain between Newhaven and Seaford, a distance of about three miles, considered that by constructing a very substantial groin on a large scale under the cliff near Seaford, which is at the east extremity of the plain above mentioned, and the foot of which cliff was washed by the sea at high water, and thus stopping the progress of the shingle, it would have some influence in protecting the whole extent of the beach to Newhaven.

He also considered that the most efficient, lasting, and economical mode of establishing such a projecting obstruction would be by throwing down the cliff, which was nearly perpendicular, and about 200 ft. high, on to the beach, by a great explosion of gunpowder.

In the main feature of the application of the two great charges, there was no difference in principle between them and the three, though there were some in the proposed modes for carrying it out, as will be subsequently explained.

The plan finally adopted was to lodge two large charges, each of 12,000 lbs. of powder, 120 ft. asunder, with lines of least resistance of 70 ft. to the face, and 58 ft. above the level of the foot of the cliff.

Five smaller charges, of 600 lbs. each, were to be placed in rear, Figs. 1163 to 1168, at a higher

Section on E F.

Section on A B.

level, to clear that part from overhanging remains; and the whole to be fired by voltaic batteries, the two main charges first and simultaneously, and the five smaller ones immediately after. In consequence of not receiving in time a supplementary demand of gunpowder, only three of the smaller charges were loaded.

The circuit of the wires connected to the two great charges was completed at the batteries, and on the instant the ignition of both took place, throwing down the face of the cliff for a length of 500 ft., and to the rear 15 or 20 ft. beyond the five shafts, so as to bring down and bury the three upper charges unfired, cracks and fissures extending nearly to the shed in which the batteries were placed.

Figs. 1169 to 1174 show the result of the explosion of these two mines; and on the sections is also described the effect produced by the action of the sea upon the mound formed by the fall of the cliff.

The projection of the mound, as first thrown out, was about 300 ft.

The mass thrown down, according to dimensions taken the day after the explosion, was about 200,000 cub. yds., or 292,000 tons nearly, at 121 lbs. the cub. ft., which was found by actual trial to be the specific gravity of the chalk.

Mining Operations at Seaford.—The opening made in the face of the cliff for the commencement of the central gallery, by which both the chambers were reached, was 35 ft. above the high-water mark (ordinary spring tides), which at this spot was the level of the beach at the base of the cliff. It was commenced from a rough stage supported by scaffold poles, and reached by a common ladder, the stage being necessary in consequence of the impossibility of making any impression on the face of the cliff by men working on the ladder itself. The cliff is composed of a very compact chalk, 121 lbs. to the cub. ft., dipping to the north at an inclination of about 15° , and intersected by veins of flint at intervals of about 15 or 20 ft. Its height was at the site of the western mine 203 ft., and at the other 225½ ft., above high-water mark. The section at the first of these spots was nearly vertical; for the whole height at the second it was only so for about 140 or 150 ft. A mound of chalk, that had fallen a few days before just at the spot, afforded, when levelled on the top, a base 14 or 15 ft. above the beach, on which to erect the scaffolding. As soon as the men had penetrated a sufficient distance into the cliff to be able to work in security, the scaffolding was strengthened, and a convenient platform with a step-ladder constructed for use during the remainder of the operations, Fig. 1166. To this scaffolding was also fixed a crane-post and derrick capable of lifting nearly half a ton, by means of which the sand-bags and chalk used for tamping were raised to the mouth of the gallery by a crab on the top of the mound. See Figs. 1175 to 1177.

At the entrance, a cave of the dimensions shown by Fig. 1176 was formed, for the purpose of keeping all tools and materials out of the way of the men working at the gallery, and this space subsequently proved of the greatest service, as a dépôt for the powder, sand-bags, and chalk, before they could be

passed along the gallery and branches. Similar advantage was found from a recess, Fig. 1176, at the end of the central gallery, formed by its prolongation, originally as the mode of arriving at the spot where a third service of 2000 lbs. was proposed, which was afterwards considered unnecessary, and the further advancement of the gallery stopped. The use made of these two dépôts fully compensated for the cost of their excavation, though, had the rock been of a hard nature, smaller spaces, particularly with reference to the upper recess, would have answered the purpose, and would have been advisable on the score of economy.

The men employed driving the gallery and branches worked in reliefs for the whole 24 hours. For the gallery, three reliefs of four men each were told off; and subsequently for the branches three reliefs of six men for the two, which were carried on for the most part simultaneously. The hours for relieving were 6 A.M., noon, 6 P.M., and midnight, excepting at periods when the high spring tides prevented the relief passing a projecting part of the cliff at the proper hours, when arrangements were made to equalize the extra time the men were consequently employed. The

work was hardly ever interrupted between 6 A.M. on the Monday and 6 P.M. on Saturday. By compelling each relief to be in barracks six hours before their turn came for work, the men were always fresh at the commencement of their time; and as the working pay was good, and the best miners were thus employed, the average amount of work performed by night fully equalled that by day.

The dimensions of the entrance gallery are given in Figs. 1176, 1177. The content was $47\frac{1}{2}$ cub. yds.; the rate of progress about 16 cub. yds. in the 24 hours.

The main gallery of the section given in Fig. 1178 had an area of 27 superficial ft., so that each lineal foot gave 1 cub. yd. of excavation. The average rate of progress was 8 lineal ft., equal to 8 cub. yds., in the 24 hours.

The branches, of the dimensions given in Fig. 1179, had a section of about $12\frac{1}{2}$ superficial ft.; the rate of progress of the two was at first about 16 ft. = 7.4 cub. yds. in the 24 hours, six men, as before stated, being employed in each relief, instead of four, as in the gallery; but as the distance from the entrance increased, this rate was not maintained, the latter portions averaging little more than 13 ft. in the 24 hours.

	Cubic yards.	Number of Hands employed.	Cost per cubic yard.	Average number of Men in the three Reliefs.
Entrance chamber	$47\frac{1}{2}$	440	2s. 4d.	12 to 18
Main gallery	$61\frac{1}{2}$			
Branches	55			

From the foregoing data, the general rate of progress of the works mentioned above may be assumed at 9 cub. yds. in the 24 hours, by five men constantly employed day and night.

In comparing the progress of the gallery and branches, it appears that the former advanced at the rate of 8 ft. in the 24 hours, and each of the latter, though less than *one-half* the area, at an average rate of only about $7\frac{1}{2}$ ft. in the same time. The increased distance of the branches from the entrance would partly account for this difference; but it is, in a great measure, to be attributed to the slow progress made by miners when working to a disadvantage in a very confined space. Had these branches been 5 ft. 6 in. high and 3 ft. 6 in. or 4 ft. broad, it is probable that they would have been completed in rather less time than was occupied by the smaller size adopted, particularly as no gunpowder was used; the subsequent tamping would, however, have been proportionally increased.

The chambers for the two lower mines were cubical, the side of the cube being 7 ft. 2 in., and giving a content for the two of 27 cub. yds., Fig. 1167. The time occupied in their excavation, and in squaring their floors and sides to receive the joists and uprights to support the rough planking with which they were lined, was about 138 hours, making the rate of progress only 4 cub. yds. in the 24 hours.

The five shafts sunk for the five mines of 600 lbs. each, intended to have been fired simultaneously, *directly* after the ignition of the lower mines, were each 40 ft. deep, and of the section shown in Fig. 1180 having an ascent of about 19 superficial ft. The total content of the five was about 140 cub. yds.

Three men were generally employed upon each shaft. The stuff brought up was piled round the mouth of the shaft, ready for tamping, and no gunpowder was used, the chalk being of a much softer character than in the gallery, and not intersected in the same manner with flint. The task set to each gang of three men for the greater part of the work was 2 ft. 6 in. for every 6 hours. The average rate of progress for the first three shafts was 3 ft. 7 in., equal to nearly $2\frac{1}{2}$ cub. yds. a day. The two last shafts, which were only decided upon within a few days of the explosion, were carried on during the night by reliefs. Their progress in the 24 hours was nearly 6 ft. = about $4\frac{1}{2}$ cub. yds. each shaft.

The returns at the bottom of the shafts, and the chambers for the powder, were as shown in Fig. 1181. The difficulty of working in so confined a space, and the trouble of squaring the returns accurately so as to admit the boxes containing the powder, were the causes of great increase in the expense.

The *directions* of the gallery and branches were laid out by a theodolite, with reference to a line assumed as parallel to that joining the centres of the two charges, fixed during the previous survey of the ground, and the inclination of their floors was tested by a mason's level, the miners being provided with a rough level adjusted to the required slope, to direct them during the progress of the work.

The tools used in the main gallery were the common miner's pick, and a large shovel, for which, in the branches, a mining shovel, 2 ft. 3 in. long over all, was substituted. Wheelbarrows were found more manageable in the gallery than miners' trucks, which, owing to the very great inclination at which the floor was driven (1 in 3), were very difficult to hold back when descending the slope filled with chalk, and to draw them up empty. In the branches, which had a rise of 1 in 9 to 1 in 10, trucks were always used; the recess at the end of the gallery, already alluded to, being found very useful for turning them and for keeping tools out of their road.

Ventilation.—The air was so pure in the whole of the galleries, and even in the chambers, that, excepting when the miners were actually at work and the candles burning, no artificial ventilation was required; had any quantity of carbonic acid gas been present, it would, owing to the steep

1180.

1181.

inclination of the main gallery, have flowed outwards along the floor towards the entrance, and its place have been supplied by a stream of fresh air along the roof of the gallery. In the branches this effect would have been much lessened, from their more gradual rise; and in the chambers, which were sunk below the level of the floor of the contiguous branches, the heavy gas would have settled immediately; but in this instance the air on the floor of the chambers appeared as pure and light as at the entrance. The air-pump by which the ventilation was effected had been used for exhausting the foul air at the bottom of a deep well sunk in the neighbourhood of Brighton; and, by mounting it upon a rough stand, it was made available in the gallery and branches. The tube, secured to the wall about 3 ft. above the floor, was, for the whole length of the gallery, part of the old wooden pipe that belonged to the air-pump; but in the branches, gutta-percha tubes, of $2\frac{3}{4}$ in. diameter and $\frac{1}{4}$ of an in. thick, were made use of.

By adding length after length to these, as required, the hot impure air breathed by the miners at work was drawn off by the air-pump, which, in fact, was all the ventilation needed. Had the air become foul as the miners advanced into the cliff, this air-pump would not have been sufficiently powerful for the purpose; to be prepared for which contingency, arrangements were made for the use of a blowing apparatus from a foundry at Brighton, which, however, was never required.

The gutta-percha tubes weighed about $3\frac{1}{2}$ oz. a foot run.

Lighting the Galleries and Chambers.—During the progress of the gallery and branches, the miners worked by the light of candles, in the accustomed manner; but to avoid any risk of accident from the use of lamps during the operation of loading the mines, fixing the bursting charges, and laying and securing the copper wires leading from them, a contrivance was resorted to for lighting the chambers by reflection from plates of bright tin tacked upon deal frames, which plan was previously tried and found to answer perfectly during their excavation. This method originated in a suggestion of Colonel Lewis, founded upon a mode he had practised of obtaining light in a magazine, by reflection from the painted copper door of the building. A board of about 4 ft. square was first covered with bright sheets of tin, and fixed at an angle of 45° with the direction of the centre line of the main gallery, at the spot where the branches turned off nearly at right angles. The light thus first obtained by reflection from the white chalk was very feeble, and hardly perceptible near the extremity of the branches, excepting at one short interval in the day when the sun was nearly in the line of the gallery, and its scattered rays were reflected from the sea (particularly when calm) up the slope; and the smaller reflector was then placed just outside the mouth of the gallery, in such a position as to catch obliquely the first rays of the sun that the overhanging cliff allowed to visit the spot, which was between 10 and 11 A.M., from which hour till sunset, by occasionally moving the outer reflector and adjusting it like a heliostat, to throw the direct rays it had attracted upon the set of plates at the upper end of the main gallery, a brilliant light was reflected along the branches and into the chambers, where the smallest and most indistinct writing was as legible as it would have been in broad daylight. Had the operations extended over a longer space of time, this outer reflector would have been fixed in a frame, and means contrived to render the adjustments in any way required more easy; but, for the short period it was needed, a rough plank to support it, and two or three sand-bags to retain it in the required position, were found sufficient.

Loading the Mines.—The gunpowder (24,000 lbs.) used for the lower mines was supplied at the lowest rate at which the Battle Mills had offered to furnish merchants' blasting powder, of good quality, but inferior in strength to cannon powder in about the ratio of 9 to 13.

It had been made up in flannel bags containing 10 lbs. of powder, nine of which bags were packed in each of the barrels, which were lined with zinc cylindrical cases, having lids fitted to openings on the top, rendered impervious to moisture by a thick coating of waterproof composition. These were sent round to Seaford Bay in a sloop, and landed, almost immediately after the arrival of the vessel (soon after low water), on the beach, before one of the martello towers which had been prepared to receive them until required for use. The whole number of barrels, weighing nearly 130 lbs. each, were carried by hand up the beach, and stored in the tower. The powder required for the mines at the bottom of the shafts sunk above the cliff, which did not form part of the original project, was not applied for at the time that the first quantity was dispatched, and, owing to some delay, did not arrive at Seaford until within two days of the time fixed for the explosion, so that it was only possible to load three of the five mines of 600 lbs. each that had been prepared.

The distance from the tower to the entrance of the gallery, nearly three-fourths of a mile, rendered it necessary to employ three carts to assist in moving the powder along the beach, on account of the time that would have been consumed in conveying all the barrels to the spot upon hand-barrows. A portion of the men were, however, so employed with nine barrows, and a party of thirty sappers, under an officer, were told off for this work, and for carrying the powder barrels up the ramp leading to the foot of the ladder, and passing the bags up the steps into the entrance chamber.

As rapidly as the barrels were brought to the top of the mound at the foot of the ladder, they were opened, and the bags passed by hand up the steps by men stationed at proper distances upon them, the convenient size of the bags enabling this to be performed with great ease and rapidity; and by the time the men went to dinner, one-third of the powder had been piled up in the outer recess, upon tarpaulins previously laid to receive the bags. After dinner, part of the men (twelve) were employed passing the bags up the gallery to the inner recess, also by hand, the men being stationed between 5 and 6 ft. apart, along one of the walls, and the gallery lighted in the manner already described.

Later in the afternoon, the men who had been occupied with the powder barrels were made to line one of the branches, sitting down with their backs to the side of the branch, and passing the bags from hand to hand to the chamber, where they were built up in a compact form, under the eye of one of the officers; the chamber having been previously floored, and lined to the height

of 5 ft. with rough planks, fastened to uprights by copper nails, to prevent the powder from coming in immediate contact with the chalk.

When one-half of one chamber was completed, the men were transferred to the other branch, and both chambers were loaded with half their quantity of powder, the whole time occupied by the above operations being only $6\frac{1}{2}$ hours. Two sentries were then mounted at the entrance of the gallery, and on the following morning the work was recommenced, and the loading entirely completed by half-past 4 p.m. Before leaving work the remaining sand-bags were all filled, and about ninety of these hoisted into the mouth of the gallery by means of the derrick, and taken up to the upper recess, to be in readiness for commencing the tamping as soon as the bursting charges should have been fixed, and the first portion of the wires leading from them secured from any risk of being moved or injured, which was effected by passing them through tubes drilled in strong pieces of scantling, secured across the entrance to the chambers, and fastening them by wooden plugs, and afterwards leading them along the floor of the branches in grooves cut in narrow strips of plank, covered by other pieces nailed over them with copper nails.

The whole of the operations detailed above, from commencing to move the powder from the tower to the completion of the loading of both the mines, occupied 3 carts and 30 men for 11 hours, and 12 men afterwards for about 4 hours.

The lines of least resistance of each mine being exactly 70 ft. and the charge 12,000 lbs., the proportion the latter bore to the cube of that line was about $\frac{1}{25}$, rather more than was originally proposed ($\frac{1}{32}$). $(70)^3 = 343000$ and $\frac{343000}{28} = 12250$ lbs.

Tamping.—The materials used for tamping in the galleries were sand-bags (filled, some with dry chalk, but the greater part with sea-sand) and lumps of chalk. The sand-bags, only 600 of which were supplied, extended about 30 ft. from each chamber along the branches, the remaining length of which, as well as that portion of the main gallery which it was considered advisable to fill up, being completed with chalk hoisted from below by means of the derrick, in large baskets containing 6 bushels, weighing about 9 cwt. The greater part of the sand-bags were lifted into the gallery in the same manner by slings, five or six together.

In the shafts above, the tamping consisted merely in shovelling down the stuff that had previously been drawn up and piled round the opening, the charges not being sufficient to create apprehension of their producing any effect upwards, the line of least resistance in that direction being 40 ft.

The sand-bags filled with dry chalk, free from any particles of flint, were used in the branches for blocking up each of the chambers, and extended about 8 or 10 ft. from them, so as to prevent the possibility of any damp reaching the powder from those filled with wet sand, which were afterwards built in promiscuously with the others.

Large blocks were built across at intervals, and the finer stuff thrown in behind and rammed sufficiently to make a tolerably compact mass, the wires from the bursting charges being secured from injury during the operation by the manner in which they were enclosed in the grooves already alluded to.

The extent of the tamping is shown in Figs. 1176, 1177, and occupied from 18 to 20 men for three days, as also 12 men for one night. The distance from the crossing of the branches down the gallery to the spot where the tamping was discontinued, was only 20 ft. 6 in., which, though not what would be generally considered necessary with moderate charges, the point A being considerably less than the length of the line of least resistance from the centre of one of the mines, was thought sufficient; the section of the gallery being quite insignificant, when the enormous expansion that would be caused by the explosion of the two charges was taken into account. The result proved that this idea was correct; indeed, it is probable that the effect would have been the same if the main gallery had been left entirely open.

In the branches the rate of progress with sand-bags was about 12 ft. the hour, rather more than 100 sand-bags being required for every 10 ft.; they were passed along nearly in the same manner as the powder, the men being necessarily placed at less distances apart, and the branches lit as before, by the tin reflectors.

With loose chalk, the rate in the branches was 7 to 8 ft. an hour, equal to about $3\frac{1}{2}$ cub. yds., the section being $12\frac{1}{2}$ superficial ft.

In the main gallery the rate of progress for the distance tamped, 30 ft. 6 in., equal to $30\frac{1}{2}$ cub. yds., was about 4 ft. 8 in., equal to $4\cdot7$ cub. yds. an hour.

The above statement of the number of men employed and the rates of progress, includes those working at the derrick and passing the sand-bags and chalk up to the party at work.

In passing the sand-bags and chalk to the end of the branches from the entrance chamber, from 20 to 24 men were required; from the upper recess, which was also used as a dépôt for these materials, 12 men were found sufficient for passing on the sand-bags, and tamping.

At the derrick seven men were employed—two at the crab, three collecting chalk and filling below, and two emptying the basket above, which was in this manner loaded with six bushels of chalk, lifted a height of 22 ft., and returned in $4\frac{1}{2}$ minutes. The same quantity carried up the ladder upon men's shoulders in half-bushel baskets occupied about six minutes with the same number of hands. Another advantage in favour of the derrick was, that there was no difficulty in continuing the work for the whole day; whereas the men could not have stood the fatigue of carrying the baskets up the steps for any length of time.

Description of the Voltaic Battery.—The position of the mines above and below is shown in Figs. 1182 to 1185. The position of the battery house, that is, the shed where the voltaic batteries were placed, and to which the conducting wires from the mines led, is also drawn in Fig. 1185.

The conducting wires from the large mines were brought up the face of the cliff, and then into the battery house.

Plan of large Mines below and Galleries leading to them.

The wires on coming from the entrance of the gallery are passed up the face of the cliff, and are represented in Fig. 1167 by Nos. 2 and 4 wires.

Nos. 2 and 4 wires lead to the charges below. Nos. 1 and 3 are connected with the five mines above through the interposition of the mercury cups. On the word *make ready*, Nos. 1 and 2 are attached to one pole of the battery, Nos. 3 and 4 being held one in each hand. On the word *fire lower mines*, No. 4 is connected to the other pole of the battery, and the lower mines explode. On the word *fire upper mines*, No. 3 is connected to same pole as No. 4, and the five upper ones explode. If instantaneous explosion of all mines be required, Nos. 3 and 4 should be previously tied together, and on touching the other pole of the battery all the mines would explode simultaneously.

It was originally intended to have fired the large mines below simultaneously by one battery, arranging the conducting wires as shown in Fig. 1183, that is, the wire proceeding from the battery was to have been carried directly to, and connected with, the bursting charge of one of the lower mines; from this, again, a conducting wire proceeded to the bursting charge of the other, which again was connected by the same means with the other pole of the battery. The whole circuit by this arrangement would have been about 360

yds. Subsequent experiments have proved that it would have been successful. When the time fixed for the explosion drew near, doubts were expressed in influential quarters of the safety of the plan, and as, from want of time, there was no means of proving its practicability by a sufficient number of experiments to remove all doubts, it was thought advisable to adopt the old method of firing each lower mine by a separate battery and a separate set of wires.

It was originally intended to have fired the five mines above by the arrangement shown in Figs. 1182, 1183. Two mercury cups situated in a convenient position, such as shown in Fig. 1183, had each to receive one wire from each mine; two main wires proceeded from these cups to the battery house, one from each cup.

The object of the cups in this case was not only to economize wire, but to prevent them from being dragged from the hands of the person who fired them.

This method was also abandoned subsequently, having the means of firing each mine by a separate battery, as will be described hereafter.

There were three voltaic batteries available for the Seaford explosion. The two principal ones were exactly similar, being both after Grove's construction.

Grove's consisted of five cells each, and by reference to the figures the description will be better understood, Figs. 1186 to 1188. The description need not extend further than for one cell, as the others were similar. The positive metal was zinc, and the negative platinum: two zinc plates 9 in. by 7 in., and the platinum 9 in. by 6 in. Sulphuric acid diluted in the proportion of one measure of acid to eight of water, and concentrated nitric acid, were the elements for generating the electricity. The zinc plates were amalgamated, and placed in a porcelain cell with the diluted sulphuric acid; between the two plates was inserted a cell of porous earthenware filled with nitric acid, and in this was immersed the platinum, which was attached to a bar of wood, the wood being rather thicker than the exterior breadth of the porous cell; a clamp of brass, as shown in the enlarged sketch, firmly received the two zinc plates, and secured them against the wooden bar; the connection of the zinc of one cell to the platinum of the adjacent one being made by slips of copper, as shown in Fig. 1188.

This form of battery was very convenient, as it could be charged without difficulty and be arranged for firing by two people in ten minutes; and those in the habit of using it could prepare it in six or seven minutes. It was also a very constant intensity battery, for at the end of five or six hours, which was the longest time the battery was ever kept in action here, it was in full strength. The same acid has been repeatedly used for charging the battery for a period of twenty hours, with simply adding a little water to the sulphuric acid solution, and up to that period no diminution in its strength has been discovered.

Plan of large Mines and the Galleries leading to them.

Plan of the top of the Cliff, showing Battery House, and the situation of the three Mines above, and also the Conducting Wires leading from them, as well as the large Mine below to the Battery Shed.

Grove's battery, of the before-mentioned size, is capable of firing one charge at a distance of 600 yds., or through a circuit of 1200 yds.; it will fire two charges simultaneously, arranging them as was originally proposed for the larger mines at Seaford, through a circuit of 1000 yds., the conducting copper wire being $\frac{1}{8}$ in. in diameter, and the platinum wire in the bursting charges $\frac{3}{8}$ in. long.

The porous earthenware cells, though they have been frequently used, are as good as at first.

The method of preserving them (as practised here) is, after the battery is taken to pieces, to soak them in a tub of water for half an hour, thus removing most of the nitric acid and metallic salt that may be in the pores, and then put them in some fresh water for an hour or so longer; the sulphate of zinc being soluble in water, is removed by this means.

The outer porcelain cells may be made of gutta-percha, which, however, though answering every purpose and not being fragile, would require a little care to keep them free from strong nitric acid; the dilute solution of sulphuric acid used has no effect on them.

This battery has many advantages: its connections are very simple, and easily cleaned, which are very essential points with a Grove's battery, for the nitric acid fumes will attack *brass*, *copper*, *solder*, and all such metals as are within the range of its influence. It is very constant in its power on different days, for whatever intensity it has shown on one occasion may always be confidently expected from it on another. With Daniell's battery this is not the case, the temperature having a great effect upon it, and the ox-gullet especially.

The third voltaic battery was of Smee's construction; it was in charge at Portsmouth, and, therefore, was made use of for firing one of the small mines above, as it is not generally adapted for firing charges at great distances: it will not be necessary to describe it minutely. The positive metal was zinc, amalgamated; and the negative, platinized silver; the exciting fluid was dilute sulphuric acid, one measure of acid to eight of water being generally used. It had twelve cells, and was very easily charged for use.

The conducting wire was composed of three strands of copper wire, $\frac{1}{10}$ in. in diameter, twisted as a rope, and then covered with tape, and a solution of shellac and varnish over that again. The advantage of twisting the wire thus is, that it is less liable to fracture, and is more flexible. A single strand of wire, having the same weight the yard, would convey electricity equally well, but

would soon get hard and unmanageable; it is very apt to break at bendings, and so break the circuit; twisted rope wire has a better chance, for one or even two strands may break, and the third be still left to complete the circuit. There was also used copper wire of single strand $\frac{1}{4}$ and $\frac{1}{2}$ in. in diameter.

Bursting Charges.—Those for the large mines below were 9 in. long, and cylinders 2 in. in diameter; and for the smaller mines about 6 in. long. They were lodged in the middle of the mine, and connected with the main conducting wire, which was brought through a piece of wood placed across the entrance of the chamber, and so jammed into it as to prevent the charges being dragged from their position.

By way of precaution, two charges were placed in each large mine, and connected with separate conducting wires, in case one pair might be damaged in tamping. The length of platinum wire for these bursting charges was different for those in each mine, one being $\frac{3}{8}$ in. long, and the other $\frac{1}{2}$ in.

It was doubtful, at the time when these charges were placed, by what method the mines would be fired. The short length of wire had been found quite sufficient for exploding charges, and it was intended to have used that if both mines had been fired by one battery; but as subsequently each mine was fired by a separate one, the bursting charges having the longer wire were attached to the main conducting wires at the mouth of the gallery, as giving a larger spark. However, either set of charges might have been used for either method with perfect success.

The twisted conducting wire, of which there were only 500 yds. available, was kept for such parts as were likely to come under the observation and close inspection of the spectators; for instance, from the battery house to the edge of the cliff, and to the top of the three shafts. That down the face of the cliff and the shafts was the single strand of thick wire before described, and covered with coarse canvas and pitch, tempered with tallow hastily made up. From the mouth of the gallery to the bursting charges below, the same thick wire was used bare, in this way:—A piece of deal, 3 in. broad, had two plough grooves run down it, in which one wire from each bursting charge of one mine was placed, and a fillet nailed over it, previously tarred. Another similar piece of deal had the other wires from these bursting charges fixed in it; these two were kept on *different* sides of the *branch*, and brought down the *main* gallery on *one* side. The same was done with the conducting wires from the other mine, which were brought down the *other* side of the main gallery, Fig. 1184.

The wires proceeding from the battery house were passed over the edge of the cliff through two double blocks, that were run out on two poles. The poles were placed about 10 ft. apart, on the ground, and projected over sufficiently to enable the wires to clear the face of the cliff. One wire from each mine was run through each double block; thus the pair belonging to each mine were kept 10 ft. apart down the face to the entrance gallery, where they were attached by soldering to those from their respective bursting charges: previous to soldering on these wires to those leading to the mines, the continuity of the circuit was tested by a galvanometer; and as every one was complete, the charge having $\frac{3}{8}$ in. platinum wire was selected for the purpose of firing. One Grove's battery was devoted to each large mine.

The three small mines above, each charged with 600 lbs. of powder, had each a battery to fire them, the two extreme ones by the two Grove's, and the centre one by the Smee's already alluded to. The wires were brought from the shafts into the battery house. The arrangement for firing was made as sketched in Figs. 1189 to 1191. M, M, M, M, are mercury cups into which the poles of the Grove's battery were plunged.

The operators stood with their backs to the cliff, facing their respective batteries, the mercury cups being between them and the batteries.

W_1 and W_2 represent two wires, one proceeding from one large mine below, and the small one above on that side. W_3 and W_4 represent two others, one proceeding from the other large mine below, and the small one on the side above. W_5 represents the wire from the centre mine above.

$W_1', W_2', W_3', W_4', W_5'$, are those corresponding to W_1, W_2, W_3, W_4, W_5 , that is, leading to the same mines.

The orders for firing the mines were to explode the large ones first, and when it was known that they had gone off, the three small ones were to be fired. On the word to make ready, W_1, W_2, W_3, W_4 , were inserted in their respective mercury cups, as shown in Figs. 1189 to 1191; and W_5 was attached to the binding-screw of one terminal pole of the Smee's battery.

W_1', W_2' , were held by the officer in charge of that battery, one wire in each hand. W_3', W_4' , were similarly held by the officer over that battery, and W_5' was in Lieut. Crossman's charge.

Captain Frome arranged to give the signal thus:—"One, two, three, fire," and "One, two, three, fire;" the first fire referring to the large mines (when the wires leading to those were to be plunged into the other mercury cups), and the second fire to the three small mines (when all three officers had to complete the circuits corresponding to those). At the first word fire, the two large mines exploded, and the effect produced separated the cliff behind the three smaller mines so quickly as to drag all the remaining wires out of the window, thus preventing the upper ones from being fired. The wire W_5 , attached to the binding-screw of Smee's battery, pulled it over, and the shock made the other batteries jump on the table, mixing and spilling the acids.

With respect to the plan originally proposed for firing the mines below, namely, by one battery, and placing the charges in one continuous circuit, it was asserted to be an uncertain method; because, if one platina wire was a little shorter than the other, the short one would fire first, and, thus disconnecting the circuit, would prevent the other from exploding.

Subsequent experiments (as has been before stated) have proved this opinion erroneous, for in all trials that have been made at Portsmouth of that method of firing, the length of platina wire was always judged by the eye, *never* accurately measured. But a safe means could have been adopted to prevent even this contingency, and have placed beyond possibility the chance of only one charge exploding. The diagram, Fig. 1192, will explain it.

The dotted lines represent the copper conducting wires leading to charges C_1 and C_2 . The length of platinum wire in C_1 may be made $\frac{3}{4}$ in. long, that in C_2 $\frac{5}{8}$ in.; and at points a and b connect copper wires of the same thickness as the conducting wires, leading towards each other, but not approaching nearer than 1 in., and this interval connected by soldering on a platina wire 1 in. long, between the two, and encasing it in wood to protect it from possible fracture in the tamping, and securing it from all strain. On completing the circuit at the battery, C_1 would fuse before C_2 , being $\frac{1}{4}$ in. shorter, but the electric circuit through C_2 would still be complete by the aid of the connections $a b$; similarly, C_2 must fuse before the platina wire at $a b$, being shorter by $\frac{3}{8}$ of an in.; and the interval between the explosion of C_1 and C_2 would not be more than $\frac{1}{2}$ of a second at the most; indeed, practically, instantaneous.

Application of Permanent Magnets to the Explosion of Mines and Submarine Charges.—Electro-magnetism and magneto-electricity may be explained and illustrated as follows: A cell of Daniell's battery is represented in Fig. 1193; a rod of zinc A B is placed within a tube C D of porous earthen-

ware, the vessel E F being of copper. The porous tube C D, containing the zinc rod A B, is filled with a mixture of one part sulphuric acid and ten parts water; the space between the earthenware tube and the copper cell E F is filled with a saturated solution of sulphate of copper; this saturated solution is prepared by pouring boiling water on a superabundance of crystals of sulphate of copper and stirring them; to this solution one-tenth acid should be added. A binding-screw H establishes metallic contact between the zinc rod A B and one end of a wire, the metals being clean at the points of contact; the other end of the wire is brought into metallic contact with the copper cell E F by means of the binding-screw G and the metal support I, which may be either of brass or copper.

In the coil of insulated copper wire at 20, when the positive galvanic current descends and passes in a right-handed spiral round the soft iron bar N S, 20, the iron bar becomes an electro-magnet, the north pole N on the right of the observer. The bar of soft iron N S loses its magnetism or becomes demagnetized the instant the continuous metallic circuit X, 20, 21, V, M Z is broken. Suppose the wire to be made fast to two metal discs L and N, 24, which do not touch, then the galvanic current will not circulate as the continuous metallic contact is broken; but the instant a plug of metal, touching both the discs, is placed in the hole M, the galvanic current circulates, and S N, 20, will be found to acquire a considerable quantity of magnetism, the cell 19 being charged and arranged as before directed. But as soon as the plug M is withdrawn, or the metal bar Q, 23, removed, the circuit is broken, and the bar S N, 20, loses its magnetism. The bar Q, 23, establishes metallic contact between the ends P, R, of the wire. It must be observed by those who are not acquainted with galvanic electricity and technical terms that positive electricity passes from the lower part of the zinc rod through the fluids and porous pot C D, to the copper cover E F, and then continues its course X, +, 20, 21, 22, V, 23, the plug M, and returns to the upper end H of the zinc bar. The electric current passes from the zinc to the copper through the porous pot and fluids, and leaves the battery by the wire (which may be of immense length) attached to the copper, passing through any apparatus that maintains continuous metallic contact, and returning to the battery by the wire attached to the end of the zinc which is not immersed in the fluid; the copper, although the negative metal, forms in this case the *positive end* (+) of the battery; and the zinc, although the positive metal, forms the *negative end* (-). A piece of soft iron, 21, when bent in

the form of a horse-shoe, round the horns of which is wound spirally a length of well-insulated copper wire, acquires a considerable quantity of magnetism while a galvanic current is passing through the wire; one end of the magnet so arranged becomes the north pole and the other the south, if the spiral be wound in the same direction throughout, supposing the horse-shoe to be unbent and made straight. When a galvanic current circulates round the horns of a horse-shoe electro-magnet 21, a piece of soft iron K, near its ends or poles, will be raised; but as soon as the plug of metal M, which is technically termed a contact-peg, is removed, the electro-magnet 21 becomes demagnetized, and K is disengaged or allowed to fall. Electro-magnets of the form 21 have been arranged so that they sustained a weight nearly equal to a ton. If a positive galvanic current passes along a wire in the neighbourhood of a magnetic needle N S, 22, the needle will be deflected, and will take a position *ns*, Fig. 1193, at nearly right angles to the wire. But when the circuit is broken by withdrawing the contact-peg M, or by removing the strip of metal S, 23, the magnetic needle will return to its original position N S. The Danish philosopher Oersted, about the year 1820, discovered the connection between galvanism and magnetism; he also illustrated his discovery by many phenomenal developments. In applying electro-magnetism to the business of telegraphy, the next important discovery was made by Steinheil, who found that the earth might be used to make up half the circuit of a galvanic current; for if a number of cells like 19 be combined, so that the battery may be of sufficient strength, the discs of metal M, N, 24, Fig. 1193, may be buried in the earth at a great distance apart, and yet the circuit will be complete although the return wire is dispensed with. Faraday found by experiment that the converse phenomena also takes place, namely, that on inserting a permanent magnet N S, Fig. 1194, into the middle of a helix of insulated wire A Z, a current of electricity is generated in the circuit of wire A B Z; the direction of the current depending upon the pole inserted and the end of the spiral with respect to the direction of its windings.

This experiment of Faraday has been much over-rated, for, when Oersted had discovered that an electric current produced a magnet, it required but little analytical skill to observe that the converse phenomena takes place, namely, that a magnet would produce an electric current.

Many vague conjectures and absurd theories were entertained about the mechanical action of the galvanic and electro-magnetic currents until Ohm, a German physicist, proved that $I = \frac{F}{W}$, in which F = the electric motive force, W = the resistance, and I = the intensity. Faraday proved experimentally that $Q = sI$, Q being the quantity of electricity conveyed by the current, I the intensity, and s = the time during which the current circulates. Dr. Joule asserts, following out the ideas of Dr. Mayer, that $U = I^2 W s$; in which U = units of work. However, the proofs by which our present mechanical equivalent of heat has been established are far from being satisfactory. This experimental proposition of Mayer and its converse may or may not be true. The proofs given by Professor Tyndall and Dr. Joule are not conclusive. Many forms of battery, a variety of mechanical contrivances, and numerous formulæ, have been employed in the business of telegraphy, the most useful of which we give elsewhere, in order of merit. But those developments, except the local battery of Morse, are of a very second-rate character compared with those we have enumerated.

To illustrate what we have stated with respect to the electro-magnet, we will explain the simple principle upon which W. Siemens constructed one of his first telegraphs. Suppose A J, Fig. 1195, to be a piece of soft iron, supported on an axis C at one end, and lifted by a spring F in the middle, so as to press A J upwards against the metallic contact-screw D. Let the positive pole of the battery B be connected by a wire *e* with one end of the wire-coil of an electro-magnet M M, the other end of the coil being connected with the contact-screw D, by a wire *e'*; while a third wire *e''* completes the circuit; *e''* connects the negative pole of the battery with C the axis of the piece of soft iron or armature A J. When the circuit is complete, the current circulates in the coils of the electro-magnet M M, magnetizes them, and causes the soft iron lever A J to be attracted to the poles; this operation breaks the metallic contact between the lever C J and the contact-pin D. When this occurs, the galvanic current ceases to circulate in the coils of M M, the soft iron cores of which become demagnetized, and have no longer the power to retain C J, which is therefore lifted by the spring F. But then contact is again established between D and

C J, and the galvanic circuit again completed. So that when the apparatus is properly adjusted, the soft iron lever A J will continue to move up and down as long as the battery and the mechanical arrangement remain in working order. One galvanic circuit may be arranged to give motion to two or more such levers as A J at the same time, which motions may be applied to move pointers on dial-plates and convey telegraphic messages.

Magnetism, or the property of permanent polarity, was formerly supposed to belong to iron only. Later researches show that this is to be shared, though not equally, with nickel, cobalt, and chromium. Occasional magnetism may be excited in most substances, as is shown by their influencing the oscillations of a freely-suspended magnetic needle. But this influence is much weaker in all other substances than in the four which we have named. *Silver*, which stands the highest of all the other metals, is nine times feebler in this respect than iron; *gold* fifteen times, and marble nearly twenty times more weak. Iron acquires magnetism by contact or suitable friction with a magnet, by being suitably rubbed or struck in a proper position, by exposure to refracted light of the sun, and even by being left to stand in a nearly vertical position. Here it is enough to say that, owing to the ease with which it is accidentally developed, it is extremely difficult to find in the shop of a philosophical instrument maker, for instance, a tool or strip of iron which is not in some degree magnetic. In all its conditions and states it is susceptible of this property, but develops it differently in each. Thus, grey crude iron becomes sooner and more intensely magnetic than white iron, but yields in both these regards to wrought iron and steel. Soft ductile iron is more easily and more strongly magnetizable than steel, but does not retain its magnetism as well. A similar relation is observable between untempered and tempered steel. The magnetism of iron may be weakened or lost by methods similar to those which originally impressed it. The filings of a magnet are less magnetic than the solid mass. A heavy sudden blow or shock against a hard body will sometimes destroy magnetism. Heat always diminishes it; although there are some peculiarities which have been observed in this regard that are difficult of explanation. It undergoes deterioration whenever similar poles of two equally strong magnets are kept in prolonged contact; and, finally, is always abated by alloying with other substances, and may be destroyed entirely by increasing the proportion of alloy. Arsenic is, in this respect, the most active of the metals, though an alloy of two-thirds arsenic does not entirely prevent the mass from being attracted by the needle. Mushet, however, affirms that 22 per cent. of manganese effectually destroys magnetism in an alloy of iron. Malleable iron is an excellent conductor of *electricity*; and although in this respect inferior to copper and zinc among the easily oxidized metals, and to gold, silver, and platinum among the others, it is yet, for economy, universally employed for telegraphic purposes and for lightning-rods. In the voltaic pile it follows zinc in the order of electro-positive metals. The *electro-magnetic* properties of iron are very remarkable, in the facility with which it is converted into a magnet of great energy during the passage through it of a galvanic or electric current. It is on this that the electro-magnetic telegraph owes, in part, its adaptation and success.

The ignition of gunpowder by the direct magneto-electric current, though well known to be practicable, had, in 1861, never been applied to military or industrial operations in England, and no satisfactory experiments showing its practical applicability to these purposes had been published.

In the first experiments of Abel and Wheatstone a powerful magneto-electric machine constructed by Henley was used.

A few trials sufficed to show that, even with this instrument, gunpowder itself could not be ignited with any degree of certainty. Results obtained with Statham's and other fuzes, though superior to those furnished by gunpowder alone, were still far from satisfactory.

The first experiments were, therefore, directed to the discovery of a suitable agent to serve as a perfectly certain medium or priming material for effecting the ignition of charges by means of the magneto-electric machine. For this purpose a variety of compositions of a more or less sensitive character were prepared for trial with the magnet.

Many of these compositions furnished results to a certain extent favourable; a number of fuzes, primed with them, having been fired in succession with the magnet, and from two to four charges in one circuit having been ignited in a very few instances. But no perfect certainty of discharge was attained with any one of the materials, the attempt to fire a fuze being frequently unsuccessful; while no difference between it and a successful fuze containing the same composition could be detected by careful examination.

These preliminary trials, however, established the fact that the sensitiveness or ready explosiveness, of a priming material was not alone sufficient to determine its success, but that those which possessed a certain, though not too considerable, degree of conducting power, were more readily and certainly ignited than others of a far more sensitive character.

Some successful results obtained accidentally with one of the experimental compositions, which had become damp by exposure to the air, led to a trial of the effect of moisture in promoting the ignition of but slightly sensitive compositions; and it was ultimately found that the impregnation of ordinary gunpowder with a small amount of moisture, by an expedient similar in principle to one adopted with considerable success by Capt. H. Scott, in connection with charges to be fired by the induction-coil machine, rendered its ignition by means of the magnet a matter of certainty.

Some important precautions were, however, indispensable to the attainment of this definite result. If the slightly damp powder were employed in a finely divided condition, it very frequently became caked between the wire terminals in the fuze, and the current would then pass through the composition without igniting it. This was found to take place occasionally, even when the powder was employed in its original granular condition. Several attempts were made to overcome this difficulty by modifying the form and position of the terminals; and an arrangement of a completely successful nature was eventually contrived, in which only the sectional surfaces of the extremities of the terminals, which consisted of fine copper wire, $\frac{1}{16}$ in. diameter, were exposed in the interior of the fuze so as not to project at all. The prepared gunpowder, therefore, simply

rested upon the surfaces, and a perfect uniformity in the action of the fuze was attained. The priming composition consisted of fine-grain gunpowder, which had been soaked in an alcoholic solution of chloride of calcium, of a strength sufficient to impregnate the grains with from 1 to 2 per cent. of that salt. The prepared powder was exposed to the air for a short time, to permit of a sufficient absorption of moisture by the deliquescent salt.

Upwards of 500 quill fuzes, of the description employed for firing guns, primed with the prepared gunpowder and fitted with the arrangement of the terminals above referred to, were fired with the large lever-magnet. The failures did not amount to more than 3 per cent., and were all proved to be due to defective manufacture.

This fuze was found to be easy of manufacture and permanently effective. While, however, it presented a certain means of effecting the ignition, by the aid of a powerful magnet, of single charges, or of a large number to be fired in moderately rapid succession, it was inapplicable to the ignition, with certainty, of more than one charge in circuit.

A new description of priming material for the fuze was prepared soon afterwards, which greatly exceeded in sensitiveness any of the other compositions hitherto tried. A very gradual separation of the armature from the large magnet sufficed to effect the ignition of the fuzes primed with this material, and the induced current obtained by means of a very small magnet, with a rotatory armature, such as that employed in Wheatstone's magneto-electric telegraph, was sufficiently powerful to produce the same result.

The fuze-head, which is of box-wood, contains three perforations, Figs. 1196 to 1198; the one passing downwards through the centre receives about 2 in. of double insulated wire *a a*, Figs. 1199, 1200, two copper wires of 24-gauge, 0.022 in. diameter, enclosed side by side, at a distance of

$\frac{1}{16}$ in., in a coating of gutta-percha of $\frac{1}{8}$ in. diameter; the other two perforations, which are parallel to each other on each side of the central one, and at right angles to it, serve for the reception of the circuit wires. The arrangement for securing the connection of these with the insulated wires in the fuzes is as follows:—

The piece of double covered wire above referred to is originally of a sufficient length to allow of the gutta-percha being removed from about $1\frac{1}{2}$ in. of the wires. These bare ends of the fine wires, which are made to protrude from the top of the fuze-head, are then pressed into slight grooves in the wood, provided for their protection, and the extremity of each is passed into one of the horizontal perforations in the head, in which position it is afterwards fixed by the introduction into the hole of a tightly-fitting piece of copper tube, so that the wire is firmly wedged between the wood and the exterior of this tube, and is thus at the same time brought into close contact with a comparatively large surface of metal. It will be seen that it is only necessary to fix one of the circuit wires into each of these tubes, in the opposite sides of the fuze-head, in order to ensure a sufficient and perfectly distinct connection of each one of them with one of the insulated wires in the fuze.

The extremity of the double covered wire, which protrudes to a distance of about $\frac{3}{4}$ of an in. from the bottom of the fuze-head, is provided with a clean sectional surface by being cut with a pair of sharp scissors, care being taken that the extremities of the fine copper wires are not pressed into contact by this operation.

A small cap of about $\frac{1}{2}$ an in. in length is then constructed of thick tin-foil, Figs. 1199, 1201, into which is dropped about 1 grain of the priming material. The double wire is then inserted, and pressed firmly down into the cap, so that the explosive mixture is slightly compressed and in close contact with the surfaces of the wire terminals.

The cap is fixed by winding a piece of twine once or twice round its upper part, tightening the ends of this, and then removing it. The actual fuze is then ready for enclosure in a small charge of gunpowder, Figs. 1202, 1203. The powder is contained in a paper case tied on to the head, or in a cylinder of sheet tin, tightly fitting on the fuze-head at one end; the other, after the introduction of the powder, being closed with a plug of clay or plaster of Paris.

It is advisable to have the fuzes ready fitted with pieces of insulated wire about 2 ft.

in length, twisted together as shown in Fig. 1205. The ends of the wires, after they are passed through the connecting holes in the fuze-head, should be tightly fixed in their position by the introduction of a short piece of copper wire.

The phosphide of copper fuze for firing cannon, Fig. 1204, differs slightly in its construction from the mining fuze. The fuze-head is longer than in the latter, and of such a form that the double covered wires, which are fitted into it in the manner already described, are completely enclosed in it, the lower extremity of its central perforation still remaining free to receive the top of the quill or copper tube charged with powder, like the ordinary tube arrangement for firing cannon.

The priming material contained in the fuze is prepared by reducing separately to the finest possible state of division the sub-phosphide of copper, sub-sulphide of copper, and chlorate of potassa, and then mixing these powdered substances very intimately, in the proportions of 10 parts of the first, 45 of the second, and 15 parts of the third, by rubbing them well together in a mortar, with the addition of sufficient alcohol to thoroughly moisten the mass. The mixture is afterwards carefully dried, and may be safely preserved in closed vessels until required.

In the experiments subsequently carried on with fuzes which contained this composition, it was found that a slight residue, consisting principally of the coke employed, occasionally remained on the surfaces of the terminals in the fuze after its discharge, and, by forming a good conducting link between them, interfered with any further effects of the magnetic current in other directions, by the establishment of a complete circuit.

The obstacle to the complete success of the composition was entirely removed by the substitution of another material, more easily acted on by the chlorate of potassa than the coke, and answering equally well with the latter as a conducting medium, namely, the sub-sulphide of copper.

No instance has occurred in the discharge of several thousand fuzes, primed with the mixture of sub-phosphide and sub-sulphide of copper with chlorate of potassa, in which the terminals have not been found quite free from adherent residue after the ignition.

The sub-phosphide of copper, which is produced at an elevated temperature, is a compound of very stable character, and the mixture of the three constituents is quite as unalterable as the explosive mixtures which are in general use for the preparation of percussion caps, and so on. The stability of the mixture has been submitted to very satisfactory tests. Fuzes primed with it have lost none of their delicacy and certainty when tried more than two years after preparation. See *ATOMIO WEIGHTS*, p. 195.

The sub-phosphide of copper, intimately blended with chlorate of potassa, forms a mixture in a high degree sensitive to the effect of heat, and possessed at the same time of some power of conducting electricity. With the employment, however, of magneto-electric machines of comparatively low power, and in cases where the resistance to be overcome by the current is considerable, this conducting property is not sufficient to ensure the ignition of the mixture by assisting the passage of the current across the interruption in the metallic circuit—across the small distance between the terminals of the wires in the fuze. It must be borne in mind that the striking distance, or the space between the terminals, across which the current from even a powerful magneto-electric machine will leap, is very small. With the large lever-magnet the spark could only be produced when the wires were almost in contact. Since, however, it is indispensable to the proper insulation of the wires in the fuze arrangement that the terminals should be at least $\frac{1}{16}$ of an in. apart, it will be readily understood how essential to success in operations with these machines it is that the priming material should possess considerable conducting power. Hence the necessity of increasing the conducting power of the mixture of sub-phosphide of copper and chlorate of potassa; a result which it has been already stated was attained in the first instance by the employment of finely powdered coke, and afterwards by the substitution of sub-sulphide of copper for that substance.

Many experiments were of course required to determine the proportions in which it was advisable to employ the conducting constituent, so as to facilitate the passage of the current through the mass as far as possible, without interfering too much with the sensitiveness of the explosive mixture, or producing an almost perfectly continuous connection between the two poles in the fuze, and thus promoting the passage of the current so greatly as to prevent the ignition of the composition.

Considerable difficulties were encountered in the endeavours properly to balance these conditions, when attempts were made, which will presently be mentioned, to apply the mixture in question to the ignition of several charges in circuit. The increase in the resistance of the current, consequent on the introduction of more than one interruption in the metallic circuit, necessitated an increase in the conducting power of the mixture, which it was difficult to attain, unless at a considerable sacrifice of the sensitiveness of the composition.

It was consequently found that when the proper conditions had been attained for ensuring the passage of the current through several—five or six—fuzes in circuit, the absolute certainty of the fuze, when applied in this manner, had been sacrificed. Thus, out of several fuzes tried together, which had been most carefully prepared, so as to be as far as possible perfectly alike, the current would ignite a few, passing through the others without affecting them, and would thus point to

minute differences in the conducting powers and sensitiveness of different portions of one and the same quantity of the mixture, which was prepared in such a way as to ensure the greatest possible uniformity.

The results of many experiments established the fact, that the proportions of ingredients already referred to furnished a mixture possessed of the highest conducting power attainable without detriment to the sensitiveness or ready explosiveness of the material. The certainty of its action, when applied in the fuze, to the explosion of a single charge, by employing a permanent magnet instead of a battery to establish the current, has been proved by the ignition of several fuzes, without failure. See Figs. 1193, 1194.

Experiments, made with the aid of this composition, established the fact that the current obtained by means even of a very powerful permanent magnet, when applied to the ignition of several charges arranged in succession in one circuit, is very limited in its powers. In illustration of this it may be stated that, on trial being made of twenty-one consecutive sets of four charges, eighteen of the sets were perfectly discharged; but, in the other three sets, only two or three of the charges were ignited. Out of five sets, of five charges each, only two sets were completely discharged; and in several attempts made to ignite six fuzes in one circuit, only four were fired in each case. In all these experiments, when charges had escaped ignition, the current had passed through the sensitive composition without firing it. When the discharged fuzes were removed, and the remaining ones properly connected, they were all fired.

It has been already stated that no beneficial effects were attained by modifying the proportions or ingredients in the priming composition, so as to diminish or increase its conducting power.

Three charges were therefore the most that could be ignited *with certainty* by means of a powerful electro-magnetic machine, when they were arranged in succession in simple circuit.

The plan, originally suggested by M. Savare, of arranging the charges in divided circuits, was next tried, and furnished far more successful results. The simultaneous ignition of twenty-five charges was repeatedly effected by means of the large magnet, each charge being connected with a separate branch attached to the main line, which led from one pole of the magnet, and their connection with the earth established by means of uncovered copper wire, the extremity of which was wound round an iron stake driven into the ground.

A still larger number of charges (forty) was similarly exploded on several occasions.

These results were all obtained with the large magnet, the current being established by rapidly separating the armature from the poles by means of a lever. By a simple arrangement for shifting the connection of the main wire with the exploded charges, from them to a second series, similarly arranged, twenty-five were also simultaneously ignited, on allowing the armature to return to the poles of the magnet. It was found, moreover, that the same number could be fired by means of this magnet, even if two folds of thick brown paper were interposed between the poles and the armature, so that on depression of the lever the armature had no longer to be forcibly detached, but simply to be removed from the magnet.

These successful results led to trials of magneto-electric machines of comparatively small size, with revolving armatures. In the employment of these machines, it was of course not expected that any single induced current obtained from them should distribute itself among a number of fuzes placed in divided circuit, as was the case with the comparatively much more powerful current obtained with the large magnet; but it was hoped that the very rapid succession of currents furnished by them would produce a very similar result, by distributing themselves over the different branches of the circuit with which the fuzes were connected, and that the ignition of the whole of the fuzes, though it could not be so positively instantaneous as when the one current was discharging the entire number, might yet be effected with such rapidity as practically to amount to a simultaneous discharge.

The results obtained fully confirm these expectations. With a small horse-shoe magnet, 7 in. in length, 1 in. in breadth, and $1\frac{1}{2}$ in. in thickness, provided with a revolving armature and multiplying wheels, by which great rapidity of motion could be attained, twenty-five charges were fired; the effect of the discharge on the ear was, however, not like that of one single explosion, as was the case in the former experiments, but like that of an exceedingly rapid volley, in which the explosion of any single charge could not be distinguished.

Still more favourable results were obtained with a very compact arrangement of six magnets, each about half the size of the above, devised by C. Wheatstone, for the production of an extremely rapid succession of currents, established in such a manner that the effect would be almost equal to a continuous current.

It consisted of six small magnets, to the poles of which were fixed soft iron bars surrounded by coils of insulated wire. The coils of all the magnets were united together, so as to form, with the external conducting wire and the earth, a single circuit. An axis carried six soft iron armatures in succession before each of the coils. By this arrangement two advantages were gained; all the magnets simultaneously charged the wire, and produced the effect of a single magnet of more than six times the dimensions, and at the same time six shocks or currents were generated during a single revolution of the axis, so that, when aided by a multiplying motion applied to the axis, a very rapid succession of powerful currents was produced. A single large magnet with a rotating armature could not be made to produce the same succession of currents without the application of considerable mechanical power. Another peculiarity of this apparatus was that the coils were stationary, and the soft armatures alone were in motion; by this disposition the circuit during the action of the machine was never broken. In the usual magneto-electric machines with rotating armatures the circuit is necessarily broken twice during every revolution, and this frequently gives rise to irregularities in the production of the currents. By the construction adopted, the currents can never fail to traverse the circuit. It must be borne in mind that our account of this investigation is taken, with some alterations, from an inflated report to the Secretary of State for War,

by Wheatstone and Abel. Such documents are generally cooked up. See 'Professional Papers of the C.R.E.,' vol. x.

The total weight of the instrument, enclosed in a case, was 32 lbs. 11 oz. It was enclosed for transport in a small packing-case, weighing about 7 lbs.

The system of firing charges by means of magneto-electricity, with the aid of the phosphide of copper fuze, having been thus far successfully developed, a series of experiments was instituted on it at Chatham, for the purpose of thoroughly testing its certainty and applicability in the field, and subsequently for ascertaining the extent to which it admitted of application to the explosion of submarine charges. These experiments extended over a period of six months, and were performed under various conditions of weather.

The magnetic apparatus employed in all the field experiments was so arranged that the whole apparatus was enclosed in a box, the only exposed portions being the binding-screws for the attachment of the wires, a handle for setting the armatures in motion, and a key, by the depression of which, at a given signal, the circuit could be completed.

To employ the instrument at any moment, the following were the operations necessary:—

The insulated wire and the copper wire passing to the earth (the earth taking the place of the return wire) were fixed to the apparatus by means of the binding-screws; the instrument was raised from the ground by being placed on its packing-case; at that height a man could operate with it when in the kneeling posture.

At a signal ready, the handle was turned with one hand, so as to cause the armatures to revolve with the greatest possible velocity; whilst the other hand was pressed against one corner of the instrument, close to the key, so as to steady the box, and to be ready at the signal fire to depress the key with the thumb.

The connection of the instrument with the earth was effected as follows:—

A moderately clean spade was selected from among those used by the men in digging holes for the charges. One end of a piece of stout copper wire was placed under the edge of the spade, in such a manner that when the latter was firmly forced into the ground it was pressed by the earth on both sides against the iron surface. The protruding wire was wound once or twice round the bottom of the spade-handle, and then attached to the binding-screw of the permanent magnet.

The gutta-percha-covered wire used in the experiments having been in occasional service at Chatham for some years, the coating had sustained some injury in two or three places. Such defects were protected from possible contact with the earth by means of waterproof cloth or sheet india-rubber. The total length of wire used was 881 yds., of which 600 were extended, lying along the ground.

To the extremity of the covered wire a number (from 12 to 25) of pieces of similar insulated wire, varying in length between 3 and 6 yds., and serving to connect it with the individual charges, were attached in the following manner:—About 6 in. of the extremity of the main wire and of each of the branch wires were laid bare, and cleansed; the end of the former was then surrounded with those of the latter, placed in an opposite direction, and the whole tightly twisted together by means of pliers, so as to be brought thoroughly into metallic contact with each other and with the main wire. The twisted wires were then bound round with moderately fine copper wire, which was made to bring every portion of the exterior of the bundle into connection. The joint was made rigid with pieces of stick tied against it, and the whole securely enveloped in a piece of waterproof cloth or canvas, to protect it from damp and contact with the earth.

These connections, though of a very rough description, and most readily prepared by any soldier, were thoroughly effectual. No instance occurred in the whole of the experiments of the failure of a charge which could be attributed to an imperfect metallic connection of its branch wire with the main wire.

The following was the method adopted for connecting the fuzes with their respective branch wires and with the earth:—

The fuzes, as they were manufactured, were always fitted, as shown in Fig. 1205, with two pieces of covered wire twisted together. They were thus ready for insertion into the bag or other receptacle containing the charge of gunpowder, the ends of the covered wires protruding from the opening of the latter to a convenient distance for effecting the junction with the branch and earth wires, so that a complete galvanic circuit might be established, which was excited by the permanent magnet. The extremities of one of the other fuze-wires and of a branch wire, from both of which the gutta-percha was removed to a distance of about 2 in., were connected by hooking them firmly one in the other with pliers, in the manner shown in Fig. 1206. A piece of fine copper

1206.

binding wire, about 6 or 8 in. in length, was then twisted over the whole of the connection, and the joint was finally enclosed in a small wrapping of oiled canvas, in a manner similar to that adopted at the principal junction with the main wire.

The extremity of the other fuze-wire was attached to an uncovered copper wire of sufficient length to bring the whole of the charges into connection with each other in this manner. The wire was fixed in a convenient position by being twisted round short stakes or pickets driven into the ground, and its extremities were buried in the earth, being attached either to spades, as already described, or to zinc plates about 8 in. square.

With reference to the earth-connection, the employment of large metallic surfaces was also proved, by repeated experiments at Chatham and Woolwich, to be superfluous. The simple insertion into the ground of the uncovered extremities of the fuze-wires was found to afford a perfectly sufficient connection for ensuring the ignition of the charges.

The largest number of charges which it was attempted to fire at once at Chatham was twenty-five. The ignition of twelve charges was repeatedly effected, and with such rapidity as to have the practical effect of a simultaneous discharge of the whole. With twenty-five charges the interval between the first and last discharge was very decided, being certainly longer than when the same number of charges were fired at Woolwich with the employment of a greater length of wire, of which, however, the larger portion was coiled up, the space between the earth-connections being only about one-half of that introduced at Chatham; yet it was considered that even the ignition of the twenty-five charges, at a distance of 600 yds. from the magnet, and with the employment of 881 yds. of covered wire, and, in addition, about 100 yds. in the form of branch wires, was effected with sufficient rapidity to allow of that number being employed in cases where a simultaneous discharge was required.

Another instance of the apparent effect of increased resistance, in the form of an increase in the length of wire laid out, in diminishing the rapidity of discharge, was observed in the employment of one branch wire of four or five times the length of the others. A distinct interval was noted between the explosion of the other eleven charges and that of the one attached to the longer branch wire.

Experiments were made to ascertain whether, to complete the circuit, the employment of a second insulated wire, in the place of 600 yds. of earth-connection, would modify the rapidity of ignition of a number of charges, but no difference of effect was observed.

It need scarcely be stated that, in dealing with electricity produced by a permanent magnet, defects in the insulation of the main and branch wires had to be very carefully guarded against. Several failures in the first experiments were eventually traced to some defect of that kind. An instance even occurred, before the proper method of protecting the connections of the charges with the insulated wires was adopted, in which the deposition of moisture upon the gutta-percha-covered wire, near the charge, prevented the ignition of the latter, by forming a connecting link between the extremity of this wire, where it was exposed and attached to the fuze, and the uncovered wire leading to the earth, in consequence of the two wires being in contact at a distance of several inches from the fuze.

It is therefore always a preliminary precaution of primary importance that the insulating covering of the wire to be employed be carefully inspected while the latter is being laid out for use, and that any imperfections be protected from possible contact with the earth or from the access of moisture, a result readily attainable by the application of some waterproof envelope to the injured portion.

The experiments instituted at Chatham with the object of applying the current produced by a permanent magnet to the ignition of *submarine* charges were attended with greater difficulties than those which served to test the system in its application to land operations; nevertheless, the results ultimately attained were also of a character to lead to definite and favourable conclusions.

The method of establishing the connections of a charge with the wire and the earth differed naturally in some respects from the mode of proceeding already described.

The charges of powder were contained in canisters of block-tin carefully soldered so as to be water-tight. Any vessels of this material, such as turpentine cans, may be employed, provided they be perfectly coated inside with marine glue, or some other description of varnish.

The fuze, with two wires attached as before, the one a few inches longer than the other, was inserted into the charge, and fixed in its proper position in the canister by means of a loose-fitting bung, pushed a little distance into the neck, and cut on one side, so as to admit of the passage of the longer insulated wire, while the bare part of the shorter wire was firmly pressed by the cork against the inside of the neck. The latter was then completely filled up with melted gutta-percha, and the extremity of the short uncovered wire was bent back over its side, so as to be in close contact with the metal surface. In this manner the enclosed fuze was brought into good metallic connection with the wet earth or water by which the canister would be surrounded. See Fig. 1207.

The insulated wire projecting from the mouth of the canister was connected with one of the branch wires in the manner already described; but, in order thoroughly to protect the connection from the water in which it would become immersed, a piece of vulcanized india-rubber tubing of suitable length, and a tin tube rather longer and wider than the latter, were slipped on to the branch wire, before it was joined to the fuze-wire; and when the junction had been effected, the india-rubber tube was pulled over it, and tied very firmly at both ends on to the gutta-percha covering of the wires. See Fig. 1208.

A small quantity of cement, consisting of beeswax and turpentine, was rubbed in between the gutta-percha and the ends of the india-rubber tube, so as thoroughly to ensure the exclusion of

water; and finally the tin tube was pulled over the joint, and fixed by compressing the ends, for the purpose of imparting rigidity to the junction, and thus protecting it from injury by a sudden twist or strain. By these arrangements the perfect exclusion of water from the charge, and from its connection with the branch wire, was effected. In an equipment prepared for effecting submarine explosions, by means of an electric current established by a permanent magnet, in China, stout bags of vulcanized india-rubber were provided for the reception of the charges. These bags were fitted with sockets and screw-plugs of gun metal. The fuzes furnished for use with these bags were attached to two pieces of covered wire, about 18 in. long, which were enclosed side by side in a cylindrical plug of gutta-percha, Fig. 1209, about 4 in. long, and carefully made to form

1209.

one mass with the coating of the enclosed wires. This plug was made to fit pretty tightly into a thick washer of india-rubber contained in the socket of the bag. An inner screw-socket, which was brought to bear with great force upon a metal ring resting on this washer, when the plug had been inserted, compressed its internal surface against the latter in such a way as to ensure a perfectly water-tight joint.

The first trials of these charges were made in a shallow canal with a mud bottom, and from which at the time of experiment the water was receding so rapidly, that before the whole of the charges had been immersed several of them were left half-imbedded in the mud. Twenty-five charges were arranged, of which thirteen were exploded, though less rapidly than in the experiments on land. On the next occasion, when twenty-five charges were regularly surrounded by water, simply resting upon the firm bed of a pond of some depth, only four of the charges were exploded. Several other attempts were made to fire a small number of (ten and five) charges similarly immersed, but in every instance only four were ignited. A careful examination into the cause of the invariable explosion of so comparatively limited a number of charges under water led to the following explanation.

It will be remembered that the explosion of numerous charges in a divided circuit by the magneto-electric apparatus with revolving *armatures* is effected by the action of an exceedingly rapid succession of currents. The rapidity with which they follow each other, however great, cannot equal that with which the terminals of a fuze, exploded in a small charge under water, come into contact with the latter after the explosion. The instant this occurs a complete circuit is established through the water, and any further action of the currents is at once arrested.

By the time, therefore, that four charges had been ignited in extremely rapid succession, so as to be apparently exploded at once, a sufficient interval of time had in reality elapsed to allow the water to re-occupy the space filled for a brief period by the gaseous products of the first explosion, and thus to rush in upon and complete the circuit with the terminals of the fuze. The piece of soft iron K, when attracted by the temporary magnet 21, shown in Fig. 1193, is termed an *armature*.

It is believed that charges are generally so arranged for submarine operations as to be partially or completely surrounded by the objects upon which the force of the exploding charge is to be exerted, and that they are even at times firmly fixed in their position by being partly or wholly imbedded in sand, mud, or some similar material. In such cases the resistance to be overcome by the explosion is greater than if, under conditions otherwise similar, the charges were simply in direct contact with the water, and hence the interval is increased which must elapse before the water can complete the circuit of electricity.

The results of some experiments made at Chatham appear to show that, under such circumstances, the number of charges ignited at one time by the magneto-electric apparatus must be greater than if they were simply immersed in water. One experiment has already been mentioned, in which thirteen charges out of twenty-five were exploded at one time, most of them being imbedded in mud.

On another occasion the charges were placed in small pits filled with water, the canisters being covered in with mud beneath the latter. Nine of the charges were fired; the branch wire of the tenth was accidentally severed at the moment of the explosion, from its lying across one of the pits.

An attempt was made to fire simultaneously fourteen charges similarly arranged, by the current obtained from a large lever-magnet, but only seven were exploded; the other seven were fired on a second trial. It should be mentioned that the length of extended wire and the interval between the earth-connections were greater in these experiments than in those made at Woolwich with the large magnet, in which twenty-five charges were fired with perfect certainty by the single current obtained from it. Possibly the very great difference in the results obtained might have been partly due to some minute defects in the insulation of the branch wires employed at Chatham, which escaped notice on the inspection of the wires, but sufficed to diminish the intensity of the current when these were immersed in water.

It is most difficult, even in a long-continued series of carefully-observed experiments, to separate the pure results furnished by the application of a system, from results which are brought about, or at any rate greatly modified, by accidental circumstances. It appears, however, apart from the latter, that in the application of electricity (whether frictional or magnetic) to the explosion of

charges the effects to be produced by the current are modified by the resistance offered to it in its passage along wires of very considerable length, and that the effects of the current seem very much less when the insulated wire is extended than when it is employed in the form of a coil.

The retardation in the explosion of several charges in divided circuit by a rapid succession of currents, and the diminution in the number of charges fired by one single powerful current, both of which results were repeatedly noticed in the course of the many experiments with the galvanic battery, and with the permanent magnet, could only be ascribed to modifications in the intensity of the electricity by the greater resistance which is encountered.

Robert Hare, Professor of Chemistry in the University of Pennsylvania, was the first who applied electricity to the explosion of mines. Hare found, if an electric current of sufficient force was established in a circuit (X Y Z, A Fig. 1193) of copper wire by either a permanent magnet, or galvanic battery, that a short piece of iron wire (Q, Fig. 1193), much thinner than the copper wire, making part of the circuit (P R, 23, Fig. 1193), was burnt, and exploded gunpowder and other explosive substances through which the iron wire was made to pass. Hare's discovery may be practically applied by the following simple process:—Two copper wires, A B, C D, Fig. 1210, being procured, about $\frac{1}{16}$ in. in diameter and 10 ft. in length, well covered with silk or cotton tarred, so that their insulation may be good. These wires are twisted together for a length *ab* of 6 in., care being taken to leave their lower extremities, at B and D, free, for a length of about $\frac{1}{2}$ in. (separating them about $\frac{1}{2}$ an in.); from the extremities B, D, the insulating envelope must be removed; and a fine iron wire is stretched between B and D. Metallic contact must be established between the iron and the copper. The upper extremities A, C, of the two copper wires are connected with a circuit. For example, if A, Fig. 1210, be connected with P, Fig. 1193, and C with R, the iron wire B D will be consumed as soon as a galvanic or electric current, sufficiently powerful, is established by inserting the contact-peg, M, Fig. 1193.

Explosive Compounds Employed in Blasting.—Nitro-Glycerine is a most powerful explosive agent, and although not extensively used in England, it has been most successfully employed on the Continent and in America. It was discovered by Ascanio Sobrero, an Italian, in 1847, but its practical application to mining purposes is principally due to the researches of Alfred Nobel, a Swedish mining engineer.

Nitro-glycerine is made in the following manner:—Fuming nitric acid (sp. gr. about 1.52) is mixed with twice its weight of the strongest sulphuric acid, in a vessel kept cool by being surrounded with cold water. When this acid mixture is properly cooled, there is slowly poured into it rather more than one-sixth of its weight of syrupy glycerine; constant stirring is kept up during the addition of the glycerine, and the vessel containing the mixture is maintained at as low a temperature as possible by means of a surrounding of cold water, ice, or some freezing mixture. It is necessary to avoid any sensible heating of the mixture, otherwise the glycerine, which is the sweet principle of oil, would be, to a considerable extent, transformed into oxalic acid. When the action ceases, nitro-glycerine is produced. It forms on the surface as an oily-looking fluid, the undecomposed sulphuric acid forming the subjacent layer, owing to its greater specific gravity. The whole mixture is then poured, with constant stirring, into a large quantity of cold water, when the relative specific gravities become so altered that the nitro-glycerine subsides and the diluted acid rises to the surface. After the separation in this manner into two layers is effected, the upper layer may be removed by the process of decantation or by means of a siphon, and the remaining nitro-glycerine is washed and re-washed with fresh water till not a trace of acid reaction is indicated by blue litmus paper. The final purifying process, pursued by Nobel, is to crystallize the nitro-glycerine from its solution in wood naphtha. This final process is not necessary when the compound is to be used at once.

As prepared in this manner, nitro-glycerine is an oily-looking liquid, of a faint yellow colour, perfectly inodorous, and possessed of a sweet, aromatic, and somewhat piquant taste. It is poisonous, small doses of it producing headache, which may also be produced if the substance is absorbed into the blood through the skin, and hence it is not desirable to allow it to remain long in contact with the skin, but rather to wash it off as soon as possible with soap and water. Glycerine has a specific gravity of 1.25–1.26, but the nitro-glycerine has a specific gravity of almost 1.6, so that it is a heavy liquid. It is practically insoluble in water, but it readily dissolves in ether, in ordinary vinic alcohol, and in methylic alcohol or wood spirit. If it be simply exposed to contact with fire it does not explode, although it is so powerful as an explosive. A burning match may be introduced into it without producing any explosion; the match may be made to ignite the liquid, but combustion will cease as soon as the match ceases to burn. Nitro-glycerine may even be burned by means of a cotton wick or a strip of bibulous paper, as oil from a lamp, and as harmlessly. It remains fixed and perfectly unchanged at 212° Fahr.; if heated to about 360°, however, it explodes. It detonates when struck by the blow of a hammer, but only the part struck by the hammer explodes; the surrounding liquid remains unchanged.

As the carriage of nitro-glycerine is dangerous, many trials have been made to render it inexplusive, and to restore its explosiveness with equal readiness. Nobel's method of making it inexplusive is at once simple and effective. It is to mix with it from 5 to 10 per cent. of wood spirit, when all attempts at exploding it are rendered utterly futile. Five per cent. of methyl-alcohol is said to be amply sufficient to transform the nitro-glycerine into the inexplusive or pro-

tested state, but Nobel now always adds 10 per cent. before sending any of his blasting liquid into the market.

The transformation of protected into ordinary nitro-glycerine is effected by thoroughly agitating it with water, and allowing the mixture to settle for a short while. By this means the water dissolves out the methyl-alcohol, and the mixture of spirit and water readily rises to the surface, in virtue of its low specific gravity, and can be removed by means of a siphon, or by simply pouring it off. The blasting liquid is now ready for use. It would seem that the methyl-alcohol is by this means separated very readily from the nitro-glycerine held in solution by it. If protected blasting liquid be kept in a closed vessel, it will remain in that state for an indefinite period of time, and ready at any moment to be reduced or rendered fit for action; if, however, it be exposed in an open vessel, it will regain its explosiveness, in periods of time proportionate to the amount or degree of exposure.

The chief advantage which nitro-glycerine possesses is that it requires a much smaller hole or chamber than gunpowder does, the strength of the latter being scarcely one-tenth that of the former. Hence the miner's work, which, according to the hardness of the rock, represents from five to twenty times the price of gunpowder used, is so short, that the cost of blasting is often reduced to 50 per cent. The process is very easy. If the chamber of the mine present fissures, it must first be lined with clay to make it water-tight. This done, the nitro-glycerine is poured in and water after it, which, being the lighter liquid, remains at the top. A slow match, with a well-charged percussion cap at the end, is then introduced into the nitro-glycerine, or a fuze, to the extremity of which is attached a small quantity of gunpowder, fixed immediately over the liquid. The mine may then be sprung by lighting the match, there being no need of tamping. Experiments were made with this new compound in the open part of the tin mines of Altenburg, in Saxony. In one of these, a chamber, 34 millimètres in diameter, was made perpendicularly in a dolomitic rock, 60 ft. in length, and at a distance of 14 ft. from its extremity, which was nearly vertical. At a depth of 8 ft., a vault filled with clay was found, in consequence of which the bottom of the hole was tamped, leaving a depth of 7 ft. One litre and a half of nitro-glycerine was then poured in; it occupied 5 ft. A match and stopper were then applied as stated, and the mine sprung. The effect was so enormous as to produce a fissure 50 ft. in length, and another of 20 ft. The total effect has not yet been ascertained, because it will require several small blasts to break the blocks that have been partially detached by this.

Nitro-glycerine has, however, one disadvantage. It freezes at a temperature very probably above 92° Fahr., and it is said that even at a temperature of 43° to 46° Fahr. the oil solidifies to an icy mass, which mere friction will cause to explode. It is probable, however, that the freezing-point of the oil lies somewhat lower than is here stated, though as yet no exact determination of the freezing-point of the oil has been made. A newspaper from Hirschberg, in Silesia, gives a sad account of an accident, caused by the frozen oil exploding by friction. Nitro-glycerine was there being used in making a tunnel. It was kept in glass vessels, packed in straw, and placed in baskets, each vessel containing one-fourth to one-eighth of a hundredweight of the oil. For several days the oil had been frozen. It was carefully handled, and pieces were separated by means of a piece of wood, and put into the bore-holes, and it was found that the frozen nitro-glycerine exploded quite as well as the fluid. One day an overseer at the shaft hit upon the unlucky idea of breaking into pieces with a pick a 700 or 800 lb. lump of the frozen glycerine. The blow caused the mass to explode, and the unfortunate man was blown up into the air, and fell back into the shaft, some 40 or 50 ft. deep, whilst two workmen, who were making cartridges a short distance from him, luckily escaped with slight injuries.

Dynamite is made by mixing 75 per cent. of nitro-glycerine with 25 per cent. of powdered sand (silica). It has been introduced by A. Nobel, whose researches on nitro-glycerine are so well known. Dynamite retains all the properties of nitro-glycerine for blasting, but is not dangerous, as it may be handled freely, and does not explode by fire alone or when accidentally subjected to percussion. In some experiments made by the inventor, a box containing about 8 lbs. of dynamite (equal in power to 80 lbs. of powder) was placed over a fire, where it slowly burned away. Another box containing the same quantity was hurled from a height of more than 60 ft. on to a rock below, no explosion ensuing from the concussion sustained. Explosion is produced by means of a percussion cap in the same manner as with nitro-glycerine.

Schwartz's Blasting Gunpowder.—This powder is now much employed in mining. Its combustion is slow but complete. The following analyses show why it is cheaper than ordinary powder:—

	I.	II.
Soluble salts	74.55	74.32
Nitrate of potash	56.22	56.23
Nitrate of soda	18.30	18.09

The treatment by sulphide of carbon produced:—

Dissolved sulphur	9.68	7.61
Carbon remaining	14.14	15.01
Moisture	1.78	11

It is a coarse-grained powder, in which one part of potash nitre is replaced by nitrate of soda.

In the first instance, one part of nitrate of soda for one part of nitrate of potash was used, but it was afterwards found best to employ a third of nitrate of soda. See ARTESIAN WELLS. BATTERY. GUNPOWDER. GUN-COTTON. ORDNANCE. QUARRYING. TELEGRAPHY. TUNNELLING.

BOTTLING MACHINE. FR., *Machine à mettre en bouteilles*; GER., *Pfropfmaschine*; ITAL., *Macchina da topbar bottiglie*.

The bottling machine, shown in Figs. 1211, 1212, is chiefly used for soda and other aerated waters. It was invented by the late Hayward Tyler, and it is on the continuous principle. The

condenser and bottling-piece are shown in section Fig. 1211, to illustrate the internal construction. The same letters of reference refer to the same parts in Figs. 1211, 1212. Fig. 1211 is a side elevation, Fig. 1212 end elevation; one-half of the iron frame is taken away in Fig. 1211 to show

1211.

1212.

more clearly the working parts. is removed for the same reason. *d*, wrought-iron beam, with connecting-rod to crank at one end, and side rods to the pump-piston frame at the other end; *e*, wrought-iron crank-shaft, with fly-wheel and two handles, *s, s*, which are used when hand-power is applied; *f*, brass wheel to work the agitator; *g*, copper solution pan; *h*, regulating cocks for gas and water, one only of which is shown; *i*, gun-metal pump, with separate valves for gas and water in the valve-pieces, which are marked *k k*. The delivery-valve is on the top of the pump; *l*, solid gun-metal piston working underneath the pump; *m*, agitator working inside the condenser to more intimately mix the gas and water together; *n*, bottling-piece fitted with a screw-valve and lever-handle; *o*, bottling nipple; *p p*, copper pipes, tinned inside, one to take the gas and water from the pump to the condenser, the other to convey them from the condenser to the bottling-piece; *q*, safety-valve to relieve the pressure in the condenser, in which there is also a pressure-gauge, not shown in the figures, to indicate the pressure suited to the different aerated waters. *S, S*, are handles for actuating the machine when worked by hand. The gas generator and gasometer, although not shown in Figs. 1211, 1212, are the same in all the machines employed for a similar purpose.

The iron frame on which the whole of the working parts are fixed is removed for the same reason. *References*:—*b*, cast-iron stool for pump; *c*, carriage for condenser;

1213.

W. F. Davidson's bottling machine, Fig. 1213, is arranged so that the liquid to be bottled is

drawn from the barrel M through a suction-pipe K by a piston, a valve L being arranged so as to prevent the return of the liquid. The liquid is let into the bottle *e* from the pump-cylinder A through the valve C, which is operated by means of levers and rods. This valve is closed by means of a spring bar acting automatically. The plunger D is raised as soon as pressure is removed from the treadle *f*; thus giving an intermittent motion the work is continued.

BOTTOMING, OR BALLASTING. FR., *Empierrement*; GER., *Besteinung, Beschotterung*; ITAL., *Imbreviare Inghiaiare*.

See PERMANENT WAY.

BOULDER-PAVING. FR., *Pavé en galet*; GER., *Rollsteinpflaster*; ITAL., *Ciottolato*.

See CONSTRUCTION.

BOULDER - WALLS. FR., *Mur en galet*; GER., *Rollstein Mauerwerk*; ITAL., *Muratura di ciottoli*.

See CONSTRUCTION.

BOUNDARIES. FR., *Limite*; GER., *Grenze*; ITAL., *Confine*.

In making a survey, the boundaries of the counties, parishes, and the several estates, are required to be marked correctly thereon; in ascertaining which, it is generally found necessary to procure the services of parties locally acquainted with the ground to be surveyed.

In the case of property divided by hedge and ditch, the brow of the ditch is generally the boundary; which, of course, forms the line to be measured. In some districts the roots of the quicks, or the foot of the bank, forms it: a width of 15 links is usually allowed for a hedge and ditch, 6 links for ditches between neighbouring estates, and 7 for those nearest roads, that is, from the roots of the quicks. See GEODESY. SURVEYING.

BOW-COMPASS. FR., *Compas à pompe*; GER., *Federzirkel*; ITAL., *Compassino da circoli*.

A pair of compasses for describing small circles with ink, is sometimes called a *bow-compass*. See COMPASSES.

BOW-PEN. FR., *Tire-ligne*; GER., *Reissfeder*; ITAL., *Penna a serbatoio*.

This pen is often termed a *drawing pen*: the part of it which holds the ink is formed of two cheeks which are bowed out towards the middle, and regulated by a screw. See COMPASSES.

BOW-DRILL. FR., *Archelet*; GER., *Drillbogen, Fidelbogen*; ITAL., *Trapano ad archetto*.

See HAND-TOOLS.

BOW-SAW. FR., *Scie à chantourner, scie en archet*; GER., *Schweifsäge*; ITAL., *Seghetto*.

See HAND-TOOLS.

BOX.

A cylindrical, hollow iron, used in wheels, in which the axle revolves, is called an *axle-box*.

A *box-drain* is a term generally applied to a small drain with vertical sides. See DRAINAGE.

BOXING OF A SHUTTER.

The part into which a shutter is folded when not required for use. It is formed by the inside lining of the sash-frame, the grounds of the architrave, and the *back lining*. See SASH-FRAME.

BOYAU. FR., *Boyau*; GER., *Gang des Laufgraben*; ITAL., *Ramo di trinceria*; SPAN., *Ramal*.

Boyaux, or boyaus, are small trenches, or branches of a trench, leading to a magazine, or to any particular point. See FORTIFICATION.

BRACE.

A brace is that part of a piece of framing which is subject to tension or compression, such as the diagonal bars of a Warren girder. It differs from a *strut*, which is subject to compression; or from a *tie*, which is subject to tension only. See BRIDGES.

BRACKET. FR., *Palier, console, tasseau*; GER., *Unterlage, Lager, Consol*; ITAL., *Mensola, Beccatello*.

A bracket is an arm which projects from the face of a wall or post, chiefly used to sustain a shelf, roof, cornice, or other overhanging structure. It is usually supported at the outer end by a strut, as A C, Fig. 1214.

The strain tending to pull the bearer A B out of its socket at B is represented by $W \tan. a$; and that portion of the load which is transmitted to the wall along the strut A C is represented by $\frac{W}{\cos. a}$; W being the

weight assumed to be concentrated at the point A, and a the angle which the strut makes with the wall. When the load is distributed over the bearer A B, the strains on it and on the strut A C will be reduced to one-half. The vertical strain or pressure on the wall or up-

right of the bracket will be equal to the load. A distributed load will cause a transverse strain on the bearer itself, in the same manner as a beam supported at both ends, or supported at one end and fixed at the other, as the case may be. In a solid bracket, or one of ornamental shape, as Fig. 1215, the strain at B is all that is usually required, and may be ascertained on the prin-

ciple of the lever. It will equal $\frac{W \times AB}{BC}$ for a load concentrated at A, and one-half that quantity when the load is distributed. See **STRENGTH OF MATERIALS**.

In large cornices, to save plaster it is usual to fix to the wall and ceiling, at intervals of 12 or 14 in., brackets cut roughly to the outline of the intended cornice; to these, laths are nailed, to take the plaster of the cornice. The brackets in the angles are called *angle-brackets*.

The term *bracket* is also applied to a projecting arm which carries on its end a gas-burner. Pieces of wood fixed on the end of the tread of stairs over the outer string-board are called *brackets*; they are sometimes made ornamental, in which case they are called *wrought* or *fancy brackets*; in other cases they are known as *cut brackets*. Brackets in stone are usually called *corbels*.

BRAKE, or BREAK. FR., *Frein*; GER., *Bremse*; ITAL., *Freno*.

A piece of mechanism for retarding or stopping motion by friction, as of a carriage or railway, by the pressure of rubbers against the wheels. In Fig. 1216 the hand-wheel on the spindle A, which is fastened to the platform R of the car, winds up the chain F, and pulls the lever B, which presses the brake-block H upon the wheel G, and pulls the rod S, which presses the brake-block upon the wheel D, and pulls the rod E, which runs to the next truck, where there is a duplicate of the arrangement, shown in Fig. 1216. Thus, turning the brake-wheel at either end of the car brings an equal pressure upon all the wheels.

Fig. 1217 shows a railroad car brake, invented by A. J. Ambler; it belongs to that class of railroad brakes in which a tensional chain, or rods and chains, are used for operating or applying power from the locomotive to the brakes of a train of cars.

1217.

This arrangement of Ambler consists of fixed and sliding sheaves E, E, in connection with a tensional chain F, and brake-chain G; so that by operating the tensional chain F a movement will be imparted to the brake-chain G, to set or apply the brakes D, D. The slack of the tensional chain F will be taken up by the falling of the sliding sheaves E, E, when the power is removed from the chain F. The power of the brakes is limited and controlled by limiting the rising and falling movement of the sheaves E, E, by having the axes *b* of the sheaves fitted into slots *a* in the bars D' D'. The sheaves C', C', are stationary.

The number of brake carriages or vans to a given train will depend on the inclinations on the line and the speeds employed: with passenger trains it has been considered that on an average, and to ensure safety, every fifth carriage should have a brake: the engine also is generally reversed to assist the brakes. It must be recollected, however, that by stopping a train too rapidly, great injury results both to the permanent way and the rolling stock. But still it is very important that those who have charge of a train should be able to stop it within a very short distance, when there is risk of collision, or any other danger is apprehended; and the greater the number of wheels to which brakes are applied, the more speedily will the effect be produced.

The following considerations appear to be those which would determine the amount of brake-power.

The forces which act on the train after the steam has been shut off are the axle friction and rolling friction of the train, and the pressure of the wind: the friction tends gradually to bring the train to rest,—the pressure of the wind to accelerate or retard it, as the case may be, and this will therefore be omitted from the conclusions to be drawn.

To stop a train rapidly, brakes are applied to some of the wheels, and the engine is reversed. The application of brakes prevents the wheels from revolving, and introduces the friction due to the weights on the wheels to which the brakes are applied. The act of reversing the engine does not immediately stop the forward motion of the driving-wheel, but forces it to revolve at a somewhat slower rate than that due to the speed of the train, and thus causes a friction of surfaces to take place between the wheel and rail.

The axle and rolling friction of the train may be assumed to be some proportion of the total weight of the train; the friction of the wheels to which brakes are applied may be taken as some proportion of the insistent weights; from experiments, it appears that the axle and rolling friction may be taken at $\frac{1}{33\frac{1}{3}}$ part of the weight of the train, and the friction due to the brakes at about $\frac{1}{2}$ of the weights on them.

Hence, if l represent the gross load of the train,

w " the weights on the wheels to which brakes are applied,

R " the retardation in feet per second,

g " the force of gravity,

and, if the train be on an incline,

$\frac{1}{p}$ represent the slope of such incline,

$$R = \left(\frac{l - w}{334} + \frac{w}{8} \pm \frac{l}{p} \right) \frac{g}{l},$$

the latter term being used with the negative sign when the train is descending, and the positive sign when ascending, the gradient.

If S = space traversed by train in coming to rest,

v = velocity in feet per second at the moment the steam is shut off and the brakes applied,

$$S = \frac{v^2}{2R}.$$

It should be observed that these estimates and formulas, although empirical, may be found useful in forming rough estimates; and that, in estimating practically the space of time which should be required for a train to stop in, one or two seconds should be allowed for time lost in applying the brakes. These combinations will be referred to presently.

Speaking in general terms, a brake consists of one or several segments of wood or metal, which can be pressed upon the circumference of a wheel, so as to produce friction, which, acting as a resistance, reduces the velocity of that wheel. Fig. 1218 represents a brake so constructed; the wooden blocks a, a, a, a , are connected by two straps of iron, movable round a fixed point O ; the ends A and B of these two straps are fastened to the bell-crank ACB . As none of the centres of motion, A, B, C , are fixed, the arms AC, CB , have the power of a toggle-joint. If the handle M of the bell-crank is moved in the direction indicated by the arrow, the blocks are forced to press upon the rim of the wheel, and friction is thus produced, which diminishes the velocity of the wheel which is supposed to be in motion. In order to distribute the pressure over a large surface, so that the materials in contact be not altered, the brake should necessarily embrace a sufficient part of the circle. Cranes, and generally all machines for lifting and lowering weights by means of handles, are provided with a brake acting upon a special wheel which influences the movement of the chain barrel.

1218.

Also trains of great velocity are either stopped on inclines or their motion is retarded on railroads, as is well known, by applying a brake to the carriages. The brakes of common carriages are wooden blocks placed near the back wheels; by means of a handle and a screw, acting upon a system of levers, the blocks are pressed upon the rims of these wheels. These brakes are substituted with advantage for the ancient wooden shoe or sabot, which is still used by carters or wagoners; the use of that shoe is to prevent the wheel from turning, and it transforms the rolling friction into a sliding friction, which is much more considerable; it produces thus a resistance which tends to diminish the velocity of the carriage and to prevent its acceleration in descending inclines. But the use of the shoe is very inconvenient, and serious accidents may happen if the chain, which holds the sabot or shoe, breaks. The brake acts in a more gradual manner, and its use is handier and safer.

In railway trains the brakes act simultaneously upon all wheels of the same carriage. Various constructions have been adopted for that purpose. Fig. 1219 shows one of the earliest, as used on the Versailles railway. The equal segments aa', bb', cc', dd' , are placed at a little distance before and behind each wheel; they are suspended from the frame of the carriage by rods moving round fixed points. The levers mp and np , jointed to the middle of the arcs bb' and cc' , are connected at p with a vertical rod pq , which has a screw at its end, and is raised or lowered by means of the nut e . The raising of the point p brings the points m and n nearer to the wheels, with the power of a toggle-joint, and the arcs bb' and cc' are pressed against the tires with great force; the same takes place with the arcs aa' and dd' , which are connected with the arcs bb' and cc' by means of the coupling-rods ac and $b'd'$; in this manner four arcs or blocks press upon the wheels at the same time. The blocks are either made of wood and hooped with iron, or they

1219.

1220.

are made entirely of iron. Fig. 1220 represents a brake operated by compound levers: in general, this latter principle of construction is adopted.

The two brake-blocks S and S' , Fig. 1220, are connected with two equal levers AB and $A'B'$,

which are again fastened to a third lever B'BC, movable round a shaft O. The rod CD connects the end C of the lever B'BC with the nut DD', which is moved backwards and forwards by the screw V; this screw, which can only move round its axis, but not in a longitudinal direction, is turned by wheel-gearing from the box of the guard or brakes-man. Therefore, by turning the brake-wheel to the right, the nut DD' advances to the right and pulls the points C and B into the same direction, whilst the point B' is pushed into the opposite direction, and the brake-blocks are consequently pressed upon the tires of the wheels. The coupling-rod C'D', jointed at D', produces an analogous effect upon the following wheels. The reverse takes place if the brake-wheel be turned in the opposite direction; that is, the blocks S, S', are then removed from the wheels.

In order to bring the brake into full action a certain time is always required, and numerous constructions have been adopted for shortening this time as much as possible. One method is that of employing a weight of an oblong form with a rack and pinion on its longest vertical side: this weight moves between guides in a vertical direction, and is kept in its place by means of a click or spring. As soon as the guard removes the click or eases the spring, the weight falls, and turning the pinion rapidly round its horizontal axis, transfers the motion to the brake-blocks, which act in the manner previously described. By means of a handle the pinion is turned in the opposite direction, the weight is raised, and again fastened in its former position. It will be seen that the action of the brake under these circumstances must be very rapid, and a train can be stopped in a very short time.

But the advantages of this very great rapidity should not be exaggerated; a train should not be stopped instantaneously. To stop quickly is equal to a sudden shock against an obstacle, and might produce serious accidents. M. Gentil, mining engineer, has compared that shock with the one which the train would sustain by falling vertically from a certain height: the following Table gives the results of his researches:—

Trains.	Speed an hour, in kilo- mètres.	Speed a second, in mètres.	Height of Fall, in mètres.	Comparison.	Remarks.
	kilos.	m.	m.		
Goods train ..	25	6·94	2·456	Ground floor	The consequences of the shock of an express train suddenly stopped, would be the same as if that train had fallen from a fourth floor, or from a height of 46 ft.
Mixed	30	8·33	3·533	1st "	
Passenger ..	40	11·11	6·293	2nd "	
Mail	50	13·88	9·825	3rd "	
Express	60	16·66	14·159	4th "	

The law in France demands one brake-van to seven carriages or less; two brake-vans if the number of carriages varies between seven and fifteen; three brake-vans for a train of more than fifteen carriages; the tender-brakes are not included in that number.

On the Turin-Genoa railway one brake-van to two carriages of a passenger train is allowed; and three wagons of a goods train to a brake-van.

In Prussia $\frac{1}{3}$ of the total number of wheels of a passenger train, and $\frac{1}{5}$ of the wheels of a goods train, have to be provided with brakes, if the inclination of the line is not more than 0^m·0033 the mètré. For an inclination between 0^m·0033 and 0^m·005, $\frac{1}{5}$ and $\frac{1}{3}$ have to be substituted for these fractions, and $\frac{1}{3}$ and $\frac{1}{5}$ for an inclination between 0^m·005 and 0^m·010.

Figs. 1221 to 1224 represent the arrangement of Stilmant's brake.

It is apparent from these figures that the horizontal shaft *a*, supported by the brackets *i i*, is moved by means of a long lever *b*, which is connected at its end, by the two rods *c c*, with the nut *d*; this nut being raised or lowered by the spindle *g*, transfers thus its motion, not only to the lever *b* and the shaft *a*, but from there also by means of the forked levers *m, m*, and the rods *n, n*, to the wedges *r r*. These wedges are made of cast iron, and form two symmetrical parts, which are supported by means of a joint or hinge; four sliding parts *o, o*, two of which carry directly the brake-blocks *p, p*, whilst the two others are kept in their respective positions by means of the pressure-rods *s, s*, serving as guides to the wedges.

The greatest angle formed by these sliding parts and the wedges, during the inactivity of the brake, is 23 degrees; at the moment of putting the brake in action this angle becomes less, since the sliding parts are pressed more towards the outside; and at the greatest pressure of the wedges against the sliding parts the angle is about 19 degrees.

The thread of the brake-screw *g* ought to be double, so that the lever *b*, the end of which has to pass through a very considerable arc, can be moved as quickly as possible. The brake-blocks which are not directly fastened to the wedges are kept in their respective positions by means of the suspension-rods *t t*, and the horizontal rods *u u*. The spiral springs *z z* keep the brake-blocks during the inactivity of the brake at a sufficient distance from the tires, and thus prevent any unnecessary friction. The free action of the suspension-springs during the stopping of the wheels has now been obtained simply by bending the sliding parts *o, o*, which serve as guides for the wedges *r r*, to a certain angle, and by making the holes in these sliding parts more oval; the same shape is given to the hole at the lower part of the suspension-rods *t t*, that is to say, where these rods

are fastened to the coupling-rods *s s*, Fig. 1225. The chief centre lines of the holes in the sliding parts form with the side *ab* an angle of 10 or 12 degrees; the diameter of these holes is 41 millimètres, their length 61 millimètres, thus giving to the springs a play of 20 millimètres, sufficient for the oscillations during the running of the wagon.

A few words may be said here with respect to brake-blocks in general, and with respect to iron blocks in particular. Some time ago brake-blocks were made of soft wood, such as elm, beech, poplar, and so on, which is less susceptible to become polished by friction than iron; the rapid wear and tear, however, requiring often and expensive renewing of the blocks, have induced many engineers to substitute metal, and especially iron, in place of wood.

The use of self-acting brakes in engines of Engerth's system requires great care in descending inclines of 8 millimètres near Loxeville. The wooden brake-blocks of the tender catch fire very often, and are entirely destroyed when the train reaches the station. In order to prevent this inconvenience, iron blocks have been substituted for the wooden ones.

The following are the results of that application:—

1. With wooden brake-blocks the wheels of the tender had to be stopped in order to prevent heating and the re-turning of the tires after a run of 9000 kilomètres. Since iron brake-blocks are adopted on some of the French railways, the wheels are allowed to turn slowly in descending inclines; several tenders have already run over 12,000 kilomètres without the tires of the wheels requiring to be cooled.

2. The wear and tear of the iron brake-blocks has been 14 or 15 millimètres for an average distance of 15,000 kilomètres.

Those results have been fully confirmed by the experiments made with Stilmant's brake; and it has since been found that a better retardation of the motion of the train is obtained if the blocks are not pressed upon the wheels during the whole time required for the stopping of a train, but are lifted up and pressed upon again at very short intervals.

It has been, however, observed that the tires of the wheels, especially those of the tender, and the iron brake-blocks used at present, acquire very quickly, not only the shape shown in Fig. 1226, but often deep grooves are cut around the whole circumference of the tires. These grooves are produced either by grains of sand, which find their way between the tires and the brake-blocks, or by impurities of the iron. In order to prevent this disadvantage, M. Stilmant has proposed brake-blocks of cast steel, shown in transverse section, Fig. 1227. The surface of these blocks, which comes in contact with the tires of the wheels, is divided into two equal parts of 32 millimètres width; the central groove has a width of 20 millimètres and a depth of 36 millimètres, which gives sufficient room for a current of air to pass through.

To find by Calculation the Pressure and Power of this Brake.—It will be seen from Fig. 1228 that the brake is composed of a combination of different simple machines, which can act each separately, and transfer the produced effect successively from one upon the other, and accumulate thus a very considerable pressure, which it would be impossible to obtain, under the same conditions, by one or the other of these simple machines alone.

The obtained pressure is very variable, and depends chiefly upon the power exercised by the guard upon the handle or wheel of the screw.

Referring to Fig. 1228, and putting

$R = 0^m \cdot 220$, the length of the handle or the radius of the brake-wheel;

$r = 0^m \cdot 023$, the radius of the brake-screw;

$h = 0^m \cdot 044$, the thread of the screw;

$f = 0 \cdot 08$, the coefficient of friction of the screw; and

$P = 30^k$, the force of the guard on the handle or the wheel;

we get as the work of the screw the pressure $Q = \frac{PR}{r} \times \frac{2\pi r - fh}{h + 2\pi rf}$; the given values being sub-

stituted, we have $Q = \frac{30 \times 0.22}{0.023} \times \frac{2 \times 3.14 \times 0.023 - 0.08 \times 0.044}{0.044 + 2 \times 3.14 \times 0.023 \times 0.08} = 727^k.89$, or about 728 kilogrammes.

The effective weight of the suspension-rods cc = 16^k has to be added to this pressure, so that the total force at the end of the lever b is equal to $Q = P_1 = 728 + 16 = 744$ kilogrammes.

Calling, therefore,

$L = 2^m.065$, the length of the lever b ;

$p = 80^k$, its own weight reduced to the centre of gravity;

$L_1 = 0^m.970$, distance of centre of gravity from the centre of the horizontal shaft;

$l = 0^m.365$, length of the small levers;

$p_1 = 18^k$, weight of the lever reduced to its centre of gravity; and

$l_1 = 0^m.200$, distance of centre of gravity from the centre of the horizontal shaft;

the pressure produced by the lever is equal to $Q_1 = \frac{P_1 L + p L_1 + p_1 l_1}{l}$; or substituting again

the given values, $Q_1 = \frac{744 \times 2.065 + 80 \times 0.97 + 18 \times 0.2}{0.365} = 4431^k.67$, or very nearly 4432 kilogrammes.

Adding again the effective weights of the suspension-rods nn , of the bolts for the joints of the wedges, &c., equal to 53 kilogrammes, we get the total pressure produced upon the wedges,

$$Q_1 = P_2 = 4432 + 53 = 4485 \text{ kilogrammes.}$$

Taking, finally, the angle formed by the two parts of the wedges at the moment the brake is applied, $\alpha = 19^\circ$, therefore $\beta = 80^\circ 30'$, and $f_1 = 0.18$ the coefficient of friction of the wedges, we get altogether the considerable pressure of $Q_2 = \frac{\text{tang. } \beta + 2 f_1 + f_1^2 \text{ tang. } \beta}{2 (1 + f_1 \text{ tang. } \beta)} \times P_2$, or

$$Q_2 = \frac{\text{tang. } 80^\circ 30' + 2 \times 0.18 + 0.18^2 \times \text{tang. } 80^\circ 30'}{2 (1 + 0.18 \times \text{tang. } 80^\circ 30')} \times 4485 = 2.699 \times 4485 = 12105 \text{ kilogrammes,}$$

which gives a pressure upon each brake-block of $\frac{Q_2}{4} = \frac{12105}{4} = 3026$ kilogrammes.

This pressure is considerably increased by the impulse given to the blocks from the wheels as they rotate; according to experiments made with the pressure or coupling rods ss , it can be taken as 4500 or 5000 kilogrammes. Now, if the coefficient of friction of the block be put equal to 0.4, the effort of this friction will be $T = 4500 \times 0.4 = 1800$ kilogrammes, which is much greater than the adhesion of the wheels.

Time required for the Action of the Brake.—Although the stopping of wheels by means of screw-brakes is generally considered a slow operation, yet stopping a train by Stilmant's system is an exception, on account of the rapidity of its action, which is as prompt as in the best constructions, while at the same time it possesses many other advantages. Besides, the small space between the brake-blocks and the tires of the wheels very much facilitates the quick and effective action of Stilmant's brake.

Supposing now that in a well-constructed brake the distance between blocks and tires is equal to $0^m.003$, and taking the play between the axle-boxes and the plates in which they move to equal $0^m.003$, we find:—That the friction between the blocks and the tires of the wheels only commences when the blocks will have passed through a distance of $0^m.003$ (a); and that the braking of the wheels takes place immediately after a distance of $0^m.006$ (which may be less) is passed (b).

It is thus necessary to determine the distance $BB_1 = CC_1$, Fig. 1229, which the wedges have to travel before the blocks touch the wheels.

1229.

For this purpose we find in the triangle EDF , at first, that $E = \frac{\alpha}{2} = 11^\circ 30'$, and $DF = 0^m.003$;

next, that $E = \frac{\alpha}{2} = 9^\circ 30'$, and $DF = 0^m.003$; and consequently (a) for the contact between blocks and tires; $EF = BB_1 = DF \cotang. E$, or $BB_1 = 0.003 \cotang. 11^\circ 30' = 0^m.01472$,

whence the distance travelled by the end of the long lever b , $HK = \frac{0.014 \times 2.065}{0.365} = 0^m.0834$, or the number of revolutions of the handle of wheel, if the thread of the screw is equal $0^m.044$, $n = \frac{0.0834}{0.044} = 1.9$ revolutions. For the stopping of the wheels (b), $EF = BB_1 = DF \cotang. E$, $BB_1 = 0.003 \cotang. 9^\circ 30' = 0^m.01793$, whence the distance travelled by the lever,

$$KJ = \frac{0.01793 \times 2.065}{0.365} = 0^m.1014,$$

and the number of revolutions of the handle or brake-wheel $n = \frac{0.1014}{0.044} = 2.3$. Thus the total distance through which the end of the lever b has to move will be $HJ = 0.0834 + 0.1014 = 0^m.1848$, or $n = \frac{0.1848}{0.044} = 4.2$ revolutions, requiring about 10 or 12 seconds. An express train, running

60 kilometres an hour, or $16^m.66$ a second, can therefore be stopped by means of two of Stilmant's brakes upon a length of less than 500 metres; this result has been corroborated by experiments.

Construction of, and Work done by, the Principal Parts of the Brake.—Amongst the many parts which compose the mechanism of the brake, there is a certain number, the dimensions of which ought to be carefully calculated. These parts are:—The shank of the screw (a); the rods transmitting the pressure of the screw to the lever (b); the main lever (c); the two small levers (d); the brake-shaft (e); and the coupling or pressure rods (f).

Screw of the Stem or Shank of the Brake (a).—Suppose the minimum diameter of the stem of the screw, Fig. 1230, be $0^m.035$, and taking the same values given above, we get $Pr = \frac{R_1 J}{n}$, or sub-

stituting for $\frac{J}{n}$ its value $= \frac{\pi d^3}{16}$, $Pr = \frac{R_1 \pi d^3}{16}$, whence $R_1 = \frac{16 Pr}{\pi d^3}$; or introducing the values, $R_1 = \frac{16 \times 30 \times 0.22}{3.14 \times 0.035^3} = 784400$ kilogrammes, or about 0.800 to the square millimetre. Taking the modulus of elasticity for the torsion, $G = 6600000000$ kilogrammes, we find the angle of torsion, $t = \frac{PrL}{JG}$; or substituting again for J its value $= \frac{\pi d^4}{32} 0.098 d^4$, $t = \frac{PrL}{0.098 d^4 G}$, or

$$t = \frac{30 \times 0.22 \times 1.5}{0.098 \times 0.035^4 \times 6600000000} = 0^o.0102, \text{ that is to say, } 0^o 0' 36'' 7.$$

Rods Transmitting the Pressure to the Lever (b), Fig. 1231.—The pressure which has to be transmitted, as has been shown previously, is equal to 744 kilogrammes; therefore for each pair of rods (there being always two) $\frac{744}{2} = 372$ kilogrammes. We thus obtain $PL^2 = \pi^2 JE$; or substituting

$$\text{for } J \text{ its value } = \frac{b^3 h}{12}, \quad PL^2 = \frac{\pi^2 b^3 h E}{12}, \quad \text{whence } E = \frac{12 PL^2}{\pi^2 b^3 h}.$$

When the corresponding values are introduced, we have

$$E = \frac{12 \times 372 \times 0.9^2}{3.14^2 \times 0.02^3 \times 0.045} = 1018546500 \text{ kilogrammes.}$$

$$\text{Now, } E = \frac{PL}{AE}, \text{ whence } i = \frac{PL}{AE}; \text{ or substituting the values,}$$

$$i = \frac{372 \times 0.9}{0.0009 \times 1018546500} = 0^m.000365.$$

i is the shortening and A the area of the transverse section of the rod.

The Main Lever (c), Fig. 1232.—The force acting at the end of the lever is again, as in the case above, $P = 744$ kilogrammes, besides the weight p of the lever, which acts at its centre of gravity.

The equation for equilibrium will be $(P + \frac{1}{2} p) L = \frac{R J}{n}$; or substituting for $\frac{J}{n}$ its value, we obtain, for the section taken in the central axis, $(P + \frac{1}{2} p) L = \frac{R b (h^3 - h_1^3)}{6 h}$, whence

$$R = \frac{6 h (P + \frac{1}{2} p) L}{b (h^3 - h_1^3)}, \text{ or } R = \frac{6 \times 0.17 \times (744 + 40) \times 2.065}{0.13 \times (0.17^3 - 0.09^3)} = 3036100 \text{ kilogrammes,}$$

say about 3 kilogrammes to a square millimetre; for the section taken before the centre, $(P + \frac{1}{2} p) L = \frac{R b h^2}{6}$, whence $R = \frac{6 L (P + \frac{1}{2} p)}{b h^2}$, or $R = \frac{6 \times 1.98 (744 + 40)}{0.04 \times 0.17^2} = 8057024$ kilogrammes, that is to say, about 8 kilogrammes per square millimetre.

The flexure of the lever is obtained by the formula $f = \frac{4 (P + \frac{1}{2} p) L^3}{E b h^3}$, or

$$f = \frac{4 \times 784 \times 2.065^3}{20000000000 \times 0.04 \times 0.17^3} = 0.007; \text{ say, 7 millimètres.}$$

The Small Levers (d), Fig. 1233.—There are also two of these levers, and they are formed like a fork. The strain upon each of them will be

$$\left[\frac{(P + \frac{1}{2} p) L}{2 l} \right] - \frac{1}{2} p_1 = \left[\frac{(744 + 40) \times 2.065}{2 \times 0.365} \right] - \frac{1}{2} = 2213 \text{ kilogrammes;}$$

and the equation for equilibrium is thus again $(P + \frac{1}{2} p) l = \frac{R J}{n}$; or substituting for $\frac{J}{n}$ its corresponding value, we get, for the section at the centre, $(P + \frac{1}{2} p) l = \frac{R b (h^3 - h_1^3)}{6 h}$, whence

$$R = \frac{(P + \frac{1}{2} p) 6 h l}{b (h^3 - h_1^3)}, \text{ or } R = \frac{(2213 + 4.5) \times 6 \times 0.135 \times 0.365}{0.13 (0.135^3 - 0.085^3)} = 2633000 \text{ kilogrammes, that is}$$

to say, 2.633 to the square millimetre; for the section before the centre, $(P + \frac{1}{2} p) l = \frac{R b h^2}{6}$, whence $R = \frac{(P + \frac{1}{2} p) \times 6 l}{b h^2}$, or $R = \frac{(2213 + 4.5) \times 6 \times 0.298}{0.03 \times 0.13^2} = 7824240$ kilogrammes, or about 8 kilogrammes per square millimetre.

The flexure of these levers will be $f = \frac{(2213 + 4.5) \times 4 \times 0.365^3}{20000000000 \times 0.03 \times 0.135^3} = 0.0003$.

Brake-Shaft (e), Fig. 1234.—The brake-shaft is submitted to two different strains, the one acting by flexure and the other by torsion. The first one is insignificant, and we shall only consider the other.

The moment of torsion for the part l_1 is $M = (P + \frac{1}{2} p) r \frac{l}{L}$, which has to be kept in equilibrium by the moment of resistance, $M = \frac{R_1 J}{n} = \frac{R_1 \pi d^3}{16}$. We get, therefore, $(P + \frac{1}{2} p) r \frac{l}{L} = \frac{R_1 \pi d^3}{16}$, whence $R_1 = \frac{(P + \frac{1}{2} p) 16 r l}{\pi d^3 L}$, or $R_1 = \frac{(744 + 40) \times 16 \times 2.065 \times 0.99}{3.14 \times 0.085^3 \times 1.5} = 8873470$ kilogrammes, or very nearly 9 kilogrammes to the square millimetre.

For the part l of the shaft, the moment of torsion is $M = (P + \frac{1}{2} p) r \frac{l_1}{L}$, therefore, as above, $(P + \frac{1}{2} p) r \frac{l_1}{L} = \frac{R_1 \pi d^3}{16}$, whence $R_1 = \frac{(P + \frac{1}{2} p) 16 r l_1}{\pi d^3 L}$, or

$$R_1 = \frac{(744 + 40) \times 16 \times 2.065 \times 0.51}{3.14 \times 0.085^3 \times 1.5} = 4571180 \text{ kilogrammes,}$$

say 4.5 per square millimetre.

Finally, taking $G = 6600000000$ kilogrammes, we find for the angle of torsion, $t = \frac{(P + \frac{1}{2} p) r l l_1}{J G L} = \frac{(P + \frac{1}{2} p) r l l_1}{0.098 d^4 G L}$, or $t = \frac{(744 + 40) \times 2.065 \times 0.99 \times 0.51}{0.098 \times 0.085^4 \times 6600000000 \times 1.5} = 0.01614$, or about $t = 0^\circ 0' 58''$.

Coupling or Pressure Rods (f), Fig. 1235.—The pressure upon each brake-block has been previously ascertained to be 4500 kilogrammes.

The equation of the equilibrium of these rods is $PL^2 = \pi^2 J E$; or substituting for J its value $= \frac{\pi}{64} d^4 = 0.0491$, we find $PL^2 = \pi^2 0.0491 d^2 E$, whence $E = \frac{PL^2}{\pi^2 0.0491 d^4}$, or

$$E = \frac{4500 \times 2.030}{3.14^2 \times 0.0491 \times 0.055^4} = 2100000000 \text{ kilogrammes.}$$

$$\text{Now, } i = \frac{PL}{AE} = \frac{PL}{\pi^2 \pi E}, \text{ or } = \frac{4500 \times 2.030}{0.0275^2 \times 3.14 \times 2100000000} = 0.0019.$$

In conclusion, we give diagrams representing some of the different types of brake frequently used.

Fig. 1236 shows the arrangement of a brake applied to tenders on the Western Railway of France. This brake shows at the same time with what facility eight brake-blocks may be adopted instead of two.

Fig. 1237 shows the brake for the goods wagons on the Eastern Railway of France.

Fig. 1238, brake as adopted on the Northern Railway. A screw with a thread of only 12 millimetres transfers the pressure directly to the wedges.

Fig. 1239 shows a hand-brake, acting either upon one wheel only, or upon the two wheels at the same time.

The weights of the brakes of these different systems are:—

1. For the brake of the tender, Fig. 1236, with eight brake-blocks, about 800 or 950 kilogrammes, of which 200 kilogrammes are of cast iron.
2. For the same brake with four blocks only, between 700 and 800 kilogrammes, of which about 150 kilogrammes are of cast iron.
3. For the brake of the goods wagons, as shown in Fig. 1237, between 600 and 650 kilogrammes, of which about 90 kilogrammes are of cast iron, and
4. For the hand-brake, Fig. 1239, between 240 and 260 kilogrammes, of which 60 kilogrammes are of cast iron.

Numerous brakes have been invented for stopping railway carriages, but nearly all of them act upon the same general principle, and are simply different methods of pressing blocks of wood against the circumference of the wheel, so as to stop its revolution, and cause the tire to slide upon the rails.

If the wheels are all stopped, the friction of the weight of the carriage sliding upon the rails is the whole amount of braking power that can be obtained by any of the plans; and the different methods used to accomplish this add no power for stopping the carriages, but are only different ways of pressing the brake-blocks against the tires, for the purpose of ensuring greater rapidity, certainty, and uniformity of action, reducing the expenses of repairs, and the jarring on the carriage—or to make the brakes self-acting, or worked in combination.

The principal object to be obtained is to have the blocks always pressed square against the wheels, and with a uniform pressure on all the wheels of the same carriage or wagon; unless this is effected there is great difficulty in stopping the wheels, and much straining is caused upon the carriage. In the earlier brakes the block is suspended by a vertical lever from the frame of the carriage or wagon, as shown in Fig. 1240, the block A being shaped to the circle of the wheel; but the varying height of the frame of the carriage, from the variation in the weight of load acting on the springs, causes much inequality in the fitting of the brake-block to the wheel, from the relative level of the brake-block and the wheel being changed, as shown by the dotted line B B; also, the action of the springs is stopped by the pressure of the brake, causing violent jarring and concussions, injurious both to the carriage and the road, and being very annoying to passengers.

1240.

Hanging Brake.

1241.

Sliding Brake.

The slide-brakes, like those shown in Figs. 1241, 1242, were invented for the purpose of remedying these defects. The relative level of the wheel and the brake-block is preserved unchanged, by the brake-block A sliding horizontally upon a bar B B, which is carried by the axle-boxes at each end, C; a difficulty is experienced, however, in preserving an equal pressure on all the brake-blocks, on account of the unequal wearing of the different bearings.

Davis' brake, Fig. 1242, consists in the arrangement of a series of levers, rods, and springs, which are made to operate upon the brakes; so that when the locomotive ceases to propel the train the brake is applied to the wheels, and released when the locomotive is started. The sliding action is effected by the use of rods *j, k, l, m*, which are thrown into or out of action by the catch *y*. The reciprocating motion is maintained by compound levers acted upon at *x*, and springs placed at *z z*.

All the above brakes have, however, the serious objection that flat places are worn upon the tires of the wheels, by sliding upon the rails; and the wheels consequently become, to a certain degree, polygonal. Any deviation from the circular form of the wheel becomes a serious source of injury both to the rails and the wheel, from the amount of concussions caused by the great velocity of rolling, and the great weight carried; this also causes increased expense in the wear of the tires and rails.

In Lee's brake, Fig. 1243, the wooden brake-block A is made of a triangular form, and is pressed both against the wheel and the rail by the lever B, which is centred upon the nave of the wheel C, by means of a ring or collar fitting in a circular groove cut round the nave; the rubbing

1242.

face of the wood block is shod with copper or iron. The connecting-rods D D have adjusting-screws, to preserve the relative position of the brake-block A and the wheel, as the surface of the block wears away.

The mechanical arrangement of this brake, it will be perceived, does not admit of sufficient pressure being applied against the wheel and the rail to form an efficient brake; but even if the pressure were sufficient to stop the wheel, the same objection would still apply as in the ordinary brake, namely, flat places would be worn on the wheel. This brake was tried on one or two railways, but has not come into use.

Adams's brake, Fig. 1244, consists of a sledge A A sliding upon the rails, upon which the whole weight of the carriage is thrown by lifting the wheels off the rails. The sledge A A is a long piece of iron, with a flange at each end to guide it on the rails, and is suspended by two links B B from the iron bar O C, which is supported by the links D D, and bears against the under-side of the axle-box at each end, E E; the links B B are in the form of a parallel rule, and when they are straightened by the action of the lever, the sledge A A is pressed upon the rails, and lifts up the wheels from their bearing on them. This brake saves the wheels from

Lee's Brake.

being worn flat; but it requires great power to put the whole weight of the carriage upon the sledge, and is consequently slow in action; and there is also an objection to it in having the wheels hanging without any support when the brake is in action. It has not come into use in England, but several brakes on this principle have been used in Belgium for some time previously.

Handley's brake, Fig. 1245. This brake is on the same principle as the ordinary skid used on common roads; the two iron arms A A are carried by the axle B, upon which a brass ring H is fitted,

turning round the axle; and at the end of these arms are fixed the shoes or skids C C, one of which is made to pass under the wheel, whichever way the carriage is running, raising it from the rails by turning the lever round upon the axle. The shoe is made the breadth of the tread of the wheel, without any flange, and the wheel is lifted only about $\frac{1}{8}$ of an in. on the average, so that the flange

of the wheel continues as efficient and secure a guide upon the rails as in the ordinary case of a wheel stopped from revolving by the pressure of a brake-block. The shoe is made in two pieces: the upper one, C, is forged on to the arm A, and the lower piece, D, which forms the skid, is hinged to it at the end. The object of this construction is to prevent the shoe from touching the wheel until it is required to be put in action; the joint opens about $\frac{1}{4}$ of an in., and the shoe falls away from the wheel when it is lifted, being stopped by the bolt E, which limits the extent of its opening; and round this bolt is placed a short spiral spring, to keep the joint open, and prevent it from shaking when the carriage is running.

The wear of the shoe is provided for by inserting two small dove-tailed pieces, F and G, at the points where the wear takes place; these pieces are slightly tapered, and are driven into their places from the inner side, being burred or riveted on the opposite side, where they remain firmly fixed, having no tendency to work loose. The lower piece is of wrought iron, which is found to answer best for the purpose; the upper one, F, which carries the wheel, is of cast iron. It has very little wear upon it, but is changed occasionally for a piece of greater thickness, to allow for the wear of the shoe-plate G, and preserve the total thickness of the shoe, within very little variation, so as to prevent much difference in the height that the wheel is lifted from the rails.

This brake is easily and quickly applied, by means of the lever L acting on the upper arm of the brake K, as the carriage runs upon the shoe when it is pressed under the wheel. The ordinary brake-screw, lever, and cross-shaft, are available for working this brake.

The brake, Figs. 1246, 1247, invented by D. Goodnow, of Albany, U.S., is very ingeniously arranged. The object the inventor had in view was to obviate those accidents that arise from applying the brakes of a railroad car to the outer sides of the four wheels of the truck, by a compact arrangement of the brakes in the centre between the wheels of the trucks, thereby exposing them to less danger of breaking, or their parts becoming detached. This arrangement further consists in so constructing the brake-bars, in combination with the jaw-braces of the trucks, that in case the bars are broken they cannot fall to the track and obstruct the wheels; further, in operating the two brakes conjointly by the direct endwise thrust of a short connecting-bar, both brake-blocks are made to act upon the wheels simultaneously.

The brake-bars F, F, Fig. 1246, extend beyond the jaw-braces *f, f*, to which they are connected by the yokes *i, i*. In Fig. 1247, E represents the position of the plank or *hang-frame* in relation to the brake-bars F, F, and the guide and safety rods *k, k*. How the brake-bars F, F, lever G, G', connecting-bar N, car-bearing E, and truck wheels B, B, are combined and arranged, is clearly shown in Figs. 1246, 1247.

Now we propose to place the subject of this article in a clear light, and in a plain practical form; since it has been handled in an erroneous, an obscure, or a slovenly manner, by most mechanical writers and experimentalists.

A carriage on a level railroad only requires a pressure of about $\frac{1}{300}$ part of the moving weight to give it motion, or from 4 to 8 lbs. a ton. The fraction $\frac{1}{300}$ is called the coefficient of friction; as these coefficients become smaller, the rubbing surfaces become smoother. All constant resistances may be expressed in a similar manner.

The work of every machine is consumed by the work done, or by the useful work, together with the useless work, or the work destroyed by the friction of the parts of the machine. We will here explain one of the most beautiful laws of motion: When the work applied exceeds the work consumed, the redundant work goes to increase the speed of the parts of the machine, and at the same time, like the fly-wheel, acts as a reservoir of work. *This acceleration goes on increasing until the work of the resistances + the useful work = the work applied; and then the motion of the machine becomes uniform.*

For example, in a railroad engine and train, at first the work of the engine exceeds the work of the resistances, and hence the speed of the engine goes on increasing; but, as the speed increases, the work of the resistances also increases, so that ultimately the engine attains a nearly uniform motion, which is called the greatest or maximum speed, and then the work destroyed by the resistances will be exactly equal to the work applied by the moving power. A few simple examples will make this law clear.

Ques.—Required the effective horse-power of a locomotive engine which moves at a steady speed of 23 miles an hour upon a level rail, the weight of the train being 100 tons, and the constant resistances amounting to 5 lbs. a ton?

Put x = the required horse-power.

The work of the engine a minute = $x \times 33000$ units of work.

The resistance = $5 \times 100 = 500$ lbs.

The distance moved a minute = $\frac{23 \times 5280}{60} = 2024$ ft.; or $33\frac{1}{3}$ ft. a second.

Work to overcome the constant resistances, in a minute = $2024 \times 500 = 1012000$ units of work.

But as the speed of the train is uniform, the work of the resistances will be equal to the effective work of the engine:

$$\therefore x \times 33000 = 1012000 \quad \therefore x = \frac{1012000}{33000} = 30.7 \text{ horse-power.}$$

Now suppose the uniform resistances and the power of the locomotive to be removed, then the train would move for a short time with a velocity (v) of $33\frac{1}{3}$ ft. a second, but would come to rest after passing over a space (s) of 7900.888 ft., when opposed by the constant resistance (f) of 500 lbs. on the level rails.

If the constant resistance (f) be 1000 lbs., this train would come to rest when $s = 3950.444$ ft. When $f = 2000$ lbs., then $s = 1975.222$ ft., and so on. The units of work conserved in a body weighing W lbs., moving with a velocity of v ft. a second, is equal to $\frac{W}{g} \times \frac{v^2}{2}$. See Byrne's 'Essential Elements of Practical Mechanics,' p. 97. In this case $g = 32.2$ lbs., the supposed weight of a unit of mass. $\frac{W}{g}$ is termed the mass of a body whose weight is W lbs.

$$\text{Whence } \frac{W}{g} \times \frac{v^2}{2} = \frac{100 \text{ tons} \times 2240}{32.2} \times \frac{(33\frac{1}{3})^2}{2} = 3950444 \text{ units of work;}$$

$$\text{and } fs = 500 \times 7900.888 = 3950444,$$

$$\text{or } fs = 1000 \times 3950.444 = 3950444,$$

$$\text{or } fs = 2000 \times 1975.222 = 3950444, \text{ and so on.}$$

Ques.—What is the rate in miles an hour of a train of 80 tons, drawn by an engine of 70 horse-power, when the constant resistances amount to 8 lbs. a ton?

Call x the uniform speed in miles an hour.

Work used in moving the train x miles = $80 \times 8 \times 5280 \times x$; this is the work done by the engine in an hour. But the work done by the engine in an hour will also be expressed by

$$33000 \times 70 \times 60;$$

$$\therefore 33000 \times 70 \times 60 = 80 \times 8 \times 5280 \times x; \quad \therefore x = \frac{33000 \times 70 \times 60}{80 \times 8 \times 5280} = 48.02 \text{ miles.}$$

When the propelling power ceases to act, and a constant resistance of 11200 lbs. (f) (five tons) is applied, then this train will come to rest after passing over a space (s) of 894 ft. Since the uniform velocity (v) in this case is 60 ft. a second,

$$\therefore \frac{W}{g} \times \frac{v^2}{2} = \frac{80 \times 2240}{32.2} \times \frac{(60)^2}{2} = 10017392 \text{ units of work;}$$

$$\text{but, } fs = 11200 \times 894 = 10012800 \text{ units of work.}$$

Ques.—An engine of 48 horse-power moves with a maximum speed of 33 miles an hour on a level rail; required the gross load of the train, when the constant resistances amount to 6 lbs. a ton?

Let x be the gross weight of the train in tons; then the work consumed an hour in moving the train = $x \times 6 \times 33 \times 5280$.

Work of the engine an hour = $48 \times 33000 \times 60$.

When the speed is uniform or at its maximum, $x \times 6 \times 33 \times 5280 = 48 \times 33000 \times 60$;

$$\therefore x = \frac{48 \times 33000 \times 60}{6 \times 33 \times 5280} = 90\frac{10}{11} \text{ tons.}$$

In this example $fs = 7497307$ units of work = $\frac{W}{g} \times \frac{v^2}{2} = \frac{1000}{11} \times \frac{2240}{32.2} \times \frac{(48.4)^2}{2}$. Hence a constant resistance (f) of 3000 lbs. will bring this train to rest after it has passed over a space (s) of 2469.102 ft., for $fs = 3000 \times 2469.102 = 7407307$ units of work.

Ques.—In what time will an engine of 66 horse-power, moving a train of 200 tons, complete a journey of 100 miles, friction and other constant resistances amounting to 5 lbs. a ton, rails horizontal?

Work expended in moving the train 100 miles = $100 \times 5280 \times 200 \times 5 = 528000000$.

Work of the engine an hour = $33000 \times 66 \times 60 = 130680000$;

$$\frac{528000000}{130680000} = 4.04 \text{ hours.}$$

$$\text{In this case } v = 36.3 \text{ ft. a second, and } \frac{W}{g} = \frac{200 \times 2240}{32.2};$$

$$\therefore fs = \frac{W}{g} \times \frac{v^2}{2} = 9166539 \text{ units of work.}$$

This work is conserved in the train, and exists in the train independent of the power of the engine and of the opposing resistances.

The following summary of experiments made to test the retarding power of different railway

brakes is taken, with some alterations and explanations, from a paper by W. Fairbairn, printed in the 'Proceedings of the Institution of Civil Engineers,' vol. xix. Suppose a train impelled by a locomotive engine until it attains a uniform velocity v in feet a second; that then the brakes are applied, and the train brought to a stand after passing a distance s in feet: it is required to find a measure of the force by which the momentum has been destroyed. Inasmuch as the brakes act by friction, which may be considered, with sufficient accuracy, to be uniform throughout the operation of braking, the train may be assumed to be stopped by a uniformly retarding force acting through the space s . If the retarding force in this case is called f , consisting mainly of the friction of the braked wheels, and, for simplicity, including also the friction of the axles, resistance of the air, and other constant resistances, then

$$f = \frac{v^2}{2s}. \quad [1]$$

But supposing, as is generally the case, that the retarding force of the brakes is proportional to a part of the weight of the train only, that is, that the retarding force generated varies as the weight on the rubbing surfaces, and supposing the brakes to be applied to a few carriages only, putting w for the weight of the brake carriages in tons, and W for the weight of the train, then

$$f_1 = \frac{Wv^2}{2ws}, \quad [2]$$

which gives the retarding force to each unit of mass of the brake carriages.

It will be convenient to reduce this force to terms of weight instead of mass. Call f_2 the retarding force in pounds a ton weight of the brake carriages, then

$$f_2 = f_1 \times \frac{2240}{32 \cdot 19} = 69 \cdot 587 f_1; \quad [3]$$

that is, $f_2 s = \frac{W}{w} \times \frac{2244}{g} \times \frac{v^2}{2} =$ the units of work done in resisting the constant force (f_2) through a space (s); $\frac{gf_2}{2240} s = \frac{W}{w} \times \frac{v^2}{2} = f_1 s$, and $\frac{w}{W} \times \frac{gf_2}{2240} s = \frac{v^2}{2} = fs$. v and s are variables, but W , w , g , are constants.

Again, supposing that, instead of being on a level line, the brakes are applied on an incline. Then the action of gravity will cause the train to go farther, if it is descending the incline, or to stop sooner, if ascending, than if the line was level; and gravity is a uniformly accelerating or retarding force, as the friction of the carriages. Hence the net result in distance and velocity of a train stopped on an incline may be supposed to arise from two forces: f , a retarding force dependent on the friction of the braked wheels; and ϕ , a retarding or accelerating force dependent on gravity, and assisting or opposing the action of f , according as the incline rises or falls; thence

$$f \pm \phi = \frac{v^2}{2s}. \quad [4]$$

Now, the value of ϕ in terms of the inclination θ of the plane to the horizon is known, for if g be the velocity generated by the gravity in one second, $\phi = g \sin. \theta$; or putting z for the vertical height fallen through by the train between the time of applying the brakes and stopping the train, $\phi = g \frac{z}{s}$;

$$\therefore f = \frac{v^2}{2s} \pm g \sin. \theta = \frac{v^2}{2s} \pm g \frac{z}{s};$$

$$\text{or, } f = \frac{\frac{1}{2} v^2 \pm g z}{s}, \quad [5]$$

$$f_1 = \frac{W}{w} \times \frac{\frac{1}{2} v^2 \pm g z}{s}, \quad [6]$$

$$f_2 = \frac{2240}{g} \times \frac{\frac{1}{2} v^2 \pm g z}{s} = 69 \cdot 587 f_1, \quad [7]$$

where the + or - sign is to be adopted, according as the gradient falls or rises.

In the increase of the brake-power of trains, the principles hitherto most successfully employed have been,—first, the use of steam acting direct on the brakes; secondly, the connection of several of the ordinary form of brakes, so as to unite them under the control of a single brakeman; and thirdly, the introduction of brake apparatus connected with the buffers, so as to make the momentum of the train itself available in generating a retarding force.

McConnell's brake, which is applicable only to the engine, consists of two wrought-iron sledges, each 48 in. in length and 4 in. in breadth, and turned up at the ends. These sledges are suspended from the lower side of the fire-box, between the driving and the trailing wheels of the engine. The pressure is placed on them by admitting steam from the boiler into two cylinders, each 9 in. in diameter, placed horizontally, one on each side of the fire-box, above the sledges, and forcing these latter down upon the rails by means of an elbow-joint. The pressure can be applied to either side of the pistons in the cylinders, according as the brakes have to be raised or depressed. The pressure of the sledges upon the rails, calculated from the pressure of the steam in Yolland's trials, would amount to about 6 tons. On the weighing machine, however, the actual pressure was found to vary from 4 tons to 9 tons, or a mean of about 7 tons; and these anomalies Yolland was unable to solve. The principal advantage of this brake appears to be that it is immediately applied without exertion, and is under the control of the engine-driver, who in

most cases is the first to perceive any obstruction on the line. It will be seen, however, that although efficiently generated, the amount of retardation caused by this brake is comparatively small, and, as Colonel Yolland concludes, insufficient to prevent collision in those cases in which its use would be specially desirable.

Newall's and Fay's brakes, which in their present condition are identical in principle, are distinguished from other brakes by this—that two or more carriages, or, if necessary, the whole train, are fitted with brake-blocks, all of which are brought under the direction of one guard by means of a longitudinal shaft, which transfers the motion of the guard's wheel to the brakes throughout the whole length of the train. In this way a great increase of retarding power may be obtained proportional to the weight of the carriages to which brakes are applied, and with this further advantage, that the retarding force is distributed equally throughout the train, instead of being accumulated at either end, and thus the shock upon the wheels and axles is much diminished. Newall and Fay have also adopted a partially self-acting apparatus of springs, by means of which the brakes are applied throughout the length of the train on the simple release of a catch by a guard.

In Newall's brake, the motion of the guard's or the engine-driver's wheel, since either or both of these may have the control of the brakes, is transferred, through the medium of a short vertical shaft in the van or tender, to the longitudinal shaft placed beneath the carriages of the train, by a pair of bevel-wheels, or by a spur-wheel and pinion. The longitudinal shaft passes either beneath the centre or at one side of the carriage, under the framework; and it is connected by simple, but very effective, jointed couplings between each pair of carriages, so as to permit the free action of the buffers, and the rise and fall of the carriages with the inequalities of the line. Near to the middle of the carriage a bevel-wheel is fixed on the longitudinal shaft, which is toothed into a similar one on a short cross-shaft, carrying also a spur-pinion geared into a horizontal rack. Thus, on revolving the guard's wheel, this rack is drawn back, withdrawing at the same time the principal arm of the rocking-shaft, at the centre of the carriage, and compressing a spring placed on the other side, to both of which the rack is attached by a simple connecting-rod. In this position the brake-blocks are off the wheels, and the brake is ready for use. If the bevel-wheel or pinion in the guard's van, or tender, is now released, or lifted out of gear by a lever or treadle, the springs throughout the train will force back the arm of the rocking-shaft, which carries the levers that press the brake-blocks on the wheels. If it is required to put on the brakes harder, and to skid the wheels, the treadle is again released by the guard, and the pressure increased by revolving the wheel in the ordinary way. In other words, Newall and Fay provide a number of springs, or in some cases weights, under each carriage, in which is stored up, ready for instantaneous use, a stock of brake-power, derived from the one guard acting through a longitudinal shaft, communicating with every brake by means of an arrangement of spur-wheels and pinions. From this it will be seen that on any emergency the retarding force may be instantly employed by simply releasing a catch, which permits the brake-blocks to be forced upon the wheels by the springs throughout the train.

In the class of brakes in which greater retarding power is obtained by increasing the number of braked carriages and combining their action, the systems just described appear the best and most comprehensive hitherto adopted. Fairbairn mentions that he received from E. W. Watkin the details of some experiments on an auxiliary brake carriage designed upon a different plan. In this case, an ordinary brake arrangement is employed, with a double elbow-joint, to which a long vertical lever is attached, moving in an arc against the side of the van. A rope from the end of this lever is conveyed to the tender, or the guard's van, and is attached to a drum on the axis of the ordinary guard's wheel. Hence, when the guard or the fireman revolves his wheel to put on his own brake, the rope coils upon the drum, drawing back the lever, and thus putting on the auxiliary brakes at the same time.

Belonging to the third class of brakes before enumerated, in which the momentum of the train itself is employed in generating the retarding force, there is only the brake of M. Guérin, which is entirely self-acting, and is brought into use by the recoil of the buffer-rods, when, by the application of the tender-brake, a retardation has been caused in front. Yolland thus describes this brake:—The buffer-rods at the after end of the carriage abut against a spring that extends across its width; one buffer-rod acting against each end of the spring. This spring, instead of being fixed against the under-framing of the carriage or the brake-van, is movable in a groove. On one side the centre of the spring is secured to the draw-bar, and on the other it is attached to the arm of a short lever, fixed almost vertically over the rocking-shaft; so that when the buffers are pressed in by the sudden check to the velocity—caused by shutting off the steam, by the application of the tender-brake in front, and by the momentum of the train in the rear—the buffer-spring is carried forcibly against the lever, the rocking-shaft is turned, and the brake-blocks are forced against the peripheries of the wheels. The brakes are prevented from being put on when a train is required to be shunted, by a cross-head or stop. But this provision interferes with the application of the brakes when the train is in motion at a low velocity. For such a speed it is assumed the tender-brake will be sufficient.

These are the brakes upon which the experiments were made, and the results tabulated and classified.

Newall's and Fay's Continuous Brakes.—In carrying out the views of the Directors of the Lancashire and Yorkshire Railway, Fairbairn arranged, in the first place, for a series of experiments on the Oldham incline, where two similar trains of carriages, one fitted throughout with Newall's and the other with Fay's brakes, were started alternately. After passing over a measured distance by the action of gravity, the brakes were applied, and the distance within which the trains were respectively brought up was carefully ascertained, as giving the measure of the brake-power of the trains. Each train consisted of three weighted carriages, and they were started by simply releasing a stop. Having descended, by gravity, a previously-measured distance,

with a uniformly accelerated velocity, they passed over a *fog-signal*, which gave notice to the guard to put on the brakes. Then the train having been brought to a stand, the distance from the point at which the train stopped to the *fog-signal* was measured back, and the train was dragged up the incline for another trial. Unfortunately, the day on which these experiments were made proved misty and foggy, with rain at intervals, so that the rails were in the worst condition for facilitating the stopping of the trains. The significance of this fact will be seen on comparing these results with later ones obtained in dry weather.

TABLE I.—EXPERIMENTS WITH NEWALL'S AND FAY'S RAILWAY BRAKES ON THE OLDHAM INCLINE, FEBRUARY 6, 1859.

Weather foggy and wet; gradient falling 1 in 27; weight of trains, 26 tons 10 cwt. each; no engine attached.

FAY'S FLAP-BRAKES.					NEWALL'S SLIDE-BRAKES.				
No.	Time of Running.		Distance Run.		No.	Time of Running.		Distance Run.

	seconds.	seconds.	yards.	yards.		seconds.	seconds.	yards.	yards.
1	35	..	150	153	1	35	14	150	281
2	40	13	200	250	2	40	16	200	336
3	48	14	300	360	3	48	17	300	459
4	58	15	400	499	4	56	25	400	608
5	59	12	400	326	5	56	14	400	371
6	62	25	500	739	6	62	19	500	663
7	72	17	600	575	7	68	17	600	545
..	..	..	..	..	8	63	32	500	798

In experiment No. 8 the self-acting part of the brake only was employed.

In these experiments the whole of the wheels were sledged, or skidded, before the train was stopped. The self-acting arrangement of springs was fitted to Newall's carriage alone. In the later experiments it was adopted also by Fay.

Taking the mean of the number of seconds required in braking each train, in experiments Nos. 2, 3, 4, 5, 6, and 7, which were made under precisely corresponding circumstances in the case of each brake, and at similar velocities, it is found that the train was brought to a stand:—By Newall's brake, in 2·16 seconds; by Fay's brake, in 19·2 seconds; or about 2½ seconds of time in favour of Fay's.

It will, however, be advisable to ascertain the precise value of the retarding force in each case by the formulæ already given. To effect this, the initial velocity of the train at the instant of applying the brakes must first be ascertained. For this purpose the least objectionable formula and at the same time the most simple is

$$v = \frac{2s}{t} \quad [8]$$

for taking the mean velocity between 0, and $v = \frac{v}{2}$ and $\frac{v}{2}$ multiplied by t second = the distance

s ; $\therefore \frac{v}{2} \times t = s$; where v is the velocity in feet per second; s is the distance run, in feet; and t is the time of running, in seconds. From this formula the following initial velocities of the train, in feet per second, in the preceding experiments, are obtained:—

No.	Fay.	Newall.	No.	Fay.	Newall.
1	25·71	25·71	5	40·66	42·85
2	30	30	6	48·38	48·38
3	37·50	37·50	7	50	52·94
4	41·37	42·85	8	—	47·61

Hence, by equation [6], since in this case $\frac{W}{w} = \frac{26 \cdot 5}{26 \cdot 5} = 1$, and therefore $f = f_1$, and $f_1 = \frac{\frac{1}{2} v^2 + g z}{s}$, the relative values of each description of brake, and their comparative efficiency in each trial, may be derived. The retarding force of each brake is found to be as follows:—

No.	Fay.	Newall.
1	1·9115	1·3246
2	1·7922	1·6388
3	1·8432	1·7030
4	1·7645	1·6946
5	2·0280	2·0152
6	1·7205	1·7811
7	1·9167	2·0480
Mean 1·8538.		Mean 1·7436.

Giving, as in the previous comparison, the advantage to Fay, in the proportion of 1·8538 to 1·7436, or as 1051 to 1000. The entire agreement of the results among themselves, and with the preceding comparison derived from the time, is sufficient evidence of the practical accuracy of the formula of reduction. The brakes stand, in these experiments, very nearly on an equality of merit.

The experiments in the next Table were made at Southport, upon a line more nearly level. The speed was obtained by means of a locomotive engine, which was detached, at the instant of applying the brakes, by a slip-coupling. The velocity, which was maintained uniform over the last half-mile, was measured by noting the time required to pass two fog-signals, placed half a mile apart. The brakes, in every trial, were applied almost instantaneously, after the report of the second fog-signal, and the distance was measured after the train had come to a state of rest.

TABLE II.—EXPERIMENTS WITH NEWALL'S AND FAY'S RAILWAY BRAKES, ON THE LINE BETWEEN LIVERPOOL AND SOUTHPORT, JANUARY 7, 1859. *

Weather fine and frosty; gradient rising 1 in 485; weight of trains, 26 tons 10 cwt. each.

FAY.					NEWALL.				
No.	Time of Running $\frac{1}{2}$ Mile, in Seconds.	Speed, in Miles an Hour.	Velocity, in Feet, a Second.	Distance of Pulling up, in Yards.	No.	Time of Running $\frac{1}{2}$ Mile, in Seconds.	Speed, in Miles an Hour.	Velocity, in Feet a Second.	Distance of Pulling up, in Yards.
1	42	42·85	62·86	184	1	31	58·06	85·16	240
2	40	45·	66·	206	2	30	60·	88·	Lost,
3	34	52·94	77·65	272	as also another experiment.				
4	31½	37·14	83·81	313	Engine alone }	30	60·	88·	960
5	30	60·	88·	329					

The second experiment with Newall's brakes failed, in consequence of the guard applying the brakes too soon; and a third was lost from the fracture of the slip-coupling.

When these results are reduced by the same formula, the following values of f_1 , representing the efficiency, or retarding force of each brake, are obtained:—

No.	Fay.	Newall.
1	3·5125	4·97
2	3·4579	
3	3·6274	
4	3·6738	
5	3·8566	
Mean 3·6256.		

These experiments give a superiority in favour of Newall's brakes, in the proportion of 4·97 to 3·6256, or as 1378 to 1000.

The value of the retarding force, f , for the tender-brake, derived from the last experiment, is 1·2791, and reducing this, in proportion of the weight of the tender to the weight of the engine and tender, it becomes $f_1 = 4·3455$.

At this period, Fay requested permission to attach a self-acting apparatus to his brakes, as he considered they were not fairly matched against those of Newall, when applied by hand. The experiments were, therefore, postponed for two months, to enable Fay to effect this alteration. They were again resumed on the 14th of April, 1859.

TABLE III.—EXPERIMENTS WITH NEWALL'S AND FAY'S RAILWAY BRAKES, ON THE LINE BETWEEN LIVERPOOL AND SOUTHPORT, APRIL 14, 1859.

Weather, dry during the first, with a slight shower during the remaining experiments; gradient falling 1 in 3453; weight of trains, 27 tons 6 cwt.

FAY.					NEWALL.				
No.	Time of Running $\frac{1}{2}$ Mile, in Seconds.	Speed, in Miles an Hour.	Velocity, in Feet a Second.	Distance of Pulling up, in Yards.	No.	Time of Running $\frac{1}{2}$ Mile, in Seconds.	Speed, in Miles an Hour.	Velocity, in Feet a Second.	Distance of Pulling up, in Yards.
1	56½*	31·8	46·7	121½	1	58	31·	45·5	101
2	53½	33·4	49·1	124	..	..	..	..	..

* Engine attached and tender-brake applied.

Reducing the results, as before: $f_1 = 3·2329$ with Fay's brake; $f_1 = 3·4161$ with Newall's brake; $f_1 = 2·9956$ with Fay's brake and tender-brake.

Here the superiority lies with Newall, in the ratio of 1056 to 1000. The experiment with the engine attached, when reduced in the ratio of the weight of the train to the weight on the wheels braked, gives $f_1 = 4·84$.

It will be observed that as the value of the retarding force of the brakes is here obtained in

terms of the coefficient of friction, for the rubbing surfaces, the efficiency of the brake varies with the condition of the weather. Thus the mean of the Oldham experiments gave a retarding force of 1·7987 ft. per second; the mean of the first experiments at Southport gave 4·2978, and the mean of the second 3·3245. On each day the experiments were consistent with one another, but they differed widely, on different days, from the change in the condition of the rubbing surfaces. At Oldham, the experiments were made with the rails in a greasy condition, from fog; at Southport, in the later of the two trials, with the rails slightly wet, and in the earlier, with rails dry, and in the best condition for braking. This is in accordance with the experiments of Morin on the friction of iron on iron, in which it was found that the coefficient of friction varied from 0·05 to 0·3, according as the surfaces were greasy, wet, or dry. This consideration must be borne in mind in estimating the results; and together with some improvements in the adjustment of the brakes, and the introduction of increased power, from time to time, will explain the discrepancies which may be found, on comparing the results obtained at different periods of the trials.

The remaining experiments upon the self-acting brakes were all made under uniform and favourable conditions; the weather was fine, and the wind blew each day from the west or the north-west. The results, also, are uniform for these days, and there can, therefore, be no error in placing these experiments in the same Tables, and averaging them together. This classification will, therefore, be adopted as more convenient, and they will be arranged under the following heads:—

1. Experiments on the friction of the carriages.
2. Experiments with slide-brakes, with the engine detached.
3. Experiments with flap-brakes, with the engine detached.
4. Experiments with the engine attached to the train.

Experiments on the Friction of the Carriages.—These experiments were made by running the train, as before, past two fog-signals, half a mile apart, to obtain the velocity, detaching the engine at the second fog-signal, and allowing the train gradually to come to rest.

TABLE IV.—EXPERIMENTS WITH NEWALL'S AND FAY'S RAILWAY BRAKES, ON THE LINE BETWEEN LIVERPOOL AND SOUTHPORT, JUNE 2, 1859.

	Time of Running $\frac{1}{2}$ Mile, in Seconds.	Speed, in Miles an Hour.	Distance run, after applying Brakes, in Yards	Time of Running, after applying Brakes, in Seconds.	Height fallen through by Train from inclination of Line, in Feet.
Fay	40·	45·	4840	430	7·06
Newall	44·5	40·45	6380	780	13·91

Reducing as before, the normal friction of the carriages, $f = f_1$, is found to be,—Fay, 0·16565; Newall, 0·10961: and therefore f_2 , or the friction per ton weight of the carriages, is,—Fay, 11·527 lbs.; Newall, 7·627 lbs.; mean, 9·577 lbs.

This shows that there is a considerable difference between the friction of the two sets of carriages; and a small correction should therefore be made, in the reductions of the experiments on brakes, in favour of Newall, if perfect accuracy were required. The correction, however, does not exceed one-sixtieth of the retarding force of the brakes, and may be neglected without appreciable error. These experiments were made with carriages fitted with slide-brakes, and the friction of those with flap-brakes was not determined.

In an experiment recorded in Yolland's Report, the friction, derived in the same way, for a train of carriages fitted with Newall's brakes, and attached to an engine and tender, amounted to 11·4 lbs. per ton. This, when allowance is made for the greater friction of the engine, nearly agrees with Fairbairn's results.

* Self-action only.

† Brakes not applied at the proper time.

‡ Train consisting of two carriages, and weighing 13 tons 4 cwt. In the other experiments there were three carriages, weighing 27 tons 6 cwt.

Experiments with Slide-Brakes, with the Engine detached from the Train.—The following experiments were made between the Birkdale and Amsdale stations, on the line between Liverpool and Southport. As before, the engine was attached by a slip-coupling to the train. At the quarter and the three-quarter mile posts from Amsdale, fog-signals were placed, and the time of passing between these, being accurately observed by stop-watches, gave the average speed of the train. At the second fog-signal, the slip-coupling was unfastened, and the brakes applied, instantly on hearing the report. The assistant, Unwin, and other persons, were placed in the guard's van, to prevent the premature application of the brakes; and others on the engine with the driver, to see that there was no change of velocity in passing over the half-mile in which the speed was observed. The line where these experiments took place rose, for 500 ft. from the first fog-signal, with a gradient of 1 in 1087, and then fell for upwards of a mile, with a gradient of 1 in 3543, a fall so slight, in the short space in which the trains were brought to rest, that it cannot appreciably affect the results; and in the reductions the line has been considered as level.

The trains with which these experiments were made consisted of three heavily-weighted carriages, each with brakes to every carriage, except in the two last experiments, when, in consequence of an accident to one of Newall's carriages, the trains were reduced to two. The carriages were loaded with iron rail-chairs, so as to weigh 9 tons 2 cwt. each.

The power of these continuous brakes was well exemplified upon the 18th May, when Fay's guard inadvertently applied the brakes whilst the train was running at a comparatively slow velocity; the strong coupling-hook which united the tender to the guard's van was instantly snapped, and the train brought to a stand.

Making a reduction of the preceding results, the following values of $f = f_1$, representing the comparative retarding powers of the brakes in each case, are arrived at:—

Fay.		Newall.	
7·9749	} Mean 6·7030.	6·7765	} Mean 5·4984.
7·0512		6·2813	
6·9480		5·0810	
7·4074		5·4292	
6·5979		4·8929	
5·3076		4·6625	
6·3062		5·2385	
6·0311		5·5555	

In this case the brakes of Fay exhibit a superiority in the ratio of 6·7030 to 5·4984, or as 1215 to 1000; or making a correction, as above stated, for the friction of the carriages, the relative efficiency of Fay's and Newall's brakes would stand in the ratio of 6·553 to 5·4084, or as 1210 to 1000.

Experiments with Flap-Brakes, with the Engine detached.—These experiments, Table VI., were made in precisely the same manner as the last, the trains consisting of three carriages with brakes to each, loaded to 9 tons 2 cwt.

TABLE VI.—FLAP-BRAKES, ENGINE DETACHED.

FAY.					NEWALL.				
No.	Time of Running ½ Mile, in Seconds.	Speed, in Miles an Hour.	Velocity, in Feet a Second.	Distance of Pulling up, in Yards.	No.	Time of Running ½ Mile, in Seconds.	Speed, in Miles an Hour.	Velocity, in Feet a Second.	Distance of Pulling up, in Yards.
1	35	51·43	75·43	158½	1	36	50·	73·33	132½
2	35	51·43	75·43	162½	2	36	50·	73·33	123
3*	32	54·54	80·	184	3*	35	51·43	75·43	192

* Self-action only.

Reducing the results, the comparative efficiency is:—

Fay.		Newall.	
5·9889	} Mean 5·8718.	6·7560	} Mean 6·3272.
5·8294		7·2870	
5·7971		4·9387	

In this case the superiority lies with Newall, in the ratio of 6·3272 to 5·8718, or as 1000 to 928.

Experiments with the Engine attached to the Train.—These experiments were made with slide-brakes, upon the same ground and in the same manner as the last experiments. The rails also were in the same dry condition. The only difference was that the engine and tender remained attached to the train, instead of being uncoupled, and the tender-brake was applied as rapidly as possible along with the other brakes.

TABLE VII.—EXPERIMENTS WITH NEWALL'S AND FAY'S RAILWAY BRAKES, WITH ENGINE NOT DISCONNECTED FROM TRAIN.

Weight of engine, 24 tons; weight of tender, average 10 tons; weight of train, $27\frac{1}{2}$ tons; weight of tank engine, 30 tons.

FAY.					NEWALL.				
No.	Time of Running $\frac{1}{2}$ Mile, in Seconds.	Speed, in Miles an Hour.	Velocity, in Feet a Second.	Distance of Pulling up, in Yards.	No.	Time of Running $\frac{1}{2}$ Mile, in Seconds.	Speed, in Miles an Hour.	Velocity, in Feet a Second.	Distance of Pulling up, in Yards.
1	56 $\frac{1}{2}$	31·8	46·7	121 $\frac{1}{2}$	1	53	33·96	49·81	124 $\frac{1}{2}$

4*	35	51·43	75·43	274	..	..	..	..	..

* Tank engine.

Reducing these results, the comparative retarding force is found to be:—

Fay.		Newall.
2·9956	} Mean 3·0934.	3·3169
3·0184		2·9160
3·2663		2·8422
		} Mean 3·0250.

where the efficiency of the brakes is almost identical. Fay having an advantage, in the ratio of 1022 to 1000.

From the above extended and somewhat laborious experiments, the following summary of results is derived:—

TABLE VIII.—GENERAL SUMMARY OF RESULTS OF EXPERIMENTS WITH NEWALL'S AND FAY'S BRAKES.

	Average Number of Experiments.		Average Efficiency of Brakes.	
	Fay.	Newall.	Fay.	Newall.
Oldham Incline, Table I. ..	7	7	1·8538	1·7436
Southport " " II. ..	5	1	3·6256	4·9700
" " " III. ..	1	1	3·2329	3·1416
" " " V. ..	8	8	6·7030	5·4984
" " " VI. ..	3	3	5·8718	6·3272
" " " VII. ..	3	3	3·0934	3·0250

The general average from this Table gives, for the efficiency of Fay's brakes, 4·0634, and for that of Newall's 4·1650, showing a slight superiority in favour of the latter.

The following conclusions seem borne out by these experiments:—

1st. That with slide-brakes the greater number of experiments gave a manifest superiority to Fay's.

2nd. That with flap-brakes there was a decided advantage on the side of Newall.

3rd. That when the train was braked, with the engine attached, the results were uniform; neither Fay's brakes nor Newall's gaining any decided superiority.

During the whole of these trials there was a strong feeling of rivalry, which rendered necessary the greatest caution, in order to prevent any interference, which might modify and vitiate the results. To reconcile these differences, and to obtain correct returns, Unwin was employed to take charge of the train, and to see that the brakes were applied at the right time; also to register the velocity of the train, and the distance of pulling up, during each experiment. There is therefore every reason to believe that the results recorded are a strict expression of the efficiency of the brakes, at their respective times of trial.

Yolland's Experiments with Newall and Fay's Railway Brakes.—It may be interesting to compare with these results the earlier experiments obtained by Colonel Yolland, on the same class of brakes, and under somewhat similar conditions of trial, as detailed in his Report to the Board of Trade, dated the 12th June, 1858. These results do not appear to have been reduced, hitherto, to any common standard of comparison. But as they embrace a wider range of circumstances of gradient, weather, weight, &c., than in Fairbairn's experiments, they will instructively test the method of reduction employed.

In the experiments on the Accrington incline the trains weighed 72 tons each, and consisted of six weighted carriages, used in all the experiments, and of three carriages fitted with Newall's, and three with Fay's brakes, respectively, and employed alternately. The required velocity was obtained by permitting the carriages to descend a distance of from three-quarters of a mile to a mile along the incline, which falls at the rate of 1 in 38 to 1 in 40. The initial velocity at the instant of applying the brakes was ascertained by observing the time required to traverse the quarter of a mile immediately preceding; and the mean velocity over this distance is used in

the reductions as the initial velocity of the train, although it is slightly below the real speed, at the instant of braking.

7		62·86	— 1 in 40	1208	
9		30·7	— 1 in 39	430	
10	Fay	60·	— 1 in 39	923	

Reducing the results in Table IX., the retarding force is:—

Newall.		Fay.
1·0275	} Mean 1·3231.	1·4754
1·4233		
1·3102		
1·1363		
1·5285		
1·3705		
1·1700		

It will be remarked that in these experiments the brakes were applied to a part of the train only. Hence, for comparison with the Southport experiments, a reduction must be made, to the condition of trains with brakes throughout, by the formula [6] already explained in that way,

$$f_1 = \frac{W}{w} f.$$

The retarding force in terms of the mass of the carriages actually braked is:—

Newall.		Fay.
3·7955	} Mean 3·5516.	3·9345
3·4940		
3·0301		
4·0759		
3·6547		
3·1200		

Showing an advantage to Fay in the ratio of 1107 to 1000. But a comparison is here scarcely fair, seeing the disproportion in the number of experiments with each brake.

TABLE X.—EXPERIMENTS ON THE ACCRINGTON INCLINE, WITH NEWALL'S AND FAY'S BRAKES, FEBRUARY 28, 1858. Weather misty.

No.		Velocity, in Feet a Second.	Gradient, falling — .	Distance of Braking, in Yards.	Remarks.
11	Fay	66·	— 1 in 39	2060	Three continuous brakes.
13		62·86	— 1 in 39	1660	
16		50·77	— 1 in 39	1070	
17		35·67	— 1 in 40	492	
12		60·	— 1 in 39	2142	
14	Newall ..	60·	— 1 in 39	1754	Tender and ditto.
15		50·77	— 1 in 39	1450	
18		69·47	— 1 in 132	880	

The results in Table X. show that the mean of the retarding force is:—

Fay.		Newall.	
1·178	} Mean 1·220.	1·105	} Mean 1·131.
1·221		1·167	
1·227		1·122	
1·257			

Or with brakes throughout:—

Fay.		Newall	
3·141	} Mean 3·255.	2·946	} Mean 3·017.
3·256		3·112	
3·272		2·992	
3·352			

Giving a slight advantage to Fay, in the ratio of 1070 to 1000.

TABLE XI.—EXPERIMENTS WITH NEWALL'S BRAKES, BETWEEN LIVERPOOL AND PRESTON, FEBRUARY 22, 1858.

Train of carriages weighing 83 tons 18 cwt.; engine, 29 tons 2 cwt.; tender, 13 tons 4 cwt.

No.		Velocity, in Feet a Second.	Gradient, rising +, falling -.	Distance of Braking, in Yards.	Remarks.
1	Newall ..	57·39	- 1 in 135	285	Tender and six brakes.
2		48·88	- 1 in 180	208	
3		66·00	+ 1 in 135	206	
4		45·52	+ 1 in 168	246	Tender and self- action of six brakes.
6		57·39	- 1 in 150	276	
7		48·88	- 1 in 130	204	Tender and six brakes.

Reducing as before, these data give $\left\{ \begin{array}{l} f = 2·165 \\ f = 2·095 \\ f = 3·285 \\ f = 2·204 \\ f = 2·201 \end{array} \right\}$ Mean 2·390;

or, reduced in the ratio of the weight on the wheels
braked to the weight of the train $\left\{ \begin{array}{l} f_1 = 4·304 \\ f_1 = 4·164 \\ f_1 = 6·530 \\ f_1 = 4·381 \\ f_1 = 4·375 \end{array} \right\}$ Mean 4·671.

This agrees with the value $f_1 = 3·5516$, obtained in the first experiments at Accrington, with the rails dry, and is in excess of the value $f_1 = 3·017$, obtained with the rails wetted by the mist.

For experiment No. 4, with the self-action of the brakes alone, $f = 1·211$, or about one-half the full brake-power.

TABLE XII.—EXPERIMENTS BETWEEN PRESTON AND LIVERPOOL, WITH NEWALL'S RAILWAY BRAKES, FEBRUARY 22, 1858.

Weight of train, 101 tons 1½ cwt.; weight on brakes, 71 tons 19½ cwt.

No.		Velocity, in Feet a Second.	Gradient, rising +, falling -.	Distance of Pulling up, in Yards.	Remarks.
8	Newall ..	73·33	0	196	Tender and seven continuous brakes.
9		57·39	+ 1 in 402	130	
10		44·	0	107	
11		60·	- 1 in 120	167	

Reducing these results $\left\{ \begin{array}{l} f = 4·567 \\ f = 2·975 \\ f = 3·015 \\ f = 4·118 \end{array} \right\}$ Mean 3·668;

or, when the train is braked throughout $\left\{ \begin{array}{l} f_1 = 6·406 \\ f_1 = 4·173 \\ f_1 = 4·229 \\ f_1 = 5·776 \end{array} \right\}$ Mean 5·146.

This would seem to indicate that the brakes act more efficiently, the more nearly they are applied throughout the whole train.

TABLE XIII.—EXPERIMENTS BETWEEN LIVERPOOL AND PRESTON, WITH NEWALL'S BRAKES, FEBRUARY 23, 1858.

No.		Velocity, in Feet a Second.	Gradient, rising +, falling -.	Distance of Pulling up, in Yards.	Remarks.
1	Newall ..	77·65	- 1 in 204	314	All the brakes.
2		73·33	0	179	
3		52·8	0	183	
4		73·33	- 1 in 132	227	All but the tender.
5		66·	+ 1 in 135	189	
6		73·33	0	249	
7		62·86	- 1 in 150	208	
8		44·	- 1 in 700	138	
9		77·65	- 1 in 120	235	All the brakes.

$$\begin{aligned}
 &\text{Reducing} \dots \dots \dots \left\{ \begin{array}{l} f = 3.3582 \\ f = 5.0068 \\ f = 3.7041 \\ f = 4.0797 \\ f = 3.5992 \\ f = 2.9516 \\ f = 2.2922 \\ f = 4.0081 \end{array} \right\} \text{Mean } 3.6249; \\
 &\text{or, when further reduced in the ratio of the weight of} \\
 &\text{the whole train to the weight on the wheels braked} \dots \left\{ \begin{array}{l} f_1 = 3.9660 \\ f_1 = 5.9130 \\ f_1 = 4.3745 \\ f_1 = 4.8181 \\ f_1 = 4.2506 \\ f_1 = 3.4858 \\ f_1 = 4.7335 \end{array} \right\} \text{Mean } 4.5057.
 \end{aligned}$$

The preceding results obtained by Yolland are as follows:—

$$\begin{aligned}
 &\text{Engine detached} \left\{ \begin{array}{l} \text{Fav.} \\ 3.9345 \\ 3.255 \end{array} \right. \dots \dots \left\{ \begin{array}{l} \text{Newall.} \\ 3.5516 \\ 3.017 \end{array} \right. \left\{ \begin{array}{l} \text{Dry.} \\ \text{Wet.} \end{array} \right. \\
 &\text{Engine attached} \dots \dots \dots \left\{ \begin{array}{l} 4.671 \\ 5.146 \\ 4.505 \end{array} \right\} \text{Mean } 4.774.
 \end{aligned}$$

TABLE XIV.—EXPERIMENTS ON M'CONNELL'S STEAM SLEDGE-BRAKE, BETWEEN BLETCHLEY AND OXFORD, JANUARY 19, 1858.

The engine weighed 29 tons; the tender, 14 tons 10 cwt.; the carriages, 102 tons 9 cwt.; the guards' vans, 10 tons $4\frac{1}{2}$ cwt.; steam-sledges assumed at 7 tons 2 cwt.

No.		Velocity, in Feet a Second.	Gradient, rising +, falling —.	Distance of Pulling up, in Yards.	Remarks.
1	M'Connell's steam-brake.	27.5	+ 1 in 150	430	None.
2		32.19	+ 1 in 142	285	Steam and guard's.
3		19.35	+ 1 in 142	163	Guard's.
4		52.8	— 1 in 214	590	All.
5		60.	— 1 in 149	870	Steam and tender.
6		48.88	— 1 in 209	673	All.
7		36.67	— 1 in 1430	623	Steam.
8		55.	— 1 in 163	880	All.
9		55.	0	763	Tender and guard's.
10		57.39	0	1320	Steam.
11		52.8	— 1 in 2211	496	All.
12		60.	0	540	All.
13		55.	+ 1 in 2211	345	All.
14		47.14	0	538	Tender and guard's.
15		47.14	— 1 in 452	388	All.
16		62.86	+ 1 in 163	669	All.
17		57.39	0	880	Tender and guard's.
18		55.	+ 1 in 209	1194	Steam.

Reducing these results:—

No.		No.	
2	$f = 0.03793$	11	$f = 0.93677$
3	$f = 0.01562$	12	$f = 1.11111$
4	$f = 0.93791$	13	$f = 1.42800$
5	$f = 0.90567$	14	$f = 0.64824$
6	$f = 0.74567$	15	$f = 1.02560$
7	$f = 0.38224$	16	$f = 0.78690$
8	$f = 0.77041$	17	$f = 0.62379$
9	$f = 0.66076$	18	$f = 0.42225$
10	$f = 0.41586$		

Separating those experiments which were made on different brakes, and taking the mean of those made on the same, the value of each brake respectively is as follows:—

For the guard's brake	$f = 0.1562$
" tender-brake	$f = 0.4989$
" steam-brake	$f = 0.4373$
" steam and tender brakes	$f = 0.9057$
" steam and guard's brakes	$f = 0.3793$
" guard's and tender brakes	$f = 0.6443$
guard's, steam, and tender brakes	$f = 0.9678$

These numbers represent the actual proportion of the brake-power supplied in the experiments by each brake or set of brakes. The efficiency of the brakes in relation to the weight upon them is:—

For the guard's brake		$f_1 = 2.2268$
„ tender-brake		$f_1 = 5.0216$
„ steam-brake		$f_1 = 9.1176$
„ steam and tender brakes		$f_1 = 6.1197$
„ steam and guard's brakes		$f_1 = 3.1930$
„ guard's and tender brakes		$f_1 = 3.8014$
„ guard's, steam, and tender brakes		$f_1 = 4.4365$

This shows that, in proportion to the weight upon it, a sledge-brake, which can be applied instantly, acts most efficiently.

Colonel Yolland's Experiments with M. Guérin's Self-acting Brake.—The train in the first four experiments consisted of an engine, tender, and nineteen carriages, two being fitted with M. Guérin's brakes. The total weight of the train was 151.88 tons. In the remaining experiments two ordinary brake-vans were substituted for M. Guérin's, the total weight being then 152.8 tons.

TABLE XV.—EXPERIMENTS BETWEEN ERITH AND WOOLWICH, AUGUST 27, 1858.

No.		Velocity, in Feet a Second.	Gradient, rising +, falling —.	Distance of Pulling up, in Yards.	Remarks.
1	M. Guérin's brakes.	50.78	— 1 in 912	597	Tender and two Guérin brakes.
2		62.86	0	738	
3		57.39	0	552	
4		45.52	+ 1 in 912	395	
5	Ordinary brake-vans.	48.57	— 1 in 912	359	Tender and two ordinary brakes.
6		66.	0	593	
7		50.77	0	521	
8		52.8	+ 1 in 912	510	

Reducing these results:—

M. Guérin's Brakes.		Ordinary Brakes.	
0.075488	} Mean 0.0870.	0.11300	} Mean 0.1013.
0.089238		0.12243	
0.099445		0.08245	
0.083898		0.08757	

From these experiments, M. Guérin's brakes appear to be less efficient than two equally heavy brake-vans of the ordinary description, when used in conjunction with a tender-brake, in the ratio of 1165 to 1000.

The value of f_1 for the mean of these experiments gives:—

For M. Guérin's brake		0.5169
„ the guard's ordinary brake		0.5874

We do not pretend to know the reason why, but Guérin's brake gave better results when tried in France.

Experiments with Ingram's Auxiliary Brake, on the Manchester, Sheffield, and Lincolnshire Railway.—When these experiments were made, the weather was bad, rain falling the whole time. The train weighed 124 tons $\frac{1}{2}$ cwt.; the tender, 17 tons; the carriages to which Ingram's brake was applied, 25 tons 17 $\frac{1}{2}$ cwt.

TABLE XVI.—EXPERIMENTS WITH INGRAM'S BRAKES, OCTOBER 18, 1858.

No.		Velocity, in Feet a Second.	Gradient.	Distance of Pulling up, in Yards.	Time in Stopping, in Seconds.
3	Ingram's brake.	46.9	1 in 124	870	90
3		44.0	1 in 124	795	77
4		51.3	1 in 133	768	65
7	Tender ..	54.2	1 in 120	1320	134
9		46.9	1 in 120	1152	114

Reducing these results, on the assumption that the gradients were all falling ones:—

Ingram's Brakes.		Tender-Brakes.	
$f = \left\{ \begin{array}{l} 0.68096 \\ 0.66545 \\ 0.81870 \end{array} \right\}$	Mean 0.7217.	$\left\{ \begin{array}{l} 0.63921 \\ 0.58646 \end{array} \right\}$	Mean 0.6128.

Hence, $f_2 =$ with Ingram's brake 3.4619
the tender-brake 4.4712

Ingram's brake thus showing a somewhat less efficiency than the tender-brake.

It should be here observed that the work employed to move a body over a horizontal distance, added to the work due to the gravity in elevating the body a vertical height, is the same as that employed in moving the body on a curve joining the extreme points, since a curve may be supposed to be made up of a number of straight lines; hence the uniform work upon the whole curve will be equal to the uniform work done upon the horizontal projection, added to the work done in opposition to gravity in raising the body, no matter what form be given to the path described. See Byrne's 'Essential Elements of Practical Mechanics,' p. 276.

Reduction of the Retarding Force to Units of the Weight of the Brake Carriages.—In the preceding reductions it was found most convenient to know the retarding force in terms of the mass of the train. For practical purposes, however, it is convenient to state the retarding force in terms of the weight upon the brake carriages, and, to be guided by precedent in this matter, it seems best to state the retarding force in pounds to the ton weight on the braked wheels, that is, in the same terms as the normal friction of the train is usually stated. Calling, therefore, f_2 the mean resistance in pounds a ton, in the moving mass of all the forces tending to destroy motion, of which the principal is the friction of the brake, then $f_2 = f_1 \times \frac{2240}{32 \cdot 19} = 69 \cdot 587 f_1$.

ORDINARY BRAKES.

Retardation, in lbs. a ton,
on Wheels Braked.

Guard's van	154·9	Yolland.
Tender-brake	349·4	"
Tender and guard's brakes	264·5	"
Tender-brake	311·0	M. S. and L. Railway.

All the above results, with the exception of the last, were obtained in dry weather.

Tender-brake	302·4	Fairbairn.
--------------------	-------------	------------

NEWALL.

Mean Retarding Force, in lbs.
a ton weight, of Braked Carriages.

Tables.				
I.	Slide-brakes (wet and foggy)		121·3	Fairbairn.
III.	" " (slightly wet)		237·7	"
II.	" " (dry and frosty)		345·8	"
V.	" " (dry and warm)		382·6	"
IV.	Flap-brakes (dry and warm)		440·3	"
IX.	" " (dry)		247·1	Yolland.
X.	" " (misty)		209·7	"
XI.	" " (dry)		325·4	"
XII.	" " (dry)		358·9	"
XIII.	" " (dry)		313·5	"

The mean of the experiments from Tables II., IV., and V., gives the retarding force at 389·6 lbs. per ton. The mean of Yolland's, from Tables IX., XI., XII., XIII., is 311·2 lbs.; or, omitting Table IX., 332·6 lbs. Bearing in mind that Fairbairn's results were obtained under circumstances of competition, and that there was in consequence the greatest care in the adjustment of the brakes, the above results agree sufficiently well. Hence also may be observed the very large diminution of the retardation of the brakes in wet and foggy weather. In wet weather the retardation does not appear to exceed 200 lbs. a ton; and in foggy weather, with the rails greasy, it appears that it may be reduced to 121 lbs., or nearly one-fourth of the maximum in dry warm weather.

FAY.

Mean Retarding Force, in lbs.
a ton weight, of Braked Carriages.

I.	Flap-brakes (wet and foggy)		129·0	Fairbairn.
III.	" " (slightly wet)		224·9	"
II.	" " (dry)		252·2	"
IV.	" " (dry)		408·6	"
V.	Slide-brakes (dry)		466·4	"
IX.	" " (dry)		273·7	Yolland.
X.	" " (misty)		226·5	"

There the maximum retardation amounts to 466·4 lbs. a ton, or nearly one-fifth of the weight of the braked carriages. The mean of Tables II., IV., V., in dry weather, gives 375·7 lbs. a ton.

M'CONNELL'S STEAM-BRAKE.

Mean Retardation, in lbs.
a ton weight, on Wheels and
Sledges Braked.

Table XIV.										a ton weight, 224 lbs. and Sledges Braked.			
Guard's van	..	..	..	..	..	..	..	..	..	154·9	..	..	Yolland.
Tender-brake	..	..	..	..	..	..	..	..	..	349·4	..	..	"
Steam-brake	..	..	..	..	..	..	..	..	..	634·4	..	..	"
Steam and tender brakes	..	..	..	..	..	..	..	..	..	425·8	..	..	"
Steam and guard's brakes	..	..	..	..	..	..	..	..	..	222·1	..	..	"
Guard's and tender brakes	..	..	..	..	..	..	..	..	..	264·5	..	..	"
Guard's, steam, and tender brakes	..	..	..	..	..	..	..	..	..	308·7	..	..	"

These reductions seem to show that, in proportion to the weight upon it, the sledge-brake is more efficient than any brake applied to the wheels. Of course it is not asserted that the sledge-brake could be employed in lieu of the present arrangement; but that it renders useful, in retarding the train, a larger proportion of the weight on it.

M. GUÉRIN'S BRAKE.

Table XV.		Mean Retarding Force, in lbs. a ton, on Brake Carriages.	
M. Guérin's and tender brakes		35·9	Yolland.
Ordinary van and tender brakes		40·8	"

Both these brakes were, for some reason, acting inefficiently.

INGRAM'S BRAKE.

Table XVI.		Mean Retarding Force, in lbs. a ton weight, of the Carriages Braked.	
Ingram's and tender brakes		240·9	M. S. and L. Railway.

GENERAL SUMMARY.

		Ratio of Weight on Brakes, to Retarding Force generated by them, or Mean Coefficient of Friction for each Brake.	
Newall's (dry)	Fairbairn	{ from 0·1544 to 0·1965	
" (wet)		{ 0·0542	
Fay's (dry)	Yolland	{ from 0·1126 to 0·2082	
" (wet)		{ 0·0576	
Newall's (dry)		{ 0·1116	
Fay's (dry)		{ 0·1020	
Ingram's (wet)		{ 0·1075	
Guérin's (dry)		{ 0·01048	
M'Connell's steam-brake		{ 0·28325	

That is, the retarding force generated by these brakes varies from $\frac{1}{100}$ to $\frac{5}{18}$ of the weight of the carriages to which brakes are applied, and is ordinarily from $\frac{1}{10}$ to $\frac{1}{8}$.

This agrees very well with the deductions from experiments on the friction of metal on metal, which give for smooth surfaces a coefficient varying from 0·15 to 0·2, or nearly identical with the best experiments above reported.

Formulas.—To find the distance on a level line required to bring a train to a stand by braking:—

Let s = the distance of pulling up, in yards;

v = the velocity of the train, in feet per second;

w = the weight on the braked wheels, in tons;

W = the total weight of the train, in tons;

θ = the inclination of the incline to the horizon, if the train is on a gradient, so that if the

incline rises 1 ft. in x ft., then $\sin. \theta = \frac{1}{x}$;

g = the action of gravity = 32·19.

Then, if the train is braked throughout, and on a level line, $s = \frac{v^2}{6 f_1}$; and if brakes are ap-

plied to a part of the train only, $s = \frac{v^2}{6 f_1} \times \frac{W}{w}$; or, if the train is on an incline,

$$s = \frac{v^2}{6 f_1 \pm 6 g \sin. \theta} \times \frac{W}{w},$$

where the + or — sign is to be taken, according as the incline falls or rises.

The value of the coefficient f_1 must be selected from the Tables of Experiments already given, that coefficient being selected which was obtained under circumstances most nearly approaching those of the case to be determined.

Thus, if the trains are stopped by the friction of their bearings, and so on, without the application of brakes, $f_1 = 0·13$ (mean), and $6 f_1 = 0·78$.

If the brakes are ordinary guard and tender brakes, applied together, $f_1 = 4$, and $6 f_1 = 24$, approximately.

For brakes, such as Newall's and Fay's, acting with maximum efficiency, $f_1 = 5·5$ to $6·5$, and $6 f_1 = 33·0$ to $39·0$.

Thus, supposing it is required to ascertain the distance in which a train weighing 60 tons, with brakes to 20 tons weight of the carriages, would be brought to rest, in ascending an incline of 1 in 27, at a velocity of 60 ft. a second; then taking $f_1 = 4$,

$$s = \frac{v^2}{6 f_1 + 6 g \sin. \theta} \times \frac{W}{w} = \frac{(60 \times 60)}{6 \times 4 + 6 \times 32 \cdot 19 \times \frac{1}{27}} \times \frac{60}{20} = 116 \text{ yds.}$$

If the rails are wetted by rain, the value of the coefficients given above must be taken at one-third less, and if greasy, their value may be reduced by as much as one-half or three-fourths.

It is convenient, in some cases, to estimate the braking power in time rather than in distance.

Now, theoretically, putting t = the time of braking, in seconds, then $t = \frac{v}{f}$. In practice this does not hold strictly true; hence $t = \frac{v}{f} - x$, where x is a constant to be derived from the experiments; $\therefore x = t + \frac{v}{f}$.

Now, from the Oldham experiments:—

For Fay's brakes		$x = 3, 6, 8, 8, 3, 8.$
For Newall's brakes		$x = 4, 2, 5, 0, 7, 8, 9.$
Hence mean		$x = 5.4.$

$$\therefore t = \frac{v}{f} - 5.4 = \left(\frac{v}{f_1} \times \frac{W}{w} \right) - 5.4.$$

The above formulas will be found sufficient for the purpose of ascertaining the amount of brake-power required to arrest the motion of any train, within such a distance as may be considered safe by the railway company, or by the engineer; or in any given case, to determine the distance within which a train of any required weight may be stopped when travelling at any velocity.

Steam-Brakes.—During the last few years engineers have undertaken to construct railway brakes which would act more effectively than those previously used. Every engineer knows the imperfections of the apparatus and of plans for effecting the retardation or stopping of trains. He knows further how urgent the demand for such means is; the more so as it is desirable to take away from the tender as much weight as possible, and strengthen and lighten the engine by an extended application of steel, so that the tender may carry more fuel and feed-water, without increasing the total weight of the engine and loaded tender, or diminishing the power of the engine. Independently of these considerations, it is generally acknowledged that the retarding power ought to proceed from the same parts of the mechanism which transfers the propelling power, and that a properly constructed brake ought to be operated by the accumulated force when not required to propel the train. With those considerations in view, numerous experiments were made, and plans tried; however, applicable and satisfactory results were not obtained.

A correct investigation will show the error of providing for the carriages or wagons a separate brake-mechanism, even should the power to operate such mechanism be taken from the locomotive boiler. With locomotives, however, means must be found which will not only allow us to accumulate a sufficient retarding force in the boiler, but which will also give us the power to regulate its application and intensity, so as to destroy, gradually, the work conserved in the train and due to the weight of the train and its uniform velocity. At the same time the means provided must have the power to diminish by degrees, and ultimately to reverse, the tractive power of the engine.

We propose to examine the four following systems of steam-brakes, namely:—

1. The reversing of the valve-gear (System Lechatelier-Ricour).
2. The compression of the steam (System Zeh).
3. The compression of the air in the cylinder (System de Bergues).
4. The repression of the steam (Frein à Vapeur de Landsee, and Steam-repression Brake of Krauss and Co.).

The steam-brake of Krauss and Co. was designed by Professor Linde, of Munich.

The systems 1 and 4 depend upon the same principle, that is, the counter-effect of the steam; but the methods of application are different.

The Reversing of the Valve-gear.—The motion of any locomotive can be diminished by simply reversing the valve-gear; but it is easy to understand that the counter-effect of the steam increases quickly the pressure of the steam in the boiler. This is, however, a minor reason why the counter-effect of the steam should be applied, to suddenly stop trains, only in exceptional cases; for another disadvantage of a more serious character is to be met with. The exhaust-port opens in locomotives, not directly into the open air, but communicates, through the exhaust-pipe, with the interior of the smoke-box. Whilst the cylinders are now drawing in the air, they will thus not be filled with pure air, but with the gases of combustion from the smoke-box, which have not only a very high temperature of 400° , 500° , and upwards, but which also carry with them a great many unconsumed parts of the fuel. The disadvantageous influence which the practice of using the counter-pressure of the steam will have upon the engine and boiler of a locomotive will thus be at once understood. But let us examine the distribution of the steam produced by the reversing of the valve-motion, and we shall find that it is very disadvantageous, and becomes still more disadvantageous the faster the engines work and the more powerful the effect becomes.

Suppose the crank to stand at one of the dead points A, Fig. 1248, that it travels in the direction indicated by the arrow, and thus contrary to the valve-motion; then the angle of advance becomes negative. The steam enters the cylinder behind the piston, until the latter has reached the point B, where, at the ordinary working of the engine, the steam in front of the piston began to be admitted. It is a very short distance, but the clearances of the pistons are filled, and a small but accelerated expansion of the steam takes place till the piston reaches the point C. The compression began formerly at that point, but now a communication with the exhaust is effected, which remains open and allows the air to enter the cylinder behind the piston during the full forward stroke. This communication with the exhaust-pipe continues in front of the piston to the point D, where formerly the release of the steam began; an insignificant compression of the air follows next, till the piston arrives at E, where formerly the expansion of the steam began. But only now, after the piston has travelled a part of its stroke and its velocity becomes great in proportion to the velocity of the crank, the admission of the counter-effect begins through the slowly-opening

port; the piston has to travel a farther distance, dependent upon its velocity, before it meets in front with steam of sufficient pressure. The most important period has almost passed inefficaciously, and the work done by the piston is thus very insignificant. That work is represented in a graphical manner in Fig. 1248, by the dark hatchings *abcd*, after the accelerated expansion work *cde* has been deducted.

Fig. 1248.—*ec*, Pressure of the steam in the boiler. *E*, Beginning of the admission of the counter-steam in front of the piston. *D*, Exhaust shut before the piston. *B*, The admission of steam cut off behind the piston. *C*, Exhaust opens behind the piston.

Fig. 1249.—*D*, Exhaust opens behind the piston. *E*, Expansion begins behind the piston. *B*, Admission of the steam begins in front of the piston. *C*, Exhaust shut before the piston.

Fig. 1250.—*D*, Exhaust opens behind the piston. *E*, Expansion begins behind the piston. *B*, Communication with the steam-chest begins in front of the piston. *C*, The admission of the counter-steam begins in front of the piston.

Fig. 1251.—*B*, Communication with the steam-chest begins in front of the piston. *C*, Compression begins in front of the piston. *D*, Admission of the counter-steam begins behind the piston. *E*, Communication with the steam-chest shut behind the piston.

Engineers have always had sufficient reason to regret that drivers should be prohibited to apply this simple and powerful means of stopping trains; and, moreover, retardation by means of friction-brakes, considered theoretically as well as practically, is imperfect, since the *vis viva* of the trains had to be entirely destroyed by an external application of the brake, to diminish the velocity.

It is not surprising, under such circumstances, that the proposition of Lechatelier was soon approved of and applied first in France and then in Switzerland. According to M. Lechatelier's plan, Figs. 1252, 1253, a pipe is led from the exhaust-pipe of the engine to a small closed vessel,

which is connected with the boiler by two other pipes, each furnished with a cock. One of these communicates with the boiler above, and the other below the water line, and by means of them

a mixture of steam and water can be introduced into the closed vessel, and from it, led by the pipe first mentioned, to the exhaust-pipe. The action of this arrangement is as follows:—When the engine is reversed for the purpose of retarding the train, the pistons would, under ordinary circumstances, pump air into the boiler, mixed with dust from the smoke-box, cutting and damaging the working surfaces of the cylinders and valves.

To prevent this damage, M. Lechatelier's plan provides for the admission of the mixture of steam and water into the blast-pipe when the engine is reversed, and the pistons then pump this mixture, instead of air, into the boiler. The water serves to lubricate the pistons, and the quantity admitted is just about as much as will be evaporated by the heat generated by the friction of the working parts. The supply of steam to the blast-pipe is generally allowed to be somewhat in excess of the quantity which can be pumped back into the boiler by the pistons, and the small quantity, which is thus constantly escaping at the blast-nozzle, serves to prevent the admission of a current of air. But experience has not only shown that Lechatelier's method, especially at a high speed of the engine, is in many cases not powerful enough, but that the admission of the proper quantity of steam and water requires great skill from the drivers.

The Compression of the Steam.—The method proposed by Zeh takes place by shutting the exhaust-pipe and placing the valve-gear on a high grade of expansion, so that the steam has to perform not only little work, but the escape of the expanded steam is also prevented, and the latter is thus compressed at the backward stroke of the piston.

The diagram, Fig. 1249, shows that the intensity of the effect can only be increased to a trifling degree. The pressure of the steam in front of the piston and at the commencement of the stroke can only be little more than that of the atmosphere, and the piston has to travel half of its stroke before the compression at C begins. When the crank arrives at B, almost at the end of the stroke, the pressure of the steam in front of the piston is still much less than the pressure of the steam in the boiler which acts now upon the piston for the remainder of the stroke. We get thus at first a retarding work, represented in the figure by the area $abecd$; next a propelling work, represented by the area $aecd$, and composed of the area ce , the work done by the full pressure of the steam, and the area ea , the work done by the expansion of the steam. The comparison between the two works shows in fact a very insignificant effect of this method.

The Compression of Air in the Cylinders has been proposed by M. de Bergues as a means for retarding the motion of locomotives. According to M. de Bergues' plan, the regulator and the blast-pipe are shut, the admission-pipe is put in communication with an air-vessel which is provided with a safety-valve, the exhaust-pipe is put in communication with the atmosphere, and the valve-motion is reversed. The counter-pressure can thus be increased to a certain degree, independently of the pressure in the boiler; but here also the disadvantages appear to be very great. In the first instance, M. de Bergues sacrifices the relation to the boiler; and hence he cannot accumulate a sufficient retarding force. Next, he reverses the valve-motion, and has thus from the beginning a disadvantageous distribution of steam, which, moreover, must produce a limited effect of the power, as the pressure of the steam is very variable.

The air-vessel must not be too large, in order to produce, quickly, highly compressed air; a perceptible reduction of the pressure of the compressed air effects the filling of the steam-cylinders. The compression produces, besides, a high temperature in the cylinders, which require special precautions and a very abundant oiling; finally, the arrangement and management of the apparatus are rather complicated. It gives very good results for short runs, but not under prolonged working.

Steam-Brake of M. de Landsee.—M. de Landsee acts upon the very correct principle to produce the retarding power by means of using steam from the boiler as a back-pressure upon the pistons in a more advantageous manner than with the reversing of the valve-gear. For that purpose, M. de Landsee adds to the engine for the admission of the steam in front of the piston a second valve-gear, to the cylinder another steam-chest and another system of ports; for the movement of the second valve he fixes an eccentric rectangular to the crank, a link and the necessary gear. In order to retard the motion of the engine, the exhaust-pipe is shut, the main valve-gear is placed on a high grade of expansion, so that the steam behind the piston performs a little work by expansion, whilst the steam in front of the piston, which has entered the cylinder through the second steam-chest G, Figs. 1254, 1255, is pressed back into the boiler, and acts thus by its repression upon the piston in comparison to the compression performed in the cylinder.

It must be admitted that this arrangement offers a satisfactory solution of the existing problem; but if the apparatus is destined to produce a more powerful effect than the apparatus previously examined, two moments of some importance have been neglected.

Let us examine what occurs during one revolution of the crank. The main valve H is supposed to have opened the port as much as the linear advance. The clearance of the piston, which in the present construction is enlarged on account of the second port communicating with the steam-chest G, amounting at least to $7\frac{1}{2}$ per cent. of the volume of the cylinder, is still filled with steam from the last repression. If we suppose $\frac{1}{10}$ to be the degree of expansion, or $17\frac{1}{2}$ per cent. the filling of the cylinders, ce will show in a graphical manner, in Fig. 1250, the

work done under the full pressure of the steam, and eD the work performed during the expansion of the steam, where D represents the beginning of the release of the steam, which takes place

after the piston has travelled about 70 per cent. of the stroke; the steam will thus have lost in a proportion of 77.5 to 17.5 of its pressure. Although the exhaust is shut and prevents the escape of this steam of almost $\frac{1}{2}$ of the pressure of the steam in the boiler, a considerable volume of fresh steam enters the cylinder from that part of the exhaust which extends to the distribution-valve S , and which had been filled during the preceding repression. If we suppose the volume of that part to be 20 per cent. of that of the cylinder, the pressure of the steam will increase in a proportion of

$$\frac{17.5}{77.5} : \frac{17.5}{77.5} + \left(1 - \frac{17.5}{77.5}\right) \frac{20}{97.5}, \text{ or } \frac{17.5}{77.5} : \frac{17.5}{77.5} + 0.16.$$

At the end of the stroke the pressure will have again decreased in a proportion of $127.5 : 97.5$, and we get thus with a pressure of 8 atmospheres in the boiler, after all, only a pressure of

$$p = 8 \left(\frac{17.5}{97.5} + 0.16 \right) \frac{97.5}{127.5} = 2.3 \text{ atmospheres.}$$

The value of the accelerated work is thus higher than at first calculated; it amounts at least to 45 per cent. of the total work performed by the piston (according to Boyle's law). But another circumstance, which reduces the retarding power at a high speed of the locomotive, has been entirely neglected, namely, the want of lead for the admission of the counter-steam. Of course, this lead could only be obtained on account of a still more disadvantageous distribution of the steam on the backward stroke of the piston, or by fixing a fourth eccentric. The valve G must thus travel a distance corresponding to its lap, before it admits the counter-steam into the cylinder, after the piston has reached the end of the stroke. At a high speed, the piston will have to travel a considerable part of its stroke before it meets in front with steam, the pressure of which is equal to that in the boiler.

The whole construction, although very ingenious, is too complicated, and the large clearances of the pistons, required by the two systems of ports, are great disadvantages. The simple principle, to admit steam into the cylinder, and to have it pressed back into the boiler by the movement of the piston, without any modification of the valve-motion, but by allowing the steam to enter the cylinders through the exhaust-pipes, instead of through the ordinary steam-pipes, has been adopted in

The Repression Brake of Krauss and Co., Munich.—This plan consists in an arrangement by means of which the steam can be made to enter the cylinders through the exhaust-pipes, instead of through the ordinary steam-pipes, the blast-nozzle being at the same time closed, and the steam admitted through the exhaust-pipes being pumped back, partly into the boiler, and partly into the steam-chests, from which it escapes through an adjustable valve into the chimney. Of course, the engine has not to be reversed, as in M. Lechatellier's arrangement.

The simplest arrangement is to place the regulator in the smoke-box, and to provide it with a segment-valve, as shown in Figs. 1256 to 1259. The regulator-valve R is connected with the blast-pipe by a tube A , and the blast-pipe is also provided with a segment-valve B . When the inlet to the steam-chest is shut by the first-mentioned valve, and the communication with the blast-pipe is open, the outlet of the latter being shut, then the steam passes from the boiler, through the tube and the blast-pipe, into the outlets or discharged ports of the slide-valve, and rushes against the piston with a counter-pressure equal to the steam-pressure during nearly the full stroke, that is to say, during the time that the steam is acting to work the engine; during this counter-pressure the steam is returned into the boiler. When about $\frac{1}{10}$ of the stroke has been

1256.

1259.

1257.

1258.

accomplished, the outlet is shut, and the steam being still in the cylinder, is further compressed till the ordinary inlet is opened by the slide-valve; and this steam can then escape to the steam-chest, and from there through a valve to the chimney. This valve is regulated by a cock, and can be put in communication through the inlet-tube, Fig. 1261, with the steam-chest, but during the working of the engine the valve is shut. This valve regulates the quantity of steam which is retained in the steam-chest, and also regulates the work of the brake. The regulation of the back-pressure may also be effected by regulating the steam-pressure in the blast-pipe, and this is done by enlarging or narrowing the inlet opening, also by admitting steam to the steam-chest through the regulator-valve and expansion-valve; that is to say, by the introduction of steam into the cylinder on both sides of the piston. To simplify the working of the apparatus, the regulator-valve, the blast-pipe valve, and the valve with the regulating cock, are connected by levers, so that by simply moving the regulator the engine can be driven at full speed, or can be reversed. By this arrangement of the apparatus it is possible nearly instantaneously to change the propelling force of the engine into a retarding force. When the piston is nearly at the end of the stroke, on the other side, the slide-valve begins to open the admission openings, and the steam passes into the empty cylinder, so that the latter is full of steam when the piston returns; this steam is now forced back into the boiler. This action continues till the slide-valve shuts the communication between the cylinder and the admission opening; the confined steam is then further compressed. This compression is at the highest point when the slide-valve is in communication with the cylinder and the steam-chest just before the crank is at the dead point; the steam then passes into the steam-chest and through the valve. It is necessary that the slide-valves should be prevented from being pressed back by the compressed steam, and Figs. 1257 to 1261 show the arrangement employed for that purpose. The valve, it will be seen, is fitted with a piston, at the back of which is a hole, which is connected by a tube with the blast-pipe, so that while braking, the steam can act upon the piston and prevent the pressing back of the slide-valve. Fig. 1251 shows the distribution and action of the steam in a graphical manner. At D, where formerly the release of the steam began, the admission of the counter-steam into the cylinder commences, so that when the piston arrives at the end of its stroke, the whole cylinder is filled with counter-steam, which has to be pressed back into the boiler by the piston, till the crank has reached the point C, when the communication with the blast-pipe is cut off. The remaining steam is compressed until the point B is reached, when it escapes through the valve into the steam-chest. Whilst the steam acts with full pressure during the whole stroke in front of the piston, the communication with the steam-chest is maintained behind the piston, until the crank arrives at the point E.

Dynamometer-Brake.—*Prony's Friction Dynamometer-Brake.*—A friction brake may be employed to measure the power applied to, and the mechanical effect produced by, a shaft or other part of a machine which revolves uniformly; it must be clearly understood that neither the power nor the effect can be measured unless the revolutions continue uniform after the brake is applied and adjusted. Piobert and Fardy, in 1821, applied a brake as a dynamometer to determine the power of water-wheels; but M. Prony first applied a brake to determine the power transmitted by steam.

It was determined by experiment that friction had a uniform resisting power that might be intensified by pressure: Prony contrived a brake to apply this retarding power to bring revolving shafts to given or required uniform velocities, so that the power applied by, or conserved in, a machine might be measured. Prony's brake, in its simplest form, is shown in Fig. 1262. Let the circle O be a cross-section of a horizontal shaft, which is revolving, but not uniformly; M, M', A, is the brake, the pressure of which may be increased or diminished by tightening or loosening the screws *e*, *e*, respectively. A circular cavity is made in the two wooden jaws M, M', which receives the revolving shaft O; the upper jaw M is lengthened to support a balance scale A P, which may be loaded with any required weight. The operation which we are about to describe must not be confounded with that of weighing a body by means of a lever and fixed prop. Now, suppose that a shaft O makes *k* uniform revolutions a minute, and, at the same time, drives any machinery whatever, and that we require to know the amount of power employed in driving such machinery. To effect this object, the communication between the shaft O and the machinery driven by it must be removed, and the brake so tightened on the shaft that it will make just *k* revolutions a minute. While the brake is being pressed by the screws *e*, *e*, to obtain the necessary amount of friction, it is prevented from being turned with the shaft by props. Then weights are placed in the scale A, to bring the arm M A into a horizontal position: the props which prevented the brake from being

whirled round with the shaft are not in contact with the brake when MA is horizontal. When the brake is thus screwed up and poised, the shaft must continue to make k uniform revolutions a minute; then the power transmitted by the shaft O may be calculated. Let P be the weight suspended at A, and p the perpendicular distance from the centre of O to the line AP; Q the weight of the scale and that part of the apparatus which assists the weight P; G its centre of gravity, and q the perpendicular distance from O to the line GQ. The reaction of the friction of the jaws M, M', upon the revolving shaft O may be resolved into normal forces $n, n', n'', \dots$ and tangential forces $f, f', f'', \dots$ acting in the direction of the rotatory motion. When the equilibrium of the apparatus is established, the sum of the moments of these different forces, in relation to the centre of O, must be equal to zero. But the normal forces have no moments, and if r be put for the radius of the shaft, we have the equation $fr + f'r + f''r + \dots - Pp - Qq = 0$. Or putting Σfr for the sum of the forces $fr + f'r + f''r + \dots$ we have the equation

$$\Sigma fr = Pp + Qq. \quad [1]$$

Taking the angular velocity at the distance of a unit from the centre of O (see ANGULAR VELOCITY), the work of friction for one revolution is found by multiplying Σfr by 2π , π being put = $3.14159 \dots$; whence, if N = the number of revolutions a minute, and if $\mathcal{Q}_f$ be put for the work of the friction in a second, we have $\mathcal{Q}_f = \frac{2\pi N}{60} \Sigma fr$. When the value of the general expression conventionally written Σfr , from equation [1], is substituted, we have

$$\mathcal{Q}_f = \frac{\pi N}{30} (Pp + Qq). \quad [2]$$

The weight P , required to bring A M to a horizontal position, and the perpendicular distance p , are known. The moment Qq may be found in the following manner:—The apparatus is weighed, as shown in Fig. 1263, by supporting the brake, detached, on a knife-edge I, and bringing the lever I A into a horizontal position by means of a weight P' attached to a cord, which passes over a fixed pulley, and is connected to the end A of the lever. The friction of the pulley being neglected, the tension T is equal to the force P' , and we have the equation

$$Tp = Qq \text{ or } P'p = Qq. \quad [3]$$

The weight P' is termed the permanent load.

Substituting $P'p$ for Qq in equation [2], we obtain the equation

$$\mathcal{Q}_f = \frac{\pi N}{30} (P + P')p. \quad [4]$$

N the uniform revolutions and P become known when the brake is perfectly adjusted.

If, for example, $p = 2^m.50$; $P' = 30^k$, and the shaft O, Fig. 1262, to make continually forty uniform revolutions a minute when $P = 120^k$, then $N = 40$, and the general expression

$$\mathcal{Q}_f = \frac{3.14159265 \times 40}{30} (120 + 30) \times (2.5) = 1570.79633$$

French units of work, or 1570.79633 kilogrammes raised the height of 1 mètre. The French consider a horse-power = 75 kilogrammes raised 1 mètre in a second. 75 French units of work are equal to 542.5 English units of work; $\frac{33000}{60} = 550$; but $550 : 542.5 :: 1 : .9864$; therefore an

English horse-power is a French horse-power, as 1 is to .9864 nearly. $1570.79633 \div 75 = 20.94$ English horse-power, according to the French method of measurement.

Again, suppose $p = 8$ ft.; $P' = 50$ lbs.; $P = 250$ lbs.; and $N = 40$; then

$$\mathcal{Q}_f = \frac{3.1416 \times 40}{30} (250 + 50) 8 = 10052.12 \text{ units of work a minute;}$$

$$\therefore \frac{10052.12}{550} = 18.28 \text{ horse-power (English).}$$

In practice, the jaws are not directly applied to the shaft; but if the latter is of cast iron, a circular frame, expressly framed and bored for that purpose, is fastened to it by means of adjusting-screws. If the shaft is of timber, and of a large size, it is surrounded by a ring formed of two parts and provided with screws for its correct centering; this ring is fastened to the shaft by means of wedges. In both cases the jaws of the brake are applied to the circular frame or ring, as shown in Fig. 1264.

If the product Σfr or $r \Sigma f$ remains the same for an equal number of horse-power, Σf is so much greater, the smaller r is taken. But the friction may thus become too great, and by altering, consequently, the contacting surfaces, it will also lose its uniformity. Experience has proved that with

a diameter of between	and a velocity of between	the power can be measured of
16 and 20 centimètres,	20 and 30 revolutions per minute,	6 or 8 horses,
30 " 40 "	15 " 30 " "	15 " 25 "
60 " 80 "	15 " 30 " "	40 " 70 "

A high speed is, besides, favourable to the regularity of the experiment, as M. Morin has confirmed at Bonchet. A uniform friction is necessary for the maintenance of the equilibrium of the lever during the rotatory motion of the shaft; the lever assumes always a little oscillating motion, which is of no consequence as long as it keeps within strict limits; but if these oscillations become considerable, an irregularity in the friction has taken place, and the retarding power of the friction cannot under such circumstances be measured.

On account of the length of the lever, the weight at A, Fig. 1262, may of itself tighten the screws; in order to remove this inconvenience, which sometimes produces false results, M. Poncelet has proposed to make the two jaws of equal length, and to place the bolts near the point A, Fig. 1265. The flexibility of the wood permits a gradual tightening, which renders this arrangement preferable to the ordinary one.

To establish stable equilibrium, M. Poncelet applied the weight, not to the point A itself, but to the end of a vertical rod AB, fastened to one of the jaws. It thus happens, that if the lever begins to turn round with the shaft, the lever-arm of the weight P increases immediately, and the friction ceasing to be preponderant, the apparatus returns to its equilibrium.

If the shaft is vertical, the weight cannot be applied directly to the end of the lever, but a cord fastened to it is made to pass horizontally in a perpendicular direction over a fixed pulley.

A plummet suspended before the end of the lever will show the position of the brake when equilibrium is established.

M. Morin has extended the useful application of the brake as a dynamometer, for he does more than measure by it the work done for a given or required uniform velocity of a shaft.

The extended application to which we allude may be thus described:—

When the shaft turns round without meeting with any resistance, and after the supports of the lever have been removed, a weight between 5 and 10 kilogrammes is placed at the end of the lever; the screws are now tightened, till an equilibrium of the apparatus is established. The uniform velocity or speed of the shaft is measured, and the units of work done are ascertained. A new weight is again added to that already acting at the end of the lever; the screws are made more tight, until equilibrium is again established, and the uniform speed of the shaft and the work performed are determined. The weight at the end of the lever is gradually increased, and the screws for the establishment of an equilibrium tightened, till the shaft stops or turns in an irregular manner. The work done, in each second, is thus obtained for a variety of uniform speeds, from the greatest to the least possible. A curve is drawn, the abscissæ of which represent the velocities, and the co-ordinates the corresponding values of the ratios between the work given by the brake and the work of the motor. This curve indicates the nature and power of the machine; it gives the performed work corresponding to an average uniform speed of a shaft, and, besides, it shows the uniform speed which corresponds to the maximum effect.

Fig. 1266 represents the results of a series of experiments made with a turbine of the System Fontaine. The abscissæ are proportional to the number of revolutions of the wheel a minute, and the co-ordinates represent the corresponding values of the actual effects multiplied by 100. It will be seen from the diagram that the maximum actual effect is produced with about forty-five uniform revolutions, and that this maximum is about 0.60, that is to say, the maximum actual effect is 0.60 of the motive power.

Writers on mechanics, and especially those who attempt to explain the action of a brake employed as a regulator to produce a uniform effect, do not draw a proper distinction between the action of a toggle, and that of a system of compound levers. To place this matter in a clear light we have only to explain the action of a simple toggle-joint, since the properties of the lever are well known.

Let $AB = BC = 144.01$ in. be the arms of a toggle-joint, Fig 1267; the point A is fixed, but the rod AB may be turned round A as a centre. The joints B and C are also loose, but C is constrained to move in a given path. In the right-angled triangle $DCB = DAB$ and DB perpendicular to AC ; putting $DB = 2.4$ in., then $CD = DA = 143.99$ in.

A little more than half the brake is shown in this figure.

Suppose a force P of 200 lbs. to be applied at B , in the direction of BD as indicated by the arrow P ; when the two bars AB , BC , are brought into a straight line in the direction of the arrow Q , what weight W may be thus moved by the action of the force P ? W is constrained to move in a given path by the action of the equal forces R and S . Units of work done by

$P = \frac{2 \cdot 4}{12} \times 200 = 40$ units of work. $287 \cdot 98 = AC$, and $AB + BC = 288 \cdot 02$. $288 \cdot 02 - 287 \cdot 98 = \cdot 04$ in., the space over which W must pass in the direction indicated by the arrow Q when B is moved from B to D . $\therefore \frac{\cdot 04}{12} W =$ the units of work done in raising W , consequently $\frac{\cdot 04}{12} W = 40$,

or $\frac{W}{300} = 40$; $\therefore W = 12000$ lbs., which exceeds 5 tons.

John George Appold's brake, which constituted the most important part of the machinery employed to pay-out the French Atlantic Cable, owes its efficiency and success to a judicious application of the toggle-principle to control and regulate the retarding power of friction. The principle upon which Appold formed this mechanical combination may be thus explained:—In Fig. 1268, O is the pivot of the brake-wheel, C the pivot on which the lever C, A, B , works; W represents the weight on the brake. The brake-wheel DE is attached to the paying-out drum. When the friction of the brake-strap $BDEA$ is greater than the weight W , the latter is lifted up and takes a position w ; CBA takes the position Cba ; the strap takes the position $bDEa$; and the force W may be resolved into two forces, one acting along abe , which is neutralized by the pivot C , and another P acting perpendicular to Ca ; the reacting force Q on the pivot C straightens the toggle OCa into its original position OCA , by a very trifling force Q . Thus the strap $aEDb$ is relaxed and allows the wheel DE to slip.

J. G. Appold's Brake Apparatus for Laying Submarine Telegraphic Cables, Figs. 1269, 1270, relates to a novel arrangement or construction of a self-acting or self-relieving brake, which may be adapted to the drums, pulleys, or shafts of the apparatus employed for submerging or paying-out telegraphic cables into the water. It is advisable that the strain on the cable while being payed-out into the water should be always maintained as uniform as possible under all circumstances, so that no danger of breaking or damaging the cable by any sudden or undue strain may be apprehended. This object is effected by adapting to the shafts of the paying-out pulleys a drum, on the surface of which a uniform friction is maintained by means of binding bands or straps, which are connected with a weighted vibrating or movable lever. This lever is capable of being weighted to any desired extent, according to the amount of friction required to be maintained. The weights or pressure put on the brake determines the friction thereof on the rotating drums, and consequently the amount of strain on the cable, which strain can be regulated with nicety and great facility. The weights or pressure acting on the vibrating lever or other convenient part of the brake has a tendency to draw the friction strap or band tight on the rotating drum, while the rotation of the drum has a constant tendency to lift the weight, and, by loosening the strap or band on the drum, to relieve the brake from the pressure to which it is subjected. From this it will be understood that these two forces are acting in opposition, and consequently the one has a tendency to counteract the other, so that a uniform strain or friction is always maintained on the rotating drum, the amount of the friction being regulated by the amount of the pressure or weight adapted to the drum.

It will now be understood that the brake is perfectly self-acting, and the friction thereof is always maintained uniform. Provision may be made for relieving the brake from pressure instantaneously when required by means of suitable gearing, whereby the weighted lever or levers is or are lifted up, and the friction straps or bands thereby loosened on the rotating drums. This may be effected by means of a hand-wheel, or by connecting the gearing with a drum or shaft to be actuated by the engine which works the paying-out gear.

Fig. 1269 is a side elevation, and Fig. 1270 a plan view, of an apparatus for paying-out cables. The cable a enters the apparatus over a grooved guide-wheel or pulley b , from whence it passes to one of the grooves of a four-grooved drum or pulley c , and after passing round this drum or pulley it is conducted round a similar grooved drum or pulley d , and so on, the cable being made to pass four times round the two-grooved drums c and d , from which it is ultimately delivered over another pulley e , either directly into the water or through a dynamometer apparatus, whereby the tension or strain on the cable may be ascertained and indicated. On the axes or shafts h of each of the grooved drums c and d are two friction wheels or drums f, f^*, f^* , which

are surrounded by friction-bands g, g^*, g^* , provided with segmental blocks of wood, which when the bands are drawn tight are made to press on the surface of the wheels or drums f, f^* , and thereby produce the necessary amount of friction to act as a brake upon the drums. On the ends of the shafts h are mounted the toothed wheels i, i , Fig. 1270, which are geared together by the pinion j , and therefore rotate at the same speed. This toothed gearing, however, is not required while the cable is being lowered or submerged, and therefore it may be thrown out of gear during this operation, and will only be required when the apparatus is used to haul in the cable, as would be required in case of accident to the cable.

1269.

1270.

The ends of the straps or bands g, g^* , are secured in any convenient manner to pins k, k , Fig. 1269, fixed on the vibrating levers l', l' , each of which passes through a hole made in the arms m . The holes in these arms form the centres of motion of the levers l', l' , and as these centres of motion are on one side of the centre of the friction wheels f, f^* , and bands g, g^* , it follows that by causing these levers l', l' to move on their centres of motion, as indicated in Fig. 1269, they will either tighten or loosen the friction-bands, according to the direction in which the levers are moved. On the upper side of the bands are fixed the blocks n, n , to which are attached the horizontal rods o, o , which are secured at one end to one of the blocks n by an adjustable attachment, as shown in Figs. 1269, 1270, and they are jointed at their opposite ends to the vibrating bell-crank levers p, p . These levers are supported in bearings fixed on the framing, and to the longer end of each is adapted a weight or weights, or a system of springs or other contrivances, whereby the levers may be depressed; and by the levers thus drawing forward the horizontal rods o, o , they will tend to tighten the friction-bands g, g^* , round the friction-drums f, f^* . It will now be understood that as the cable is being payed-out, it (by passing round the grooved pulleys c and d) draws the friction-wheels f, f , round, and by the friction of the wheels f on the bands g^*, g^* , tends to open

the latter, and thereby relieve the wheels from the friction of the bands. At the same time the weights or springs on the ends of the bell-crank levers p, p , will draw the friction straps or bands g, g^* , in the opposite direction, thereby having a tendency to tighten them on the friction-wheels f, f^* . These two forces will always be acting in contrary directions, and any increase in the action of the one will be counteracted by the other. In order to prevent any jar in the machinery by the weights at the end of the bell-crank levers p, p , suddenly descending when the friction on the bands or straps g, g^* , alters, it is convenient to attach to the weights, which are made of a cylindrical or other convenient form, a piston, which is made to work in a cylinder q . This cylinder or dash-pot is supplied with water, and as the piston is made pretty nearly to fit the internal diameter of the cylinder q , the water will to some extent moderate and regulate the motion of the weights, and will prevent them from jumping up and down. It is convenient to cause the friction-wheels to rotate or work in water, as shown at Fig. 1270, for the purpose of keeping them cool.

When a dynamometer apparatus is employed in conjunction with the paying-out apparatus, for the purpose of indicating the changes that take place from time to time in the tension of the cable, Appold employs an apparatus constructed upon an improved plan, whereby weights are dispensed with, and springs employed in place thereof. The cable when delivered from the paying-out apparatus above described, passes from the delivery pulley under or over a movable pulley, which is mounted on a block that works up and down in vertical guides. This block is supported at a given altitude in the guides by means of coiled or other springs placed either above or below the pulley, which is made to bear against the cable, and as the tension thereof varies, so the pulley with its block is caused to rise or fall in its guides, as is well understood in reference to ordinary dynamometers. This invention shows that John George Appold was a man of considerable genius and profound mechanical skill.

The Prony dynamometer-brake employed by J. B. Francis in making experiments on hydraulic motors is shown in Figs. 1271, 1272; Fig. 1271 is a sectional elevation, and Fig. 1272 is a sectional plan. The friction-pulley A is of cast iron, 5.5 ft. in diameter, 2 ft. wide on the face, and 3 in. thick. It is attached to the vertical shaft by the spider B , the hub of which occupies the place on the shaft intended for the bevel-gear. The friction-pulley has on its interior circumference six lugs C, C , corresponding to the six arms of the spider. The bolt-holes in the ends of the arms are slightly elongated in the direction of the radius, for the purpose of allowing the friction-pulley to expand a little as it becomes heated, without throwing much strain upon the spider. When the spider and friction-pulley are at the same temperature, the ends of the arms are in contact with the friction-pulley. The friction-pulley was made of great thickness for two reasons. When the pulley is heated, the arms cease to be in contact with the interior circumference of the pulley, consequently they would not prevent the pressure of the brake from altering the form of the pulley. This renders great stiffness necessary in the pulley itself. Again, it was found that a heavy friction-pulley

increases more regularity in the motion, operating, in fact, as a fly-wheel, in equalizing small irregularities.

The *brakes E and F* are of maple wood; the two parts are drawn together by the wrought-iron bolts *G G*, which are 2 in. square.

The *bell-crank F'* carries at one end the scale *I*, and at the other the piston of the *hydraulic regulator K*; this end carries also the pointer *L*, which indicates the level of the horizontal arm. The vertical arm is connected with the brake *F* by the link *M*, Fig. 1273.

The *hydraulic regulator K*, Figs. 1271, 1272, and 1274, is a very important addition to the Prony dynamometer-brake, first suggested by Boyden in 1844. Its office is to control and modify the violent shocks and irregularities which usually occur in the action of this valuable instrument, and are the cause of some uncertainty in its indications.

The hydraulic regulator used in these experiments consisted of the cast-iron cylinder *K*, about 1.5 ft. in diameter, with a bottom of plank, which was strongly bolted to the capping-stone of the wheel-pit, as represented in Fig. 1271. In this cylinder moves the piston *N*, formed of plate iron 0.5 in. thick, which is connected with the horizontal arm of the bell-crank by the piston-rod *O*. The circumference of the piston is rounded off, and its diameter is about $\frac{1}{16}$ in. less than the diameter of the interior of the cylinder. The action of the hydraulic regulator is as follows:—The cylinder should be nearly filled with water, or other heavy inelastic fluid. In case of any irregularity in the force of the wheel, or in the friction of the brake, the tendency will be either to raise or lower the weight; in either case the weight cannot move, except with a corresponding movement of the piston. In consequence of the inelasticity of the fluid, the piston can move only by the displacement of a portion of the fluid, which must evidently pass between the edge of the piston and the cylinder; and the area of this space being very small, compared to the area of the piston, the motion of the latter must be slow; giving time to alter the tension of the brake-screws before the piston has moved far. It is plain that this arrangement must arrest all violent shocks; but, however violent and irregular they may be, it is evident that, if the mean force of them is greater in one direction than in the other, the piston must move in the direction of the preponderating force, the resistance to a slow movement being very slight. A small portion of the useful effect of the turbine must be expended in this instrument; probably less, however, than in the rude shocks the brake would be subject to without its use.

For the purpose of ascertaining the velocity of the wheel, a counter was attached to the top of the vertical shaft, so arranged that a bell was struck at the end of every fifty revolutions of the wheel.

To lubricate the friction-pulley, and at the same time to keep it cool, water was let on to its surface in four jets, two of which are shown in Fig. 1272. These jets were supplied from a large cistern, in the attic of the neighbouring building, kept full by force-pumps. The quantity of water discharged by the four jets was, by a mean of two trials, 0.0288 cubic ft. a second.

In many of the experiments with heavy weights, and consequently slow velocities, oil was used to lubricate the brake, the water, during the experiment, being shut off. It was found that, with a small quantity of oil, the friction between the brake and the pulley was much greater than when the usual quantity of water is applied; consequently, the requisite tension of the brake-screws was much less with the oil, as a lubricator, than with water. This may not be the whole cause of the phenomenon; but, whatever it may be, the ease of regulating in slow velocities is incomparably greater with oil, as a lubricator, than with water applied in a quantity sufficient to keep the pulley cool. The oil was allowed to flow on in two fine continuous streams; it did not, however, prevent the pulley from becoming heated sufficiently to decompose the oil, after running some time, which was distinctly indicated by the smoke and peculiar odour. When these indications became very apparent, the experiment was stopped, and water let on by the jets, until the pulley was cooled. As the pulley became heated, the brake-screws required to be gradually slackened.

In the experiments, in Table II. (see *TURBINE WATER-WHEEL*), the lubricating fluid was as follows:—

In the first twenty-six experiments, water alone was used.

In the four experiments numbered from 27 to 30, three gallons of linseed-oil were used.

In all the experiments requiring a lubricator, and numbered from 31 to 48, inclusive, linseed-oil was used.

In experiments 49 and 50, resin-oil was used.

In experiments numbered from 51 to 60, inclusive, water alone was used.

In experiment 61, resin-oil was used.

In experiment 62, resin-oil and a small stream of water were used;—in the latter part of the experiment, a good deal of steam was generated by the heat of the friction-pulley.

In experiment 63, resin-oil alone was used.

In experiments numbered from 66 to 72, inclusive, water alone was used.

In experiments numbered from 73 to 79, inclusive, resin-oil and a small stream of water were used.

In experiments numbered from 81 to 84, inclusive, water alone was used.

In experiments 85 and 86, resin-oil and a small stream of water were used.

In experiment 87, resin-oil alone was used.

In experiments 90 and 91, water alone was used.

In experiment 92, resin-oil and a small stream of water were used.

A special apparatus was provided to indicate the direction in which the water left the wheel. For this purpose the vane P, Figs. 1271, 1275, 1276, was placed near the circumference of the wheel, and was keyed on to the vertical shaft Q, which turned freely on a step resting on the wheel-pit floor. The upper end of the shaft carried the hand R, Fig. 1271, and directly under the hand was placed the graduated semicircle S, divided into 180° . When the vane was parallel to a tangent to the circumference of the wheel, drawn through the point nearest to the axis of the vane, and the vane was in the direction of the motion of the wheel, the hand pointed at 0° , and, consequently, when the vane was in the direction of the radius of the wheel, the hand pointed at 90° . To prevent sudden vibrations of the vane, a modification of the *hydraulic regulator* was attached to the lower part of the vane-shaft. This apparatus is represented in detail by Figs. 1275, 1277.

The quantity of water discharged by the wheel was gauged at a weir erected for the purpose at the mouth of the wheel-pit.

As the water issued from the orifices of the turbine with considerable force, particularly when the velocity of the wheel was much quicker or slower than that corresponding to the maximum coefficient of effect, there were often such violent commotions in the wheel-pit, that, unless some mode was adopted to diminish them before the water reached the weir, or even the place where the depths on the weir were measured, it would have been impossible to make a satisfactory gauge of the water. For this purpose a grating was placed across the wheel-pit. This grating presented numerous apertures, nearly uniformly distributed over its entire area, through which the water must pass. In the experiments with a full gate, the fall from the upper to the lower side of the grating was generally from 3 to 4 in. The combined effect of this fall and of the numerous small apertures was to obliterate almost entirely the whirls and commotions of the water above the grating. About 4.5 ft. in length of the grating was so nearly closed that but little water passed through that part of the grating; this made it very quiet in the vicinity of the gauge-box.

The weir consisted of two bays of nearly equal length; the crest of the weir was almost exactly horizontal, and the extreme variation did not exceed 0.01 in. The crest of the weir was of cast iron, planed on the upper edge, and also on the upstream face, to a point 1.125 in. below the top; below this there was a small bevel, also planed, the slope of which, on an average, was $\frac{1}{8}$ in. in a height of $\frac{1}{2}$ in.; the remainder of the casting was unplanned. The crest of the weir was $\frac{3}{8}$ in. thick, and was horizontal. The upstream edge was a sharp corner. The ends of the weir were of wood, and of the same form as the crest, except that there was no bevelled part. The crest of the weir was about 6.5 ft. above the floor of the wheel-pit. The ends of the weir projected from the walls of the wheel-pit, and also from the central pier, a mean distance of 1.235 ft. The length of one bay was 8.489 ft., and of the other 8.491 ft., making the total length of the weir 16.98 ft.

The depth of the water on the weir was taken in a gauge-box by means of the hook-gauge L, which is represented in detail in Figs. 1278 to 1280.

The hook-gauge is the invention of Boyden, and is an instrument of inestimable value in hydraulic experiments. In 'Versuche über den ausfluss des wassers durch schieber, hähne, klappen und ventile,' by Julius Weisbach, Leipzig, 1842, page 1, is described an instrument for observing heights of water, having a slight resemblance to the hook-gauge; it was, however, used by Boyden in a more perfect form several years previous to the publication of that work. All other known methods of measuring the heights of the surface of still water are seriously incommoded by the effects of capillary attraction; this instrument, on the contrary, owes its extraordinary precision to that phenomenon. The point of the hook A, Fig. 1279, is represented as

coinciding with the surface of the water. If the point of the hook should be a very little above the surface, the water in the immediate vicinity of the hook would, by capillary attraction, be elevated with it, causing a distortion in the reflection of the light from the surface of the water. The most convenient method of observing with this instrument is, first, to lower the point of the hook, by means of the screw, to a little distance below the surface; then to raise it again slowly, by the same means, until the distortion of the reflection begins to show itself; then to make a slight movement of the screw in the opposite direction, so as just to cause the distortion to disappear; the point will then be almost exactly at the level of the surface.

With no particular arrangements for directing light on the surface, differences in height of 0.001 ft. are very distinct quantities; but by special arrangements for light and vision, differences of 0.0001 ft. might be easily appreciated.

As this instrument cannot be efficiently used in a current, it was placed in a box in which the communication with the exterior was maintained by a hole, when, by partially obstructing this communication, the extent of the oscillations could be diminished at will.

For very exact observations it is essential that the surface of the water should be at rest. If, however, it should oscillate a little, a good mean may be obtained by adjusting the point of the hook to a height at which it will be visible above the surface of the water only half the time.

The movable rod to which the hook was attached was of copper, and graduated to hundredths of feet, but by means of the vernier thousandths were measured, and in some cases ten thousandths were estimated. In later and more perfect forms of this instrument, the point of the hook is immediately under the graduation.

The heights of the water in the fore-bay and in the wheel-pit were taken by means of gauges, placed in the gauge-boxes. Both gauges were graduated to feet and hundredths, and both had the same zero-point, namely, the level of the crest of the weir, so that the difference in the readings at the two gauges gave at once the fall acting upon the wheel; and the difference between the depths of the water on the weir, as observed at the hook-gauge, and the reading at the gauge, gave the fall at the grating.

The heights of the regulating-gate were taken at the rack. The weights used for measuring the useful effect were pieces of pig-iron of various sizes, each of which had been distinctly marked with its weight.

Mode of Conducting the Experiments.—A separate observer was appointed to note each class of data; the time of each observation was also noted, which gave the means of identifying simultaneous observations. To accomplish this, each observer was furnished with a watch having a second-hand; the watch by which the speed of the wheel was observed was taken as the standard; all the others were frequently compared with it, and when the variations exceeded ten or fifteen seconds they were either adjusted to the standard, or the difference noted.

This mode of observing must, evidently, lead to more precise results than that in which a single observer, however skilful, undertakes to note all the phenomena, or even several of them. By the method adopted a regular record is made of the state of things at very short intervals, furnishing the data for a mean result for any required period, and also the means of detecting, in most cases, the causes of apparent discrepancies. It also relieves the experimenter from the distraction of having numerous exact observations to make in a very short time, and leaves him much more at liberty to exercise a vigilant watch over the general course of the experiment.

As it may be useful to experimenters not accustomed to this mode of observing, and at the same time afford the reader some means of judging of the accuracy of the results obtained in these experiments, the following extracts are given from the original note-books. The extracts include the data observed for experiment numbered 30 in Table II. (see TURBINE WATER-WHEEL). This experiment is selected simply because it

gave the maximum coefficient of effect.

When the vane pointed in the direction of the radius of the wheel, the reading of the index was 90°. 0° was in the direction of the motion of the wheel.

Previous to the commencement of the experiments, the apparatus for measuring the useful effect was carefully adjusted. The bell-crank was balanced when there were no weights in the scale. For this purpose the link M, Fig. 1273, was removed, and the chamber of the hydraulic regulator filled with water; weights were then applied to the top of the bell-crank, near the end to which the hydraulic regulator was attached, until the whole was in equilibrium; the final adjustment was made, by placing a weight of about 2 lbs. at the extremity of one of the horizontal arms of the bell-crank,—the arm was retained horizontally until a signal was given, when it was left at liberty to descend, and the time occupied in descending a certain distance was noted; the weight was then removed to the extremity of the other arm, and the same process repeated. The balance-weights were altered until the times of descent were equal. To overcome as much as possible the friction of the fulcrum, the pin forming it was lubricated with sperm-oil, and during the descent the head of the pin was struck lightly and rapidly with a small hammer.

After the bell-crank was satisfactorily balanced, the link M was reattached, and the brake adjusted by means of the screw which formed the connection between the link and the brake. It was adjusted so that a line upon the brake was perpendicular to the axis of the link, when the horizontal arm of the bell-crank was horizontal. The length of the brake was then measured upon this line.

The length of the brake as thus measured was found to be Feet.
9·745

The effective length of the vertical arm of the bell-crank was .. 4·500

And the effective length of the horizontal arm to which the scale was hung, was 5·000

Consequently, the effective length of the brake was $\frac{9·745 \times 5}{4·5} = 10·827778$

The gauges in the fore-bay and in the wheel-pit were carefully adjusted by levelling from the top of the weir. This was repeated by different persons, so as to remove all chance of error.

The Hook-gauge was compared with the weir by a different method. When the regulating-gate of the turbine was shut down as tight as possible, it was still found that a quantity of water leaked into the wheel-pit, exceeding, a little, the quantity that leaked out of the wheel-pit, so that a small quantity continued to run over the weir. The principal leak into the wheel-pit was between the regulating-gate and the lower curb, the leather packing not being perfectly adjusted. The Hook-gauge was firmly attached to a post, placed in the wheel-pit for that purpose, and at a height known to be nearly correct. The regulating-gate was closed, and after the water had arrived at a uniform state, the height of the water at the Hook-gauge was noted, and, at the same time, the depths of the water on the weir were measured directly with a graduated rule. To perform this accurately, a board, about 4 in. long, was held by an assistant on the crest of the weir, at the place where it was intended to measure the depth; the author then applied the rule, previously well dried, vertically, on the top of the weir, in front of the board. On first immersing the rule, the water in contact with it did not stand at the true level of the surface, but formed a little hollow around the rule; it immediately commenced rising, however, and after a few moments came to a level, which was indicated by the reflection of a light from the surface, a lamp being held by an assistant, in a proper position, for that purpose.

The depths on the weir, taken in the manner just described, February 20, 1851, were as follows:—

Depths on the westerly Bay of the Weir.				Depths on the easterly Bay of the Weir.			
inches.				inches.			
0·37	..	..	..	0·36	..	..	..
0·36	..	..	..	0·36	..	..	..
0·37	..	..	..	0·36	..	..	..
0·37	..	..	..	0·36	..	..	..
Means ..	..	0·3675	..	..	..	0·36	..
Or in feet ..	0·0306	..	..	..	..	0·0300	..

While the heights given in the preceding Table were being measured, the depth by the Hook-gauge was constantly 0·0318 ft.; consequently, by this comparison, the zero of the Hook-gauge was 0·0012 ft. below the mean height of the top of the weir, in the westerly bay, and 0·0018 ft. below the mean height in the easterly bay, or 0·0015 ft. below the mean height in both bays. A similar comparison was made February 22, 1851, when the zero of the Hook-gauge was found to be 0·0024 ft. below the mean height of the weir. The mean of the two comparisons, or 0·0020, was adopted as the correction to be subtracted from the reading of the Hook-gauge, to give the mean depth upon the weir.

During the experiments, the levels of the water in the upper and lower canals were maintained nearly uniform. The height of the lower canal, at the place where the water, passing the weir, fell into it, varied a little, depending upon the quantity of water discharged by the wheel. It was highest when the wheel was running with the regulating-gate fully raised, and the brake removed; under these circumstances the surface of the water was from 0·3 ft. to 0·4 ft. below the top of the weir. In the other experiments with the regulating-gate fully raised, the fall from the top of the weir to the surface of the water in the lower canal was from 0·4 ft. to 0·6 ft. The brackets and the planks were not put on until after the turbine experiments were concluded, so that the water passing the weir met with no obstruction until it struck the water in the lower canal.

The obstruction caused by the planks was scarcely appreciable, which renders it certain that the effect of the lower canal, in obstructing the flow over the weir, must have been entirely inappreciable.

Emerson's Dynamometer-Brake.—A reliable dynamometer-brake, like that of James Emerson, Fig. 1281, which would show the amount of power transmitted at all times and under all circumstances, is a useful instrument. When the object is merely to ascertain the amount absorbed or required by a single machine, a series of machines, or a line of shafting, or the necessary means of transmitting power, a temporary attachment of the power-measurer, Fig. 1281, will be sufficient; but there are cases where a permanent attachment of the device is desirable. Such are all cases where the users of mechanical power are hirers, and pay so much for each horse-power used. The method of guessing or averaging, based on width of belt, size of pulleys, and weight of shafting, is hardly accurate enough where the cost of production of power is felt, as where the power is supplied from a steam-engine, or a water source liable to diminish in amount, or fail entirely. The dynamometer-brake should also be so simple in construction, and so exact in operation, as to be readily understood, and afford no possible or justifiable cause for controversy between hirer and letter of power. Such is the design of the device of Emerson.

It is very simple in construction, and direct in operation. The pulley A is loose on the shaft, and receives the power. Its connection with the shaft is made by means of a wheel, keyed or screwed firmly to the shaft in close contiguity with the receiving pulley, its hub, in fact, forming one of the guides to the position of the pulley on the shaft. To connect this fixed wheel with the loose receiving pulley, a bell-crank lever is pivoted into projecting ears on the rim of the fixed wheel on opposite sides, the long arm of which connects with an annular slotted collar on the shaft by means of the short bars B. The short arms of the bell-crank levers connect on the inside of the fixed wheel with two radial bars, one parallel to the outer arm of the bell-crank, and the other at right angles to it, receiving near its upper end a pivot passing through a swivel hung to the rim of the fixed wheel, and having its extreme end pivoted to a stud fixed on the inner side of the rim of the receiving pulley. It will be seen from this description that the strain of the power received through the belt on A will necessarily react on the levers, and, through them, on the fixed wheel, which may be considered nothing more nor less than a support to these levers in sustaining them in position to connect the loose receiving pulley with the shaft.

At B it will be seen the levers are connected by pivots with the sliding collar, in the annular groove of which is seated a strap with which is connected a forked lever, the fulcrum at C. To the end of the long arm of this lever a rod with a short section of machine chain is attached. This chain runs over the cylindrical head D of a pendulum weight E, having a pointer that traverses a fixed quadrant F, properly divided by a scale to denote the relative pressure exerted through the medium of the receiving pulley on the shaft. The pulley G is fixed to the shaft, and delivers the power.

It will be seen that all the motions are absolute, there being no chance for play and back-lash, except that of joints and pivots; and this, by good workmanship, can be reduced to the minimum—too little to be taken into consideration practically. There is no dependence upon springs, spiral, or other forms, which are so liable to be affected by changes of temperature, and so unreliable between extremes of demand. It is a weighing machine as correct in principle as the old-fashioned steelyards or the platform-scales; in fact, it is simply a rotary platform-scale, and each machine may be weighed and tested in place by hanging to the pulley A sealed weights,

and marking the index as each weight is added. The lengths of the connecting-bars and chain are adjustable. The machine may be made of different sizes, and in different styles, suitable for testing all kinds of machinery. One kind especially adapted for spinning-frames, looms, &c.; another to be connected by belt to a line of shafting, or any kind of machine. And one especially adapted for testing turbine water-wheels, to which it is easily applied, with but comparative small expense.

1281.

John F. Gilman's *Hemp-Brake* has an adjustable cross-rail I, Fig. 1282, secured to two inclined arms J arranged in front of the revolving beaters D in such a manner as to admit of the cross-rail being adjusted higher or lower when the hemp is passed over it on its passage to the beaters; the beaters being operated by means of the cog-wheel C.

1282.

1283.

1284.

In the Flax and Hemp Brake of A. W. Hall, Figs. 1283, 1284, a bar F underlies all the beaters C, and by means of a lever-handle may be turned up edgewise to raise all the beaters evenly when

desired. The beaters, provided with openings C, knives and cutters *d*, and saws *e*, are operated by means of pins *a* placed in one or more spiral rows on a cylinder A in connection with the slotted bed B, and a suitable spring or springs, all arranged so that the beaters will work consecutively in pairs and perform the operations of braking, scutching and feeding simultaneously. The knives *d* and saws *e* are attached to a few only of the beaters on the discharge side of the machine to cut the flax or hemp, and also to separate the fibre from the woody portion, and divide it into finer threads.

Fig. 1285 shows J. Bryant's Hemp and Flax Brake. A is the frame, B the bed, and H the treadle. The beater C is operated in such a manner that in the event of its being impeded by tough hemp or flax, it may yield, and thus avoid undue straining. To this end the rod E, which connects this water with the working-beam F, is pivoted at its upper end to a zig-zag bar *h'*, which has a limited range of motion on a pivot which secures it to the beam. A strong spring G upon the top of the beam bears constantly on the zig-zag bar to hold it quite rigidly, but yet allow it and the beater to yield slightly when necessary.

Referring back to Fig. 1268, let E D be a drum, O its axis, and let the direction of rotation of the drum be in the direction of the arrow Q. Let *p* and *q* represent the tensions of the two ends of the strap A and B, respectively. The tension *p* exceeds the tension *q* by an amount equal to the friction between the strap B D E A and the drum D E. If *c* be put for the length of the arc of the flexible brake which embraces a greater or a less arc of the drum or pulley, then putting *r* for the radius of the circle D E, and *f* for the ratio of the friction to the pressure, we have the equation

$$p = q e^{\frac{fc}{r}}. \quad [1]$$

To solve equation [1] for any of the quantities *p*, *q*, *r*, *f*, *c*, in a direct and simple manner has defied the skill of mathematicians who, with much labour and uncertainty, obtained results, from [1], by tables, two systems of logarithms, cumbersome series, and empirical formulas. However, equation [1] is readily solved, in a simple and direct manner without the use of tables, by dual arithmetic, a new art, invented by Oliver Byrne, the compiler and editor of this Dictionary.

From [1] we have $\downarrow, \left(\frac{p}{q}\right) = (100000000, f) \times \frac{c}{r}$; [2]. Since 100000000, = the dual logarithm of $e = 2 \cdot 71828183$.

Ex. 1.—Let *r* = 32 in., the radius of a drum; the coefficient of friction *f* = .473; *c* = 48 in., the length of the arc of contact; the ratio of *p* to *q* or the value of $\frac{p}{q}$ is required.

From [2] the dual logarithm of $\frac{p}{q} = \frac{47300000, \times 32}{48} = 31533333$, which may be reduced to a dual number and the corresponding ordinary number found in a few minutes without extraneous aids. 31533333, = 3, 2, 9, 5, 0, 6, 6, 3, $\downarrow$, = $\downarrow$, (1.3707161). Hence the ratio $\frac{p}{q} = 1.3707161$ exactly; that is, if the tension *p* = 411 lbs., *q* = 300 lbs.

Ex. 2.—Required the length of the arc of contact *c*, without the use of tables, when *r* = 10 in.; the tension *p* equal four times the tension *q*; and the coefficient of friction *f* = .384.

From [1] we have $\downarrow, \left(\frac{p}{q}\right) \times \frac{r}{(100000000, f)} = (c)$; [3]. In this example $\frac{p}{q} = 4$, therefore, since $\downarrow, (2) = 69314718$, $(c) = \frac{138629436, \times 10}{38400000} = 36.10144$ in., the required arc of contact.

BREAD AND BISCUIT MACHINERY.

The process of bread-making is closely connected with that of fermentation. Wheaten flour consists, essentially, of starch and gluten, combined with a small portion of dextrine and sugar. The tenacity of *bread-dough* is due to the gluten present in the flour; the dough being produced by simply mixing the flour with a little water.

If bread-dough be tied up in a piece of fine muslin, and kneaded under a stream of water, the starch will be suspended in the water, having passed through the muslin; the gluten remains as a tough elastic mass, which soon putrefies if exposed to the air in a moist state, and dries up to a brittle horny mass at the temperature of 212° Fahr. Gluten is a compound substance, and is found to contain carbon, hydrogen, nitrogen, and oxygen, in the proportions, nearly, of 24, 20, 3, and 7 respectively.

When gluten is boiled in alcohol, a portion of it refuses to dissolve; this portion is termed *vegetable fibrine*. When this dissolved matter and alcohol are allowed to cool, a white flocculent substance, similar to the *caseine* which composes the curd of milk, is deposited. On adding water to this cold solution, the *glutine* is separated, which resembles the albumen found in considerable quantities in the blood. Although *gluten* presents three substances similar to the three principal components of the animal body, yet gluten separated from the flour by the process just described would be found very difficult to digest, on account of its resistance to the solvent action of the fluids in the stomach; for it is well known that *bread-dough*, composed of flour and water, even when baked, is indigestible. In order to render bread-dough fit for food, it must be rendered spongy, that is, porous, so as to expose a larger surface to the action of the digesting fluids; the most direct method of effecting this is the one adopted in the manufacture of *aërated-bread*, which consists in mixing the flour with water that is highly charged, under pressure, with carbonic acid gas; the mixing by this method is effected in a closed iron vessel, an aperture in the lower part of which is opened, then the pressure of the accumulated gas forces the dough out of the strong iron vessel into the air; the gas which has been confined in the dough expands and gives porosity and sponginess to the dough.

Another process for preparing *unfermented bread* consists in mixing the flour with a little bi-carbonate of soda; this mixture is then made into dough with water acidulated with hydrochloric acid; the bread is thus rendered porous. The chloride of sodium, formed at the same time, remains in the bread. In the making of cakes and pastry, the same object is attained by adding carbonate of ammonia to the dough. When baking, the salt is converted into vapour which distends the dough.

The tenacity of gluten, even in wheaten flour, is liable to variation; and in order to obtain good bread from a flour the gluten of which is inferior in this respect, it is customary to employ a small quantity of alum. This addition being considered unwholesome, it would be better to substitute lime-water, which has been found by Liebig to have a similar effect. Sulphate of copper improves in a very striking manner the quality of the bread prepared from inferior flour, but this salt is far more dangerous than alum.

Wheaten flour is particularly well fitted for the preparation of bread on account of the great tenacity of its gluten. Next to wheat, with respect to glutinous capacity, stands rye; whilst the other cereals contain a gluten so deficient in tenacity that they cannot be converted into good bread.

In the ordinary process of bread-making, the carbonic acid that confers sponginess upon the dough is evolved by the fermentation of the sugar contained in the flour; the flour having been kneaded with the proper proportion, usually about half its weight, of water, a little yeast and salt are added, and the mixture is allowed to stand at a temperature of about 70° Fahr. for some hours. The dough swells or *rises* considerably, in consequence of the escape of carbonic acid, the sugar being decomposed into that gas and alcohol, as in ordinary fermentation. The spongy dough is then baked in an oven, heated to about 500° Fahr., when a portion of the water and all the alcohol are expelled, the carbonic acid being, at the same time, much expanded by the heat, and the porosity of the bread increased. The granules of starch are much altered by the heat, and become more digestible. Although the temperature of the inside of a loaf does not exceed 212° Fahr., the outer portion becomes dry and hard, the hottest part being scorched into crust.

Instead of yeast, *leaven* is often employed, in order to ferment the sugar: leaven is a name given to dough which has been left in a warm place until decomposition has commenced.

The passage of new into stale bread does not depend, as was formerly supposed, upon the drying of the bread consequent upon its exposure to air, but is a true molecular transformation which takes place equally well in an air-tight vessel, and without any loss of weight. It is well known that when a thick slice of stale bread is toasted, which *dries* it still further, the crumb again becomes soft and spongy as in new bread; and if a stale loaf be placed in an oven, it is reconverted into bread resembling new.

With William Watson's bread-making apparatus, Figs. 1286 to 1292, the entire operation, from the mixing of the flour and the other ingredients to the final deposit of the dough in the oven for baking, is performed by machinery.

The mixer consists of a horizontal cylinder, with flanges at each end, and a door at the upper part, throughout its length, for introducing the materials, and through which the agitator or stirrer of the mixer may be removed. The cylinder is supported on suitable feet, and at one end is enclosed for about a third of its diameter by a fixed plate, which descends below the flange, and forms the base or foot at that end; the upper two-thirds of the cylinder end is closed by a sluice-door, which can be raised as required to form an opening for the exit of the dough. The other end of the cylinder is fitted with a piston, which forms a close end for the cylinder during

the mixing; this piston can be traversed in the cylinder, in which it fits sufficiently tight for the expulsion of the dough. An opening is made in the piston for the passage of an axis to carry the agitator of the mixer, which axis is carried by a bearing supported by a bracket from the flange of the cylindrical chamber; the axis at the other end passes through an opening in the sluice-door fitted with a bearing fixed thereto, or the bearing may be separately supported from the flange of the cylinder. The agitator of the mixer is made of a zig-zag kind of form, occupying the diameter of the cylinder, the several limbs of which extend across the diameter of the cylinder, and are all in the same plane, the angles at the extremities being all right angles, or nearly so. It has no central axis passing through it, being supported by a short axis at each end fitting into square holes in the extreme limbs of the agitator, which increase much in strength at those points. In order to strengthen and bind the several radial limbs or blades together, tie-rods are disposed in the direction of the axis, but distant about one-third the radius from the centre. The absence of the central axis prevents the dough collecting in the centre of motion. The limbs are inclined on both sides in opposite directions on opposite sides of the axis, in the manner of a screw, so that in rotating the agitator it forces the dough from one end to the other of the mixer, and on being reversed carries it in the opposite direction. The agitator is dropped in edgewise by a tackle at the door above, the ends of the cylinder being so adjusted that the bosses of the end limbs of the agitator bear hard against the ends and make the axis-holes dough-tight; the end limbs are also in close proximity to the ends, in order to scrape the adhering dough from them. The flour, water, and other ingredients having been emptied into the mixer, motion is communicated to the agitator by winch-handles at either end on the axis, or by means of a wheel and pinion. The dough having been mixed, the agitator and its axis are removed, and a long rack placed in the piston resting in a bearing, substituted for the axis-bearing, which is removed; a pinion is disposed to take into the rack, the axis of which pinion is carried by bearings on the flange, and if the machine is small, may be driven by crank-handles on the pinion axis, but if large, a multiplying toothed gear and fly-wheel shaft is used, by communicating motion to which the piston will be forced forwards by the rack, and the dough expressed as required; the same fly-wheel may also be made otherwise available when removed by placing it on the axis of the agitator. The sluice-door opens by means of a hand-lever, and is so adjusted as to emit the desired thickness of plastic dough, which is of a width proportionate to the size of the machine. The dough, when expressed, is received on an endless cloth moving on rollers and other supports, which is speeded to travel at the same rate as the expressed dough; in emerging, the dough passes under a duster, a perforated box containing flour receiving a lifting and dropping motion from a cam acting on a lever carrying such box; it then passes under a smooth roller, which smooths and reduces the dough to a uniform thickness, and under two or three rollers, if necessary. The thickness of dough which is sufficient for the substance of a loaf then passes under a rotating dividing cylinder, consisting of a series of dividing discs placed on a shaft; these discs are thick in the centre, but thinned towards the edge at the periphery, and present somewhat of a **V** form in a cross-section taken from the centre to the circumference; these discs are disposed on the shaft at distances apart, according to the size of the loaf to be made; there are also dividing edges placed between the discs, parallel with the shaft, separating the circumference into equal parts, which are two, three, or more in number, according to the size of the loaves to be formed and also to the diameter of the divider itself. This divider is driven at a speed uniform with the endless cloth, down upon which it presses and divides the plastic dough into loaves. It does not actually cut the dough, the dividing edges being rounded, but simply presses sufficiently deep creases in it to produce the subsequent separation required; thus the breadth of dough is cut up into a greater or less number of loaves, according to its breadth: after passing under the divider the divided dough passes from the endless cloth on to trucks to be conveyed into the oven. The cloth turns backwards under its carrying roller, from under which the trucks are pushed forwards at same rate as the dough travels, and these move on rails up to the oven-mouth. The cloth dips a little at the delivery end, and turns back under a very small roller, so that the drop of the dough on to the truck is very slight, and all moving at same speed it is readily carried away unintermittently as it is made, and the truck or car, which may or may not be of the length of the oven, is pushed forward on the sole until it occupies its position therein.

The oven is constructed of two, three, four, or more chambers, one above another, each of the width of dough delivered by the machinery; these chambers are of cast or wrought iron, placed between two brick walls, running from end to end of the oven, above the one chamber and below the other; the flues traverse from end to end, the longitudinal flues communicating alternately at opposite ends, so that the mouths of the several baking chambers or ovens are alternately at opposite ends, and must be filled in opposite directions. The fire and first flue is immediately under the chamber, and is considerably narrower than the chamber, in order to modify the heat; the succeeding and upper flues are wider than the lower one, but still considerably less than the width of the chambers, in order to prevent excess of heat at the sides near the brick walls, which would otherwise be apt to burn the bread at each side. When one chamber is full, the truck-carrying rails are shifted to a higher one, and the next truck is carried into the next chamber above, and so on until all the ovens are filled and the full batch delivered. Between the fire and lower flue and the first chamber is a cold-air flue, which protects the chamber from the immediate heat of the fire; the cold air traversing therein is admitted to the fire near the door, and supplies it with air with the door or blower closed, and so keeps the bakehouse cool. The trucks or cars consist simply of two parallel angle-irons, disposed and braced together at a sufficient breadth, and mounted on four or more wheels. The bottoms of the trucks are made of tiles or metal plates, which may have any given pattern, so as to impart an impression to the bottoms of the loaves placed thereon. The ovens are closed by doors that fall down and form a sole or stock-plate in front; the door being jointed to the sole of the door-frame in the manner of a butt-hinge, forms a close joint both with the door closed, and a level surface with the sole of the oven when open.

When baked, the bread is withdrawn from the oven, and may be broken asunder and handled and distributed as usual.

Watson, also, adapts this mixer to what is termed the expansion system of baking, that is, mixing the yeast with a small portion of the dough first, and such first portion with a larger portion, and so on. For this purpose an agitator is employed with a through axis and screw, and fixed radial arms therein, which have bevelled sides.

Fig. 1286 is a side elevation of this machine, which exhibits the arrangement of the one usually employed; Fig. 1287 represents a plan of the same with the dusting-box removed; while Figs. 1288 to 1292 represent some of the parts detached.

Fig. 1288 is a vertical longitudinal section of the mixing and expressing vessel; Fig. 1289 is an end view of the same at the end from which it is driven.

A is the cylinder or containing vessel of wood or iron; if of iron it should be lined with wood. It is mounted on feet or standards B, B, and is furnished with a hinged lid or cover a. C is the piston, which forms one end of the mixer, the other end being fitted with a sluice-door for allowing the dough to pass out. The agitator or mixer properly so called is formed of a series of pieces of iron united together by means of stays b, b. The pieces D, D, are twisted in opposite directions

1290.

from the centre of motion so as to form inclines or screw surfaces, which in rotating have a tendency to force the material on which they are operating in one direction, that is to say, towards the end of the vessel; the end limbs *D', D'*, are somewhat stronger than the others, and have bosses with holes in which short shafts *c, c'*, are inserted from either end, and motion being communicated to which causes the rotation of the mixer. To transit the motion a screw wheel or pinion *d* is fixed on the shaft *c'*; this gears into an endless screw *e* fixed on cross-shaft *E*. On this shaft is fixed a pinion *f* gearing into wheel *g*, mounted on the main shaft *F*, which may be driven by a winch-handle *h* or otherwise. The ingredients having been placed in the mixer, and mixed and treated as before described to form dough and bread, and after allowing sufficient time for the dough to rise, it is forced out of the chamber *A* in the following manner:—We remove the short shafts *c, c'*, from the agitator *D, D'*, and lift it out of chamber *A*, and then close and fix the lid *a*. A rack *H*, Fig. 1290, is now placed in the piston *C*, which it fits into and rests in a crutch-bearing *h'*, formed on the top of the outside bearing of shaft *c'*. The pinion *d* is fitted to slide on shaft *c'*, but to carry it round with it by means of a feather. To communicate motion to

the piston *C*, the shaft *E* is moved in the direction of its length, which has the effect of throwing a pinion *e'* fixed thereon into gear with the rack *H*, and at same time throwing pinion *f* out of gear with wheel *g*, and wheel *i* into gear with pinion *k*, which reduces the speed of rotation of shaft *E*, and the pinion *e'* taking into rack *H*, imparts to it a longitudinal motion, and forces the piston *C* from its position at one end of the cylinder *A* towards the other end, and thereby compressing the dough in that chamber. To allow the dough to escape at the other end of the cylinder *A*, the sluice-door *L* is lifted up by a lever *m* to either of the dotted positions *m'*, shown, the first being suitable for the formation, say, of 2-lb. loaves, and the second for 4-lb. loaves. The gland of bearing *n* of the shaft *c* is previously removed, and a solid plate substituted for it to prevent the dough being forced out thereat. The sluice-door *L* being lifted and fixed, say, at the lowest position, the dough contained in *A* by the pressure of the piston *C* will be forced out of the entire breadth of the opening of the sluice-door, and of regulated thickness, which will be contained in one uniform substance so long as any dough remains in the chamber *A*. From this chamber the dough is received on an endless web *M*, carried on rollers *P* and *P'*, mounted on a suitable framework *N, N*. The endless web *M* is further supported by a table *Q*, extending under the entire breadth, supporting the weight of the dough, which forms a continuous slab, so to speak. It travels at a uniform rate, the endless cloth *M* being driven at the same rate of speed as the dough travels by its expulsion from the chamber *A*. The cloth *M* is driven by a strap-pulley fixed on the axis of *P* and strap *p*, communicating with a rigger on the main driving-shaft *E*, and in its backward course underneath is rubbed in a tray containing flour to prevent the dough adhering. After emerging from chamber *A*, and while travelling on *M*, the dough is submitted to a dusting

1291.

operation from a dusting-box R, mounted above on a fulcrum *q*. This box or tray is the breadth of the dough, and has a perforated bottom. It contains flour, and preponderates on its fulcrum so as to fall against a stop or rest *r*. It is agitated by means of a double arm S, mounted on a rotating axis *u*, the arms coming in contact with a truck-roller *t*, mounted on the side of the dusting-box R. The axis *u* is driven by a strap from a rigger on same axis as P, and power is transmitted thereto by strap-riggers to an axis S', on which the divider T is mounted. This divider consists of a series of cutting ridges arranged in circular and longitudinal directions, the edges of which come down on the endless web, or nearly so. This divider is driven at about the same speed as the dough, which, on passing under it, becomes separated, or nearly so, into blocks of a given size, say, for 2-lb. loaves, which was the size before mentioned as arranged by the sluice-door L. If for larger loaves the mass of dough should be double the thickness, or another divider with larger cavities used. The several shafts are fitted in bearings in the framework N, and otherwise appointed, as shown in the figures. The divided dough, which is prevented sticking to the divider by the flour dredged on it, continues its course on the endless web M until it arrives at P', where the divided dough Q is transferred to a truck U, disposed underneath in readiness for its reception. So soon as the dough begins to fall on to this truck, the truck also has a forward motion imparted to it, by a projection *u* on an endless strap *v* coming in contact with a projection *w* on the under-part of the truck. This endless strap is mounted on suitable pulleys, driven by a strap *x* from the axis of P'. The truck being mounted on wheels and suitable rails Y, travels along with its load towards the oven, which, as seen in the side view and plan, is immediately on end of the machine, so that as the truck is propelled forwards it enters the oven with its load of divided dough or loaves, and as the oven-chamber is by preference just the size to contain one truck, the oven-door is closed, and the baking proceeded with. Another truck is similarly disposed to receive the dough, and is carried forward into another chamber of the oven, and so on. The bottoms of the trucks, which are simply sheets of metal laid on the truck-frames, are roughened or indented, as seen in the plan, Fig. 1287, so as to imprint the bottoms of the loaves; they should also be dusted with flour to prevent the dough adhering. The rails Y are shifted for each oven-chamber, so as to rest on the door of each chamber, and conduct the truck to it. The truck having received its load of dough ceases to be propelled by the machine, but is pushed forward by hand into the oven, which is closed, and another one prepared with the rails to receive the next in succession.

Fig. 1292 represents a longitudinal section of an oven used with Watson's machinery.

W, W, are the oven-chambers, which have their mouths alternately in opposite directions. They are formed between two brick walls X, X, the spaces being divided off by iron plates 3, 4, 5, to 11, the spaces between each pair of plates 3, 4, forming the flues to heat the oven-chambers, while below the plate 11 the furnace V is disposed. In order to protect the lower oven from the

immediate heat of the furnace, plate 11 is covered with a thickness of brickwork, or it may be both above and below, as seen at *z, z*, with an air-flue *o* through the middle, and of equal width with the fire, or nearly so. Air enters at the back end of *o*, which is regulated as required by a sluice-door to limit the supply to the fire through that channel: a constant change of air taking place in this channel assists in preventing the direct heat of the furnace overheating the lower oven-chamber. *Z* is the furnace-door. The flue from the furnace passes up in two branches, one on each side of air-flue *o*, at the end of the lower oven-chamber, then along above it under the second chamber, thence passing up at the end, and back under the third oven-chamber, and so on. To prevent excessive heat at the end of the oven-chambers, fire-lumps, as seen at 12, 12, are used to protect them, the metal plates of the oven being so made as to hold them in position. 13 is a water-tank, to be heated from the waste-head for bakehouse purposes; 14 is a slide-valve in the top of each oven-chamber, enclosed in a case except at the end that is not opposed to the draught of the flues. These valves are opened by thumb-rods when it is desired to allow steam to escape from the ovens; 15, 15, are hollow box ends of metal, closing the ends of the flues, by removing which the smoke-flues may be easily cleaned. These boxes being open from the outside are convenient for the insertion of thermometers, as seen at 16, to see and ascertain the heat of the ovens at all times. The escape of the flues to the chimney is at 17.

Vicar's Machinery employed in the Manufacture of Bread and Biscuits.—Fig. 1293 represents a side elevation of a soft-dough mixing machine; Fig. 1294 a front elevation; and Fig. 1295 a ground plan. Fig. 1296 is a side elevation of a breaking machine, which is employed for preparing the dough for the moulding machine. Fig. 1297 is a sectional elevation through Fig. 1298, which represents a top plan view of the moulding machine; Fig. 1299 is an end elevation. Fig. 1300 is a front elevation of a machine employed for moulding or shaping the dough into loaves or biscuits; Fig. 1302 is a ground plan of the dough-shaping machine; Fig. 1301, a sectional elevation. Fig. 1303 is an end elevation of Fig. 1302 at C.

On Figs. 1293 to 1295, *A, A*, is a tank or reservoir capable of holding water; *B, B*, is a frame-work, to which are connected the following parts:—*C*, a hollow shaft working in bearings in the castings *D*, fixed to the framing *B*; *E* is a shaft capable of sliding in the shaft *C*, and of rotating therewith near the lower part of the shaft *E*; a cross-head *G* is connected and slides on guide-rods *H*. *I* is a skeleton framing mounted loosely upon the shaft *E*, and connected thereto by a nut at *a*, Fig. 1294; *K, K*, are spindles, the upper parts whereof work in bearings in the framing *I*. The lower parts of these spindles are formed with prongs *b*. *c, d, e*, are wheels gearing into each other, that marked *c* is fixed on the shaft *E*, and those marked *d* and *e* are respectively fixed on the spindles *K, K*; *L, L*, are bevel-gearing for imparting rotary motion to the shaft *C*; *M*, a counterbalance weight connected by a chain *f* to the lower end of the shaft *E*, to facilitate the raising of *E*; *N* is a vessel to contain water to mix with the flour; *O, O*, are vessels in which the dough is mixed.

The operations of this machine are as follows:—The operator takes the ferment or yeast commonly used, and instead of mixing it in a trough by hand, as commonly practised, he places the yeast or ferment and flour in one or other of the vessels *O*, and, placing same under the machine, lowers the prongs *b* thereinto, and proceeds to impart rotary motion thereto, the effect of which is to cause the wheels *c* to rotate the wheels *d* and *e*, and also the axes *K*, on which the prongs *b* are fixed, thus producing three distinct rotatory movements simultaneously, namely, one rotation of the framing *I*, which carries the wheels *d, e*, and the axes of the prongs *b*, and another rotation of each of the wheels and axes and prongs, thereby effectually mixing and incorporating the ingredients together into a sponge; and when this operation has been continued a sufficient length of time, according to the judgment of the operator, he removes the tub *O* from under the machine, and places it in another part of the vessel, and taking another tub charges it with yeast and flour as before, and proceeds in this manner with each tub in succession. When the sponge is sufficiently risen or fermented, the tub is again brought under the machine, and the required flour and water added to the sponge, and made by the machine into dough. The dough is then left to *prove*, and when sufficiently proved is removed to the machine, Figs. 1296 to 1299, there to

1296.

1297.

1298.

be operated upon by the brake-rollers of this machine for the purpose of taking the proof out of the dough. As regards this machine, Figs. 1296 to 1299, it should be distinctly understood that its construction forms no part of the machine shown in Figs. 1293, 1294. Both machines are described in conjunction, for the purpose of completing the description of the machinery necessary to be used in manufacturing bread, biscuits, and like articles. When the dough has been sufficiently operated upon by the brake-rollers it is removed from this machine to the shaping machine, Figs. 1300 to 1303, and operated upon thereby in the manner presently described.

We would here remark, that the means above described which we propose to employ, and have found to answer well in practice, for ensuring the proper amount of fermentation forms a very important feature in this invention, for by the use of cold water in hot weather we are enabled to prevent excess of fermentation, and by employing warm water in cold weather we can induce fermentation, the temperature of the water being regulated according to circumstances and the judgment of the operator.

We now proceed to describe the operations of the moulding or shaping machine. With respect

1299.

to the three rollers, marked A, B, C, Figs. 1300 to 1303, that marked A is employed to form the upper crust, and those marked B and C to form the lower crust, the soft dough being placed upon the table D, so as to pass with the two aforesaid crusts between the rollers E and F, by which the whole is compressed as the machine rotates, the endless travelling belt or web G advancing the dough under the moulding mechanism at H, where it is momentarily held still by the mechanism until the knives I descend and ascend by the action of the side rods K. The dough thus scored or shaped now passes onward by the action of the belt G, and when it comes under the stamps at L receives the impress therefrom of words, such as, for example, *machine-made bread*, this movement being simultaneous with the shaping movement with which it is connected; and in this manner the machine continues to mould and shape the dough into the form of loaves, which, as they are advanced forward by the endless belt or web G, are deposited on to trays, the trays being placed upon another endless belt or web N, the operation and construction of this part of the machinery and implements employed being as follows:—First, as regards the trays; they consist of flat pieces of wood, about 3 ft. by 2 ft., with ledges at the sides only thereof. Upon each of these trays is placed a piece of coarsely-woven cloth, and to each end thereof loops of tape, about 6 in. asunder, are affixed, and so as to project beyond the ends of the cloth about 2 or 3 inches, the loops being used for a purpose which will be described in another place. See OVENS. These trays, each with their respective cloth, are separately placed on the part M of the endless belt or web N, so that as this belt advances and comes under the part I of the belt or web G, the shaped

1300.

1301.

1302.

1303.

dough will be deposited on each of such said cloths and trays in succession, the operator dividing the dough when the tray is filled therewith; and in this manner several trays may be filled in succession.

A *bressummer* is a beam placed breastwise to support a superincumbent wall; used principally over shop-windows to carry the upper part of the front, and supported on posts or columns.

BREWING APPARATUS. FR., *Machines de brasserie*; GER., *Braugerüthschaften*; ITAL., *Macchine ad utensili da birraio*.

In making beer, the brewer first mashes the ground malt with water of a temperature of 176° to 182° Fahr., when the *diastase*, or substance containing nitrogen, operates to convert the mass into dextrine and sugar. The greater part of the starch, which has not been changed during the germination, and the *wort*, or new unfermented beer, is ready to be drawn off to be converted into beer. Brewers' grains, or the undissolved part of the malt, is employed to feed cows and pigs, as it contains much gluten.

To find whether malt contains more *diastase* than is necessary to convert its starch into sugar, it is only necessary to add a little fusion of malt to the viscid solution of starch; when this compound is maintained at a temperature of 150° Fahr. for a few hours, and the *diastase* is in excess, the mixture will become far more fluid, and will no longer be coloured blue by solution of iodine.

Distillers take advantage of the excess of *diastase* in malt, by adding from two to four parts of

unmalted grain to the diastase, the whole of which becomes converted into dextrine and sugar, and thus the labour and expense of malting are avoided. The wort produced by infusing malt in water contains not only sugar, dextrine, and diastase, but a large quantity of nitrogenized matter formed with the gluten of the barley. Before subjecting the wort to fermentation, it is boiled with a quantity of hops, usually amounting to from $\frac{3}{10}$ to $\frac{1}{10}$ part of the weight of the malt employed. Hops are found to prevent the tendency of the beer to become sour: the sourness of beer is produced when the alcohol of the beer is converted into acetic acid. Hops contain from 9 to 10 per cent. of an aromatic yellow powder, termed *lupuline*, and is the active portion which contains a volatile oil of particular odour, together with a bitter substance. When the compound of wort and hops is run off into a vat, it is allowed to deposit the undissolved portion of the hops, then the clear liquor is drawn off into coolers, where the temperature of the compound is lowered as rapidly as possible to about from 58° to 61° Fahr.; the cooling is usually expedited by cold water circulating through pipes which traverse the coolers. When the wort is cooled too slowly, the nitrogenized matter which it contains undergoes a change from the action of the air, in consequence of which beer becomes acid. After cooling the mixture, it is placed in the *fermenting tun*, where the fermenting is carried on by adding *yeast*, which is about $\frac{1}{100}$ part of the compound.

It has been found, with the aid of the microscope, that *yeast* is a minute fungoid vegetable that grows in solutions containing sugar combined with particular nitrogenized substances, such, for instance, as a salt of ammonia, and the salts—phosphates of potash, soda, lime, and magnesia.

The conditions under which the yeast plant grows were not ascertained and scientifically examined until recently; for a long time, after the growth of this substance was ascertained, the seeds or germs from which it originates eluded detection, although its growth resembles some of the lower mosses.

The process of brewing may be divided into four distinct stages:—1. The *malting*, of which the object is to produce in the barley the principle which effects the conversion of starch into dextrine and glucose, and which essentially consists in causing the barley to sprout under the influence of a proper temperature and degree of moisture, diastase being formed at the origin of the sprouts, and in the succeeding operation converting the starch into soluble dextrine and glucose. 2. The preparation of the *wort* (*mout*), or saccharification of the malt, which consists in treating the ground malt with water at a suitable temperature, in order to cause the diastase to act on the starch and dissolve the dextrine and glucose which result from this action. 3. The boiling with hops, which consists in heating the wort with hops in order to give it a peculiar taste and aroma. 4. Fermentation, which consists in mixing the cooled wort with a ferment, in order to effect the conversion of glucose into alcohol.

The barley is first placed in large vats of mason-work, with four times its volume of water, being stirred frequently to expel the bubbles of air between the grains, while those which arise on the surface, being generally defective, are skimmed off. The object of this process is chiefly to swell the grains, in order that they may sprout more easily; and it lasts 24 or 36 hours in winter, during which time the water is renewed three times; while in summer it requires only 10 or 12 hours, but the water must be renewed four or five times.

The barley thus swollen is carried to the malt house, a kind of cave or cellar, the floor of which must be kept scrupulously clean to avoid all injurious fermentations. Germination requires the assistance of moisture, air, and a temperature of from 59° to 62°, which conditions are most readily realized in spring or autumn; whence the name of *March beer* is given to that made in the spring, and is considered superior to that made in any other season. In the malt house the barley is spread in a layer of about 1½ ft. in depth, and thus left until it becomes heated; but when it begins to sprout, the thickness of the layer is reduced to 1 ft., and then to 3 in. when the germination approaches the proper point. It is also frequently stirred, in order to renew the air in the interior of the layer. In the hot season, the germination is terminated in 10 or 12 days; while it requires 15 or 20 days toward the close of autumn, the sprout having then become two-thirds as long as the grain.

When the barley has properly sprouted, it is dried rapidly, in order to arrest the loss of the amylaceous matter which would ensue from a longer growth of the sprout and radicles. The drying is first made in the open air, by spreading the grain over the floor of a well-aired granary, and then in a stove traversed by a current of hot air, and called a *malt kiln*. Desiccation renders the radicles of the barley very brittle, but they are easily removed by sifting them in a *winnowing machine* or *fan*. The sprouted barley, thus freed from the radicles, is exposed for some time to the air, when it imbibes a small quantity of moisture, which facilitates its grinding. This operation is effected between horizontal stones, kept at such a distance from each other that the grain is broken and torn without being reduced to flour. The product is *malt*, which is stowed away for future use.

The saccharification of the malt is effected in large wooden vats, having a double bottom pierced with holes, intended to support the barley and facilitate the introduction and escape of the liquid. In the space between the two bottoms are the discharging-tube and one which conveys hot water. When the malt is placed in the vat, water at 140°, and equal in weight to one and a half times that of the malt, is poured in, the mixture being actively stirred with a kind of fork. It is then allowed to rest for half an hour, until the malt is thoroughly moistened, when water at 196° is added, until the temperature of the mixture attains 167°, which is the most favourable for saccharification; after which it is again stirred, the vat covered, and the reaction allowed to continue for three hours. The saccharine fluid, or *wort*, is then conveyed into a reservoir, and thence into the boilers intended for the decoction of hops.

As the first digestion with water only abstracts from the malt 0·6 of the saccharine matter it can furnish, an additional quantity of water at 176° is added, equal to one-half of that used in the

first operation, and is allowed to act for one hour, the liquid produced being added to the first. Lastly, the malt is exhausted by water at 212°, and a liquid obtained which is used in making small-beer. The exhausted malt (called, in this country, *grains*) is used as food for animals.

The wort is heated to ebullition with hops in boilers, which must be kept covered to prevent the escape of the essential oil, to which beer owes its aroma, and are furnished with an apparatus which constantly stirs the mixture. The strength of the wort is sometimes increased by the addition of glucose, molasses, or raw sugar. The wort, thus hopped, is conveyed into reservoirs, where it is clarified by rest, and then run off into other reservoirs, where it is cooled as rapidly as possible, by allowing the liquid layer only a thickness of 4 or 5 in.; the cooling vats being placed in large rooms surrounded by Venetian blinds, in order to afford a free circulation of air. The proportion of hops is about 1 kilogramme for every hectolitre of table-beer, and 2 kilogrammes for every hectolitre of strong beer.

When the wort is cooled, it is poured into a *fermenting vat or tun*, and a quantity of yeast added, varying, according to the season and strength of the wort, from 2 to 4 kilogrammes for every 1000 litres, and maintained at a temperature of about 68°. The fermenting house should be well aired, in order to allow the carbonic acid to pass off rapidly. The fermentation lasts from 24 to 48 hours, producing a large quantity of froth, which falls from the tun into spouts arranged for the purpose, and which, when collected and expressed in bags, constitutes *beer-yeast*.

The tuns are always kept full by adding the liquid separated from the froth. The fermentation of table-beer is completed in small casks filled to the bung, and placed on a scaffolding over a spout which carries off the froth still arising from the liquor; and when the fermentation is finished the kegs are plugged, and the beer only requires a clarification with fish-glue.

Strong beer is allowed to ferment slowly for several weeks after the fermentation in the tun, in large vats, holding as much as 2600 gallons.

BRICK-MAKING MACHINES. FR., *Machine de briqueterie*; GER., *Ziegelpresse*; ITAL., *Macchina da far mattoni*.

The Brick-making, Pugging, and Crushing Machine of H. Clayton, Son, and Howlett, is shown in Fig. 1304. The clay to be made into bricks is thrown into the hopper A of the machine. In this hopper revolves a shaft on which are keyed several small knives, which cut up the clay previous to its being crushed. It next passes through the crushing-rollers B, B, which effectually reduce to powder any stones or hard lumps of clay that may enter the hopper A.

The clay, thus partially prepared, next passes into the horizontal pug-cylinder C, where it is thoroughly mixed and incorporated by the pug-knives which are fixed upon the central shaft. These knives are so placed that they force the clay towards the farther end of the cylinder, where it is pushed by means of a rotary blade or piston, and taken by the small feeding-rollers D, D'. The mixture having been drawn by the small feeding-rollers D, D', into the chambers, which are placed before the dies E, E, situated one on each side of the machine, the brick material issues through the rotary orifice dies in a smooth and regular stream, the angles well formed and the surfaces clean. It is then cut into bricks, of the required size, upon the cutting-tables F, F. This construction of machine is made of two sizes, and requires no masonry foundations, the whole being fixed upon cast-iron foundation-plates G.

The larger machines are worked by a 16-h.p. engine, and each is capable of producing from 20,000 to 30,000 bricks a day, varying according to the quality of clay used.

The smaller machine is generally worked by a 10-h.p. engine; this machine is capable of producing from 15,000 to 20,000 bricks a day.

In ordinary hand-made bricks, the main expense of the process of making, besides the burning, consists in the preparation of the clay, so as to render it sufficiently ductile to allow of its being forced into the moulds by hand-pressure; this necessitates the mixing of water with it, and thus requires also the further process of drying the bricks before placing them in the kiln. The risk of damage and the delay from weather also add materially to the expense of hand-made bricks. The application of machinery to the manufacture of bricks has for its objects economy, certainty, and expedition of production, and improvement in the quality and appearance of the bricks. It is still a question how far these objects have been attained; and out of the large number of machines invented for brick-making, but few are at present in regular work; omitting *tile and pipe-making machines*. The machines now at work may be divided into two classes—those which operate upon the clay in a moist and plastic state, and those for which the material requires to be dried and ground previous to being moulded. In the former class, the plastic column of clay, having been formed in a continuous length by the operation of a screw, pugging-blades, or rollers, is divided into bricks by means of wires moved across, either whilst the clay is at rest, or whilst in motion by the wires being moved obliquely at an angle to compensate for the speed at which the clay travels. In consequence of the clay having to be made sufficiently soft to allow of this wire-cutting, the bricks made are but little harder than those made by hand, and require similar drying before being placed in the kiln; and this drying, together with the expense of preparing the clay in the requisite manner, renders the expenses of manufacture similar to those involved in hand-made bricks. In the second class of machines, a superior finish of appearance is obtained in the bricks by their compression in a dry state in the mould; and the objection of subsequent drying is avoided: but the additional preparation requisite in drying the clay and reducing it to a sufficiently fine and uniformly pulverized state, and the more expensive character of the machinery involved, add materially to the cost of manufacture.

By means of the brick-making machine invented by a Mr. Oates, and described by John E. Clift in a paper read before the Inst. of Mechanical Engineers, the difficulty of previous prepara-

1304.

tion of the clay required in the second class of machines is not incurred; while at the same time the subsequent drying of the bricks required with the other machines is avoided. In this machine the clay is used of such a degree of dryness as to allow of its being mixed up and macerated and compressed into bricks by a single continuous action; the clay being formed into a continuous column and compressed into the moulds by the action of a revolving vertical screw. The clay requires generally no previous preparation beyond that given by the ordinary crushing-rollers, and is sometimes ready to be put into the machine direct from the pit; in other cases, where containing a mixture of stones, it is first passed through a pair of crushing-rollers.

The machine is shown in Figs. 1305 to 1311. Fig. 1305 is an end elevation of the machine;

Fig. 1306 is a front elevation, and Fig. 1307 a plan; Fig. 1308 is a vertical transverse section enlarged; Fig. 1309 a plan of the screw; and Fig. 1310 is a longitudinal section of the machine.

The cast-iron clay cylinder A, Fig. 1308, is expanded at the upper part to form a hopper into which the clay is supplied, and the lower cylindrical portion is about the same in diameter as the length of the brick-mould F at the bottom of the pressing-chamber B. The vertical screw C is placed in the axis of the clay cylinder, and carried by two bearings in the upper frame D: this screw is parallel at the lower part, the blade nearly filling the parallel portion of the clay cylinder, and is tapered conically at the upper part to nearly double the diameter. When the clay is thrown loosely into the hopper, it is divided and directed towards the centre by the curved arm E revolving with the screw-shaft, and drawn down by the tapered portion of the screw into the parallel part of the clay cylinder, in sufficient quantity to keep this part of the cylinder constantly charged, any surplus clay easily escaping laterally into the loose clay in the hopper. The clay is then forced downwards by the parallel portion of the screw into the pressing-chamber B, and into the brick-mould F, which consists of a parallel block. This block is equal in thickness to a brick, and slides between fixed plates above and below; these plates containing the two moulds F and G, Fig. 1310, corresponding in length and breadth to the bricks being made.

The mould-block F, Fig. 1310, is made to slide with a reciprocating motion by means of the revolving cam H, which acts upon two rollers in the frame I connected to the mould-block by a rod sliding through fixed eyes; and the two brick-moulds are thus placed alternately under the opening of the pressing-chamber B to receive a charge of clay; the mould-block remaining stationary in each position during one quarter of a revolution of the cam H. When the brick-mould F is withdrawn from under the press-chamber, the brick is discharged from the mould by the descent of the piston K, which is of the same dimensions as the brick-mould; the piston is pressed down by the lever M worked by the cam N, when the brick-mould stops at the end of its stroke, and is drawn up again before the return motion of the mould begins. A second piston L acts in the same manner upon the second brick-mould G; and the discharged bricks are received upon endless bands O, Figs. 1305 to 1307, by which they are brought successively to the front of the machine, where they are removed to the barrows for conveying them to the kiln to be burned.

The solid block that divides the two brick-moulds F and G is slightly wider than the discharge-opening at the bottom of the pressing-chamber B, having an overlap, so that the making of one brick is terminated before that of the next begins, in order to ensure completeness in the moulding. During the instant when this blank is passing the opening at the bottom of the pressing-

chamber, the discharge of the clay is stopped, and it becomes necessary to provide some means of either relieving the pressure during that period or stopping the motion of the pressing-screw. The latter plan would be impracticable; and in this machine the former mode is established by a very ingenious contrivance, forming in effect a safety-valve, which prevents the pressure in the chamber from increasing when the brick-mould is shut off, and also serves to maintain a uniform pressure during the formation of the brick, so as to ensure each mould being thoroughly and equally filled with clay. This is effected by an escape-pipe P, Fig. 1308, which is similar in form to the brick-mould, but extends horizontally from the side of the pressing-chamber, and is open at the outer extremity. The regular action of the screw forces the clay into this escape-pipe as far as its outer extremity, forming a parallel bar of clay in the pipe: the resistance caused by the friction of this bar in sliding through the pipe is then the measure of the amount of pressure in the machine; and this pressure cannot be exceeded in the machine, for the instant that the brick-mould is full the further supply of clay fed into the pressing-chamber by the continuous motion of the screw escapes laterally by pushing outwards the column of clay in the escape-pipe. The uniform pressure of every brick in the mould up to this fixed limit is ensured by the escape-pipe not beginning to act until that limit of pressure is reached. Its action is similar to that of a safety-valve; and the amount of pressure under which the bricks are made is directly regulated by adjusting the length of the escape-pipe.

The important result of this arrangement is that it prevents any risk of overstraining the machine; and the action of the screw has a special advantage in filling the brick-mould with a continuous uniform stream of clay, which is being constantly supplied at a uniform moderate pressure, so as to ensure the mould being thoroughly filled with a uniform density of clay throughout, without requiring any sudden excessive pressure that would cause the brick to be more dense on the outside than in the centre. The pressing-chamber is made larger in transverse area than the supplying screw cylinder, in order to increase the uniformity of pressure on the clay in the chamber; and the regularity of action is shown by the working of the escape-pipe, which discharges a continuous bar of solid clay, advancing by intermittent steps of $\frac{1}{4}$ to $\frac{1}{2}$ in. of length each time that the brick-mould is shut off and changed. The projecting piece of clay from the end of the escape-pipe is broken off from time to time and thrown back into the hopper of the machine.

The upper side of the solid block separating the two moulds F and G is faced with steel, as shown in Figs. 1308, 1310, and the upper face of the brick is smoothed by being sheared off by the edge of the opening in the pressing-chamber; the under face of the brick is smoothed by being planed by a steel bar R, Fig. 1310, fixed along the edge of the under-plate, having a groove in it for discharging the shaving of clay taken off the brick.

The screw-shaft is driven by bevel-gear from the shaft S, Fig. 1305, which is driven by a strap from the engine, the speed being adjusted according to the quality of the clay or the wear of the screw. The screw is driven at about thirty revolutions a minute, delivering the bricks at the rate of about 30 a minute when at full speed, or one brick for each revolution of the screw. The machine completes regularly in ordinary work 12,000 bricks a day, or an average of 20 good bricks a minute. The amount of power required for driving the machine and the wear of the screw vary according to the material worked. At the Oldbury Brick Works, where two of the machines have been working regularly for three years, the clay is a calcareous marl, and the power required for each machine is about 12 horse-power; the rate of manufacture is 20 bricks a minute.

The wear of the screw varies considerably, according to the material of which it is made and the quality of the clay worked in the machine. In a machine used by Peto and Betts at Cobham, cast-iron screws have been worn out in a short time with very siliceous material; but in two machines working at Gosport for two years, the screws were renewed only once in that time, although as many as three million bricks were made by the machines. In another machine

working for two years at the Blaenavon Iron Works, the screw and mould-block were made of gun-metal, and were found considerably more durable.

With regard to the burning of the bricks made by these machines, no difficulty has been found from the bricks not having been dried before stacking in the kiln; and a very small proportion of waste is made in the burning. Where the clay contains much alumina and retains more moisture in consequence, it is found advisable to stack the bricks in the kiln in *lifts*, as they are termed, of from fifteen to twenty courses each: as soon as the bottom *lift* has been stacked, small fires are lighted to drive off the steam from the bricks, which might otherwise soften those stacked above; the middle *lift* is then stacked and similarly dried, and then the top *lift*, after which the full fires are lighted. In other cases the whole kiln is stacked at once, and no difficulty has been experienced from the lower bricks not being able to bear the weight of the upper bricks.

Sections, elevations, and details of Platt and Co.'s dry-clay brick-making machine are shown, Figs. 1312 to 1319. We take a description of this machine from a paper read before the Inst. of Mechanical Engineers, by B. Fothergill. The clay is taken from the bank in tramway trucks to a large shed or covered storehouse, which keeps the machines from injury while being worked in bad weather, when the clay cannot be got sufficiently dry. Under the shed floor is an arrangement of flues that can be heated to dry the clay as it is taken from the bank. From this shed the dry clay is taken by an elevator A, Figs. 1312, 1313, and shot into a hopper at the upper end of a revolving pulverizing machine B, consisting of a screen fixed at a slight inclination from a horizontal position, and so constructed and arranged that the clay is pounded and forced through it by crushers, while stones and other hard substances are ejected at its lower end.

which the bricks are formed. C is the sliding mould-charger, to take the clay from the hopper D to the brick-moulds; an adjustable striker E is fixed upon the front of the hopper to gauge the charge of clay when being conveyed to the moulds by the forward motion of the lever F, which is actuated by the cam G, shown dotted in Fig. 1319, fixed upon the bottom cam-shaft H. The lower ram I rests upon and is actuated by the cam-shaft H, and is formed with four pistons K upon the upper surface: each of the pistons fits into a separate brick-mould. The top cam-shaft L gives motion to the upper ram M, which is also formed with four pistons N upon the lower surface, exactly corresponding with the four lower pistons K and fitting into the same brick-moulds. The two cam-shafts are driven at the same speed by the spur-wheels O which are driven by the pinion P.

The cams RS lift the upper ram M, and are so arranged as to produce two successive elevations and allow two falls of the ram and pistons in the formation of each series of four bricks made at each revolution of the machine. The first blow of the pistons, after being raised by the first cam R, drives the clay out of the four apertures in the mould-charger C, which have been brought directly over the four brick-moulds by the motion of the lever F; and compresses the clay into the moulds, thereby expelling the air from it: a very heavy blow is given by the pistons upon the clay, the total weight

of the falling parts being nearly 1 ton. The pistons are then raised by the second cam S to a suitable height to allow the mould-charger C to move back to its former position underneath the hopper D, for the purpose of being filled with another charge of clay. A second blow of the pistons then takes place, thoroughly condensing the clay in the moulds; and the final pressure to finish the bricks is then given on the top side by the pressing cams T acting upon the friction-rollers U which are fixed on the upper ram M: this downward pressure is met by a simultaneous upward movement of the lower pistons K, given by the eccentric form of the bottom cam-shaft H. The shaft H is also formed so as to raise the bricks up to the top surface of the mould-bed B after the pressure is completed, whence they are removed to the table V by the forward movement of the mould-charger C, when delivering the charge of clay for the next set of bricks. An india-rubber buffer-spring X is placed in the upper ram M, to receive the concussion of the fall of the ram upon the cams RS, in case the machine should from any cause run without clay. By this arrangement of applying the pressure both below and above simultaneously, the bricks are kept in continued motion, sliding through the moulds whilst the severe pressure of the cams is taking place; which gives a fine polished surface to the sides of the bricks, and ensures the angles being all filled up completely square.

The faces of the moulds are formed of wrought-iron plates casehardened and secured by pins, so that they can be easily removed and replaced, when necessary.

The whole process is thus self-acting, from the crude clay being fed into the pulverizer out of the drying-shed, to the bricks being finished by the press ready for the clamp or kiln; and no waste of material takes place, other than the rejection of the stones by the pulverizer in the first process; and no process of drying the bricks being requisite, they are taken direct from the machine and stacked in the kiln ready for burning, thus avoiding all risk of damage from handling whilst in an unbaked state. The clay may be mixed with breeze or ashes, or chalk for white bricks, or other such substances, the machines working any sort of clay or mixture equally well; the press by its extreme pressure forms a perfect brick in an unburned state, and an uncommon hardness and closeness is obtained.

By this process of manufacture, within a quarter of an hour, clay may be taken from the shed in its crude state, and the bricks delivered by the press, taken by a tramway, and landed in the kiln ready to be burned in the usual way. Buildings have been erected with these bricks; and

it is found that with care in setting the bricks the inside surface is as perfect as the outside, and is finished without any occasion for plaster. For bricks so perfectly formed it might be expected that great care would be required in manipulation, and the production must necessarily be slow. The reverse is however the case, and the following is the result of actual working. The machinery prepares the clay and completes the bricks at the rate of 30 bricks a minute, or 1800 an hour; in one day of 10 hours' work 18,000 are produced, giving a total production of 5,400,000 a year of 300 working days. Thus with a very moderate amount of attention paid to burning, which is rendered easy by the great firmness of the bricks, 5,000,000 of perfect bricks may be burned from one machine in a year.

Fig. 1320 is of a brick machine, which requires from 6 to 8 horse-power to produce 12,000 to 18,000 bricks a day, according to the nature of the clay operated upon. This small machine of Clayton and Howlett crushes the clay, pugs the material, and moulds the bricks: it is a very complete machine.

The rough clay A is taken from the heap in barrows and wheeled up an incline, or it is drawn up the incline by suitable gearing by the power of the machine, and then shovelled into the feeding-hopper B, in which revolves a shaft which has several small knives fixed upon it; the duty of these knives is to cut up the large lumps of clay, and at the same

1320.

time to press it down upon the rollers incased in B, and further, to prevent the receiving-hopper from becoming choked.

The crushing-rollers next grip the clay, and crush all hard lumps and large stones, and force the thus partially-prepared material to the pug-cylinder C, in which revolves a strong shaft fitted with a number of knives, set in such a manner so as to form sections of a screw, which by their rotary action thoroughly *pug* or mix the *clay*, and at the same time force the homogeneous mass towards the end D of the cylinder, where it passes through the die or moulding orifice on to the cutting-off tables.

David Murtha's *brick machine*, Fig. 1321, has a series of rotating circular disks I, arranged so

as to operate upon the clay, which, after being forced from the narrow opening *b* of the clay receptacle, is cut into strips of the proper width of the length of the brick. In front of the disks *I* is a transverse series of similar disks *J*, for the purpose of cutting the strips of clay into the proper widths. The feeding-table *E'E'e* is made in sections, so as to admit of being passed successively through the machine.

Fig. 1322 shows S. M. Parish's apparatus for drying bricks. It has a combination of adjustable supports G, to prevent the weight of the bricks from sagging the board, which rests on a carriage. A rod which connects

the slats is pivoted on journals, and used in connection with a carriage E and movable rails. B B are covered tracks; G H adjustable loading-stays; B' B' movable extension-rails; A A posts; I stringers; C the return tracks; and D the roof of the shed.

Pugging.—The pug-mill is one of the most useful and essential implements in brick and tile manufacture. The object of pugging the clay is to bring it into a complete homogeneous state of consistency. In the clay as dug, with rare exceptions, the strata are various. In some portions the unctuous, in others the sandy, siliceous, or other qualities prevail. In order to work brick-

clay properly and effectively, it is indispensably necessary to incorporate its various component parts, and to make it of one *uniform character*. The pug-mill is therefore the most valuable and important precursor of the subsequent processes of brick as well as of *tile manufacture*, inasmuch as the equal consistency and integrity of the raw material can alone ensure the uniform strength and good quality of the completed brick or *tile*. H. Clayton and Co.'s improved Archimedian knife pug-mill, Fig. 1323, produces these desirable results.

In Fig. 1323, A is a cast-iron cylinder into which the clay required to be pugged is thrown. Upon the central shaft B are fixed wrought-iron steel-tipped knives C, C, C, C (so placed as to form a section of a screw), which cut up and mix the clay, and at the same time force it downwards to the outlet D at the bottom of the cylinder, which can be adjusted with a sluice-door and lever for letting the clay out at certain times.

There is a door E, fastened with a strong wrought-iron bar, in the middle of the mill, for convenience, when it is necessary to inspect and clean the knives from roots and other foreign materials that may adhere to them.

The bottom end of the pug-shaft B works in a steeled bushed step F.

Clayton, Son, and Howlett's Brick-cutting and Self-delivery Table, Fig. 1324.—When a stream of clay of sufficient length to cut the desired number of bricks has been expressed from the die or

1324.

moulding orifice of the machine on to the receiving-rollers *a, a, a*, the single cutting-wire *b* is caused to pass through the stream of clay to sever or divide it. The desired length of moulded clay being now cut off from the mass, it is drawn forward by hand over the receiving-rollers on to the cutting or plate table *c*, in front of the cutting-wires *d, d, d*, so that the expression of the main stream of clay from the moulding machine may continue without interruption, whilst the severed portion intended to be cut up remains stationary.

This portion of the moulded clay is now ready to be cut up into bricks, which is done by causing the wires to pass through it by means of operating the handle *e*, which simultaneously transmits motion to the pinions *f, f*, the racks *g, g*, and the whole rack-frame *h, h*, carrying with them the series of wires *d, d, d*, and also the plate-table *c* and platen or board *i*, causing the plate-table *c* to pass from under the clay through which the wires are passing, and to be replaced by the portable platen or board *i*. The handle *e* is now to be moved in the opposite direction, by which the whole movable parts described are returned to their original position, taking with them the clay now in form of cut bricks on the platen or board *i*: this platen or board *i* is then removed with the bricks upon it. Another board being substituted, the machine is now in position to repeat the operation.

One of the great advantages of this table over those previously in use consists in the perfect ease with which a large number of bricks can be cut and safely removed from the machine in a given time. This is effected, not by increasing the quantity of material coming from the moulding machine, but by the greatly-increased facility for the required operations, and by lessening the number of the waste pieces of moulded clay. It also wholly supersedes the risk and labour in the removal of the bricks from the machine. In other machines of the kind the cut bricks have to be removed from the table separately to place them on the barrow, rendering this portion of the operation subject to loss or damage of the bricks by negligence of the workmen.

In this table these practical objections are avoided, as by its arrangement a positive number of (ten or twelve) bricks is cut and delivered, by one simultaneous operation, each time of cutting on to a receiving palette or board ready to be placed upon the brick barrow without the cut bricks having been handled in any way.

This table also possesses the advantage of being available for any variation of length of brick and for any required angle of cut, or for arch bricks, simply by removing the two strain-bars between which the wires are stretched, and by replacing them with other bars of the desired gauge, thus superseding the necessity of the outlay hitherto necessary for a series of separate cutting-tables. The action of this table is such, that whilst the wires are passing through the

clay, it is held true and firmly against a smooth metallic resistance-plate; thus the finish of the cut is clean and the ends of the bricks are square, and not left ragged or torn.

Hand-power Brick-pressing Machine, Fig. 1325.—This little machine of Messrs. Clayton and Howlett is the most perfect of the kind that has fallen under our notice. A is the mould box or chamber,

1325.

upon the piston, and the lever is brought over to the right stop I. The curved end K travels upon the friction-rollers, and the whole cam-shaft, side arms, top-cover, and the piston with the brick, are lowered until the lever arrives at a perpendicular position, by which time the cover has been brought into its proper position on the top of the box by the guides; the cam-shaft is now entirely supported by the side arms and cover, and simply reciprocates upon its own centre, which motion causes the cam to raise the piston and compresses the brick. The lever is now thrown sharply back to the opposite side, which action causes the curved end of the lever to ride upon the roller, and bodily raises the cam-shaft, the top-cover, and the piston, and delivers the brick ready to be taken away.

One of the great features in this press is the patent self-lubricating piston, whereby a great saving of time is effected, and the great desideratum of preventing the adhesion of the brick to the mould has been obtained.

The process of washing is resorted to for the effectual separation of limestones and other substances from earths into which they, injuriously to the manufacture of clay wares, intrude; or for those classes of bricks, such as London stocks, with which for a special object chalk is largely mingled with the clay. For such object Roller and Harrow Wash-Mills are much used, and they are applicable separately as chalk-mills. These mills are also used in cases where a special manufacture renders the washing of the clay, or of the whole of the raw material, necessary.

1326.

Fig. 1326 represents a cross-section of one of Clayton and Co's Clay and Chalk Washing-Mills; there are two races D, C, the minor one D for chalk, and the outer C for clay. A is a central iron shaft,

supported at the top, bottom, and centre by the steps V, W, W'; to this shaft is fixed a 6-way beam-socket Y, into which are fitted and secured six harrow beams, two of which are shown at E, E, Fig. 1326, radiating from Y. Upon these beams E, E, are fastened harrows F, F, by means of chain slings g, g, which when the mill is at work permit of the harrows making a zig-zag motion. The chalk race D is furnished with three spike-rollers, one of which is shown, in Fig. 1326, at H. Besides the harrows we have mentioned, there are two others attached to their respective beams E in the chalk race D.

The ends of the harrow beams E are supported by tie-bolts K, K, K, K, which are secured to a lug-ring b at the top of the centre shaft A. The tie-bolts are carried through the lugs on the beam-caps p, and can be tightened up when required by the nuts at p. Scrapers T T are fixed at the ends of the beams to keep the sides of the races clean. Motion is given to the central shaft through a bevel-pinion R on the lay shaft S and bevel-wheel O keyed on the central shaft A. This bevel-wheel O works on antifriction rollers P, P, fitted beneath it. Chalk is thrown into the hopper B (secured on to and revolving with the beams E), and passes into the chalk race D, where water is introduced. The material becomes quickly liquefied, and passes through the apertures Z Z into the clay race C, wherein is thrown the clay, &c., required to be washed, which is here worked by the harrows, reduced to a thick liquid state, and amalgamated with the chalk water. The limestones precipitate, and the liquid mixture is let off through the sluice L and outlet M to the "back," or reservoir, where it remains until of suitable consistency for being moulded.

Crushing.—In Fig. 1327 A is the receiving-hopper of Clayton's Clay-crushing Mill, into which

1327.

the earth requiring to be crushed is thrown. B, B', are cast-iron chilled rollers, bored and keyed upon wrought-iron shafts, which work in gun-metal bearings. The rollers B, B', may be set nearer or closer, as desired, by means of the set screws C, C', so that the stones and lumps of hard clay may be crushed as well as the finer material. The machine is fixed upon a strong timber framing; round the receiving-hopper A a platform is usually erected for the convenience of wheeling the clay to the mill.

Vertical Pugging and Moulding Machine.—The machine of which Fig. 1328 is a side elevation and Fig. 1329 a plan, is sometimes termed a *two-process* brick-making machine. This machine of Clayton and Co. is very substantial and complete; C is a cast-iron vertical cylinder fitted at top with a sheet-iron hood or guard H (for convenience in feeding), mounted and bolted firmly upon a strong cast-iron framework F F and foundation-plate F'. S S are two side frames, also bolted to framework F F and to foundation-plate F', whose duty is to carry the expressing or mould-feeding rollers R R. The vertical cylinder C is furnished with a strong, square, wrought-iron pug-shaft S', turned at ends, and into which are fitted and secured single wrought pugging-knives or blades B B B B, so disposed as to form sections of a screw, and at bottom of the cylinder one double delving-blade or sweeper D, forged in form of 8. Motion is given to this pug-shaft S' by means of bevel-wheel W, keyed upon the vertical shaft, and pinion W fitted upon the pulley-shaft A underneath the cylinder-plate F. The vertical shaft S' runs in a step T bolted to the foundation-plate F', and is supported by a collar B' in the cylinder-plate F, and also by a bridge-bar B' fitted at the top of cylinder, thus rendering the whole substantially rigid. A sluice-valve V is adjusted at the bottom and outside of the cylinder C, opposite to the expressing-rollers R R, fitted with regulating-screw and wheel S'. Two wrought-iron carriage-bars C' C' are bolted to cylinder-frame F F and roller-frame S S, into which are fixed small rollers R' R', making a framework bridge for the passage of the pugged earth from the sluice-valve V to the rollers R R.

P P are segmental packing-pieces of wrought iron inserted in suitable recesses inside the roller side frames S S fitted with set screws, so that they may be pressed against the ends of the rollers R R, to prevent the passage of the clay between the rollers and the side frames, and compensate for the wear of these parts. The rollers R R receive motion by suitable strong spur-wheel gearing from the horizontal pulley-shaft A and pinion P', through the intermediate shaft

A² and wheel E to lower feeding-roller shaft A³ and wheel E', the top roller being geared on the opposite side by a pair of spur-wheels G G.

N N are steel scrapers with regulating-screws fitted upon the delivery mouth-piece of the machine, for cleaning the rollers as they revolve.

In front of the delivery mouth-piece is attached the rotary die or mould, of which M M are the rollers, which are covered with cloth or fustian. These side moulding-rollers are driven by small bevel-wheels and horizontal shaft N on the top side of the die, receiving motion from the lower roller-shaft A³ by pulleys and belt. A water-tank T¹ is attached over, fitted with pipes and regulating-cocks, for keeping moist the cloth-faced rollers M M, to prevent the clay adhering thereto as they rotate. In front of the rotating die or moulding orifice is shown the self-delivery cutting-table, of which a description has already been rendered.

The brick-making machinery, invented by Henry Large, which is employed to make hard bricks, and especially those which do not require burning, is illustrated by mechanical drawing, Figs. 1330 to 1337.

The materials of which the bricks are to be made when properly mixed are placed in a mould, which is then brought under a plunger worked by a crank-pin, eccentric, or other equivalent mechanical device, whereby the materials in the mould will become consolidated and compressed into the form of a brick. The mould with the compressed brick therein is then carried forward to a second plunger, the rod of which is connected by a rocking lever to the rod of the first plunger, so that immediately after a brick has been compressed the brick that has just been passed forward will be by the descent of the second piston forced out of the mould on to a receiving-table attached to the end of a weighted lever, from which the finished brick is removed by hand, and then the table is carried up by a weighted lever into its original position, ready to receive another brick.

1332.

Fig. 1330 is a side elevation, and Fig. 1331 a front elevation, of one of Large's brick machines, which may also be employed for moulding or compressing peat or small coal into bricks of artificial fuel.

A plunger *a* is employed, to which a vertical reciprocating motion up and down in suitable guides is communicated by an axis *b* driven in any convenient manner by steam, horse, or manual power, and carrying a crank-pin *b**, which is received into a horizontal slot in the stem of the plunger *a*; beneath which is a table *c* to support the moulds *d*, which moulds are shown detached in side view at Fig. 1332, end view at Fig. 1333, and plan view at Fig. 1334, and are rectangular frames open at the top and bottom, and perforated on both sides and both ends. The mould is placed on the table, and into it there is first inserted an iron pallet or bed, shown detached in Fig. 1335; this bed is perforated, and having a projection upon it to form an indent in the brick to hold the mortar. The brick-making composition or material, or peat, turf, or small coals, or other substance to be operated upon, is then filled into the mould in suitable quantity, and over it is inserted another pallet also perforated, and having a projection upon it to form an indent on the other side of the brick. Or plain iron pallets can be used, which would be the case for compressing peat, turf, or small coal. Then the iron plate *e*, shown detached Fig. 1336, which gives the required thickness to the brick, is put on the top pallet. The mould thus charged is pushed along the table *b* and brought under the plunger *a*, and the plunger coming down on the top of the iron plate *e* powerfully compresses the contents of the mould and forms the material into a brick, or any other form desired. The plunger immediately rises, and the first mould is pushed on, and the plate *e* is taken out, whilst another similarly charged mould is brought into position to receive the pressure at the next descent of the plunger. Each mould after passing the moulding plunger is pushed onwards until it comes over an opening in the table, as at *c**, slightly larger than the inside of the mould. While the mould is resting on the

table *c* it receives a second plunger at the lower end of the rod *f*, whereby the brick or substance in the mould is forced out of it on to a palm *g*, which is held up against it by a counter-balance weighted lever *h* acting against the lower end of the vertical rod *i*. The second plunger has a reciprocating vertical motion given to it by means of a link, whereby it is connected to a rocking lever *j*, the opposite end of which is similarly connected to the rod of the first plunger *a*. The finished brick or substance in the mould, together with the bottom and top pallets, remain on the palm *h*, their weight being sufficient to keep

the palm down. As each brick or substance is removed the palm *h* again ascends to receive the next brick, and the empty mould is conveyed away to be refilled. On the same principle that one brick or substance is compressed in the manner described, two or more can be made at one stroke by using several plungers, and also can be driven out of the moulds by a second set of plungers.

Figs. 1337, 1338, show another arrangement of Large's machine. The bricks made by this machine are not burnt, but merely mixed, in proportions of sand and cement, and pressed into moulds of the required size; they are then laid on the ground or on shelves for forty-eight hours, to harden, after which they are stacked in the open air, exposed to the weather, and in fourteen days are ready for use. These bricks increase in hardness for twelve months, after which they resist the action of frost, and do not absorb moisture. The first patent for making concrete bricks was that of Hustwayte and Gibson, in 1853. In 1856 L. D. Owen introduced a plan of making concrete bricks which has been worked most successfully in South Wales. In the town of Newport many of the houses are built of these bricks, and one firm in the town manufactures 50,000 a week.

Thomas Don, the eminent machinist, gives the following as the result of some experiments by hydraulic pressure:—

	Showed 1st flaw.	Crushed at.
	Tons.	Tons.
1. A stock brick, as ordinarily made, cracked at	1½	8
2. A compressed concrete brick, composed of 1 part cement and } 6 parts coarse sand, 14 days made	10	18½
3. Hand-made concrete brick, 1 part cement, 6 parts burnt ballast } and hoggin mixed, made 7 weeks	7	17½
4. A malm paviour, very well made and burnt	5	31½

Moulding of Bricks.—The mould, Fig. 1339, for forming the bricks is $\frac{1}{12}$ to $\frac{1}{20}$ larger than the size of the brick to be made, as the clay shrinks in burning.

Brick-moulds may be made of any hard wood, which should be thoroughly seasoned, and the edges, which wear very fast, should be protected by a thin strip of iron. Moulds should be frequently gauged, especially when the brick-makers find their own moulds, or the bricks made will vary very much in thickness. Brick-moulds are now made lined with brass, which shows the importance attached to the correct moulding of bricks.

Two methods of moulding are employed, namely, *slop* and *sand* moulding. In the former the mould is dipped in water every time it is used; in the latter it is sprinkled with fine sand, or with ashes from an old brick kiln. In either case the brick-earth should not be used too wet; and it should be pressed carefully and thoroughly, so as to fill the moulds. The superfluous earth is then removed by a *strike*, which is a straight-edge of wood or metal passed along the top of the mould, and pressed well down on its edges. Steel strikes are best, as wooden ones are cut by the edge of the brick-mould, and then scrape away too much of the surface of the brick, thereby rendering its thickness irregular.

Bricks made by hand are moulded on boards or benches; in India, mostly on the ground, which should be made as smooth and even as possible. At Roorkee, smooth plastered terraces have been used, the surface sprinkled with fine sand or ashes. The bricks are moulded side by side till the terrace is covered; they are then left on it till dry enough to be turned on edge without loss of shape; then, after another short interval, stacked, or, as it is called, laid in a *hack*.

Drying.—The bricks should be left in stack until thoroughly dry, as, if put into the kilns damp, the strong heat of the kiln will dry them too suddenly, and probably split or partially disintegrate them.

In drying bricks, they must be protected from the sun, wind, rain, and frost; and each brick must be dried uniformly from the surface to the centre.

Slop-moulded bricks are usually dried on flats or on drying-floors, where they remain from one day to five or six, according to the state of the weather. When spread out on the floor they are sprinkled with sand, which absorbs the superfluous moisture, and renders them less liable to crack in the sun. After remaining on the floors until sufficiently hard to handle without injury, they are built up into hacks under cover, where they remain from one to three weeks, until ready for the kiln. In wet weather they are spread out on the floor of the drying-shed, and great care must then be taken to avoid draughts, which would cause the bricks to dry faster on one side than the other. To prevent this, boards set edgewise are placed all round the shed to check the currents of air.

The ground required for drying bricks in this manner is comparatively small, as they remain on the floors but a short time, and occupy little space when hacked in the hovels. The produce of a single moulding-stool by the slop-moulding process seldom exceeds 10,000 a week, and the area occupied by each stool is, therefore, small in proportion. Half an acre for each kiln may be considered ample allowance for the working floor and hovel.

In places where brick-making is conducted on a large scale, drying-sheds are dispensed with, and the hacks are usually built in the open air, and protected from wet, frost, and excessive heat, by straw, reeds, matting, canvas screens, or tarpaulins.

Bricks intended to be clamp burnt are not dried on flats, but are hacked at once on leaving the moulding-stool, and remain in the hacks much longer than bricks intended to be kilned. This is rendered necessary by the difference between clamping and kilning. In the latter mode of burning,

the heat can be regulated to great nicety; and if the green bricks, when first placed in the kiln, be not thoroughly dried, a gentle heat is applied until this is effected. In clamping, however, the full heat is attained almost immediately, and, therefore, the bricks must be thoroughly dried, or they would fly to pieces.

We append some useful directions and practical remarks on the burning of bricks, taken from 'The Roorkee Treatise on Civil Engineering,' edited by J. G. Medley.

The *burning of bricks* is an operation of great nicety, because if not burnt enough they will be soft and worthless, and if overdone, they vitrify, lose their shape, and often run together so as to be inseparable and useless. Various methods have been adopted for producing the due degree of firing. In general, bricks are burnt, both in America and England, in a brick kiln; but in London, the burning constantly takes place in the open air, the bricks being made up into immense quadrangular piles or clumps, consisting of from 200,000 to 500,000 bricks in each. In India both kilns and clamps are used.

English Kiln.—A brick kiln, as usually constructed, is formed of bricks built in a square form like a house, with very thick side walls, and a wide doorway at each end, for taking in and carrying out the bricks; but these doors are built up with soft bricks laid in clay, while the kiln is burning, and a temporary roofing of any light material is generally placed over the kiln to protect the raw bricks from rain while setting, and so made that it may be removed after the kiln is fired. The English kilns are generally 13 ft. long, 10 ft. wide, and 12 ft. high, which size contains and burns 20,000 bricks at once. Wood is the usual fuel used in these kilns, and they are frequently built with partitions, for containing the fuel and for supporting the bricks, in the form of arches, as will be presently described. The bricks must be placed in the kiln with great care, and this operation is called *setting* the kiln, and is performed by one or two men who understand the business, and to whom the raw bricks are delivered in barrows. The form of the setting is pretty nearly the same in the country kilns and in the London *clamps*, except that in the latter the arches are much smaller, because wood is only used for kindling and not for burning.

The bottom of the kiln, Fig. 1340, is laid in regular rows, of two or three bricks wide, with an

interval of two bricks between each, and these rows are so many walls extending lengthwise of the kiln, and running quite through it; they are built at least six or eight courses high, so as to give the kiln the appearance shown in the figure, which is an end view of the kiln. And this is permanent work, in kilns that have fire-places built in their floors, or it has to be formed every time the kiln is set, when it has a flat bottom. The intervals between the walls are laid first with shavings, or brushwood, or anything that will kindle easily, then with larger brushwood cut into short lengths, that it may pack in a compact manner; and lastly, with logs of split wood. This done, the over-spanning or formation of the arches is commenced; for this purpose every course of bricks is made to extend $1\frac{1}{2}$ in. beyond the course immediately below it, for five courses in height, taking care to *skintle* well behind, that is, to back up, or fill up with bricks against the over-spanners. An equal number of courses, on the opposite side of the arch, is then set as before, and thus the arch is formed, which is called *rounding*, and is a nice and important operation, for if the arch fails or falls in, the fire may be extinguished, or many of the bricks above the arch may be broken. The intermediate spaces between the arches are now filled up, so as to bring the whole surface to a level, and then the setting of the kilns proceeds with regularity until it obtains its full height. In setting the kiln, not only in its body, but in the arches also, the ends of the bricks touch each other, but narrow spaces must be left between the sides of every brick for the fire to play through, and this is done by placing the bricks on their edges, and following what is called by brick-makers the rule of three upon three, reversing the direction of each course, as shown in Fig. 1341. The kiln being filled, the top course is laid with flat bricks, so disposed that one brick covers part of three others; which process is called *plating*.

Indian Kiln.—There are various methods in practice in India of filling and firing a kiln of the same construction as the above.

1st. Laying alternate complete layers of wood fuel and of bricks, the flues passing only 5 or

6 ft. into the interior of the kiln, all the rest of the floor being occupied by the first layer of fuel.

2nd. Arranging the bricks in a second set of flues five or six courses above the first, and crossing them at right angles; and so on with flues alternately in these two different directions to the top; or,

3rd. Having, as before, one series of flues at bottom, and above alternate complete layers of bricks and fuel.

Firing.—The kiln being filled, the *firing* succeeds, and this is a most delicate operation, and one that requires much experience. The fuel is kindled under the arches, and requires close watching and attendance, for being in a large body, it would burn violently and produce a sudden heat such as would crack and spoil the lowest bricks. To check the burning, the arch holes or mouths are closed with dry bricks, or even smeared with wet clay, in order to prevent the entrance of air and the rapid combustion that would ensue. The fire must be made to smother rather than burn, as in making charcoal, in order that by its gentle heat it may evaporate the humidity that remains in the bricks, and produce drying rather than burning. This slow fire requires to be kept up about three days and three nights, by occasionally opening the vents to supply air and additional fuel, and closing them until the fire *gets up*, as the workmen call it, that is to say, until it has found its way through all the chinks and openings between the bricks, and begins to heat those at the top of the kiln. To ascertain the progress of the fire, the top of the kiln must be watched, and as soon as the smoke changes colour from a light to a dark hue, the drying is complete, and the fire may be urged. The first, or white smoke, called water-smoke, is in fact little else but the steam of the water while evaporating, and when that is gone, the real smoke of the fuel succeeds. Now the vents may be opened to admit full draught, and a strong fire kept up for from forty-eight to sixty hours; but the heat must not be white or so strong as to melt or vitrify the bricks, and whenever it appears to be increasing too rapidly, the vent must be partly closed. By this time the kiln, if it contains thirty-five courses, will be found to have sunk about 9 in.; but the stronger the clay the more it will shrink, and it is by this sinking that the workman knows when the kiln is sufficiently burnt. The experience of burning a few kilns will show how much the clay of that particular place yields to the firing. When it is thus ascertained that the kiln is ready, the vent-holes, and all other chinks through which air can enter, are carefully stopped with bricks and clay. In this state it remains until the bricks are cold enough to be taken down, when they are distributed for use.

From the nature of the above process it will be evident that bricks of very different qualities must be found in the same kiln; for as the fire is all applied below, the lower bricks in its immediate vicinity will be burnt to great hardness, or perhaps vitrified; those in the middle will be well burnt; and those at the top, which are not only most distant from the fire, but more exposed to the open air, will be too little burned; consequently, if they can be used, they must be reserved for inside work that is not exposed to the weather, or they will soon fail and crumble to pieces.

English Clamp.—In the English method of *open clamp* burning, without any kiln, the piling and disposition of the bricks is the same as above described, except that the bottom arches are much smaller, as they are only intended to contain brushwood to produce the first kindling, and not for the future supply of fuel. No fuel is used except the *breeze* cinders and small coal, and this is distributed, by means of a sieve with wires about half an inch apart, over every course, as it is laid near the bottom, and over every alternate course, or every third course higher up in the kiln. The first layers of this fuel are from 1 in. to 1½ in. in thickness; but they diminish as they ascend, because the action of the heat is to ascend: consequently, there is not the same necessity for fuel in the upper as in the lower part of the kiln. The brushwood in the bottom ignites the lower stratum of fuel, and from the nature of its distribution the vertical as well as horizontal joints will be filled with it, and thus the fire gradually spreads itself upwards, and the whole clamp is nothing but a mass of bricks and burning fuel. The heat is therefore much more generally distributed throughout the whole mass, and in order to confine it, the entire outside of the clamp is thickly plastered with wet clay and sand, the bottom holes being opened or shut, as occasion may require, for regulating the draught of air.

Notwithstanding the heat is much more equally distributed throughout this form of kiln, yet the outside bricks all around receive very little advantage from the fire, and are never burnt; but being on the outside they are easily removed, and are reserved for the outside casing of the next clamp that may be built; and being then turned with their unbaked sides inwards, some of them become available. On taking down the clamp, the bricks are assorted into three separate parcels or varieties, according to their perfection and goodness. Those that are burnt very hard and have not lost their figure or shape, may be selected for arches. The main body of well-burnt bricks are called *stocks*, and those which are imperfectly burned are called *place* bricks.

These several varieties of brick have each a separate price, the best being worth twice as much as the worst. If the fire has not been carefully attended to, and has been permitted to get too violent, some of the lower bricks will become distorted by partial fusion, and may fuse and adhere together, when they are called *clinkers*, and are useless for building purposes, but form an excellent road material.

A coal clamp of 100,000 bricks rarely burns out under a month. There is a great saving of fuel in burning large clamps; but where time is an object, small clamps ought to be made. The bricks ought not to be opened out before they are thoroughly cool, as they are apt to crack by the breeze playing upon them when hot. The amount of coal to be used depends upon the quality of the fuel, and the degree of hardness to which it is wished to burn the bricks. Six hundred and fifty or seven hundred maunds of moderately good coal ought to be sufficient to burn 100,000 bricks; a great deal, however, depends also upon the clay; a light sandy clay, such as is found by river sides, takes less fuel than a hard, strong clay.

A maund is an Indian weight, varying in different localities from 24 to about 82 lbs. avoirdupois.

The Madras maund is 24 or 25 lbs.; the Bombay maund 28 lbs.; the Surat maund 41 lbs.; and the bazaara maund 82½ lbs.

In London, close instead of open clamps are employed, no spaces being left between the bricks. Each brick contains in itself the fuel necessary for its vitrification; the breeze or cinders serving only to ignite the lower tiers of bricks, from which the heat gradually spreads over the whole clamp.

Indian Clamp.—The native clamp, or *pajawah*, is an arrangement for brick-burning in the open air, somewhat resembling the English clamp. The bricks and fuel are laid alternately, the former in courses of four or five bricks, the latter of 2 or 2½ ft. in thickness, the proportion of fuel being diminished towards the top. The whole is generally built with one side abrupt and nearly vertical, and with a long slope on the other. The fuel consists of dry grass, wooden chips, *khât* (manure), *koorah* (litter, miscellaneous dry sweepings), and *oopla* (dried cow-dung), and very generally a layer of wood under all.

The form of the *pajawah* is generally triangular; its floor smooth and sloping at an angle of 15°, being lowest at the angle, where it is lighted. The upper surface slopes at an angle of about 30°, in the direction of its length.

The following is a note on brick-burning in *pajawahs*, by Lieut. J. Finn, formerly Executive Officer of Materials at Roorkee:—The quantity of fuel used in the Hindoostanee kilns at and near Roorkee is about 6 in. thicker than the layer of bricks placed over it; that is to say, if the fuel is 3 ft. in thickness, the layer of bricks placed on the top of it should be 2½ ft. or five bricks high; each brick being 6 in. wide. A kiln now being filled at Roorkee has a layer of wood about 1 ft. deep all along the bottom, but none in the second or third tiers, excepting a small quantity at the mouth of the kiln to ensure its speedy ignition. When the kiln is ready for firing, about 1 ft. in thickness of fuel is spread all over its top, and over that 1 ft. of ashes.

The under-mentioned quantity of fuel will burn one lakh of bricks in a native kiln, namely, 325 2-bullock cart loads of *khât*, 750 maunds of *oopla*, and 100 maunds of fire-wood.

Once a kiln is filled, covered over on the top with ashes, and fired, it is not liable to injury from high strong wind; nor will a heavy fall of rain harm a kiln when in the above-mentioned state.

The size of bricks used in masonry works of the Northern Division, Ganges Canal, is 12 × 6 × 2½ in.

The sooner a Hindoostanee kiln is fired the better. When about one-third filled, the kiln ought to be lighted, for the fire will burn quicker and more equably before the fuel becomes compressed and partly decayed than it would otherwise.

The fuel used in a *pajawah* consists of all kinds of combustible refuse of towns and villages, and *oopla* and dung made into cakes well dried in the sun. *Oopla* and *huddy khuddy* (bones and pigs' dung) have been weighed before being put into kiln; of the former, from 1500 to 1800 maunds; of the latter, from 300 to 600 maunds; and about 6000 maunds of *koorah* (village refuse) are required for one lakh of bricks. Small quantities of wood have sometimes been put into kilns, but it proved disadvantageous, and the use of wood and *koorah* conjointly is injurious.

The time occupied in loading a kiln varies from two to three months for each lakh. Experience has convinced brick-makers in India that the sooner a kiln is fired the better. The rule is that when 40,000 or 50,000 bricks were piled into the kiln, it should be lighted; the progress of the fire being slow, any number of bricks can be piled afterwards.

Figs. 1342 to 1344 show sections of a brick clamp as burnt by Captain Sage. Contents of kiln, Fig. 1342:—Small wood and chips, 600 maunds; coal in layers, 750 maunds; bricks, 206,000. Contents of kiln, Fig. 1343:—75,000 bricks; 1185 maunds of wood.

Plan of Chulahs.

Various experiments were made in Bengal, and the result published by the Military Board, in 1827 and 1828, on the burning bricks in *clamps*, both with wood and coal. The clamps were built with flues as described in the English *kilns*, but smaller, and filled with well-dried chips or brushwood. For the fuel above the flues, green wood was preferred, as retarding the fire; wood-loaded kilns generally burning too rapidly, and causing great loss by vitrifying the bricks in the centre. The wood was split up into pieces not exceeding 4 or 5 in. in thickness, and so arranged as to leave level surfaces, for the layers of bricks to be laid upon. The flues were 2 ft. high and 9 in. wide, with three bricks laid flat on them, having narrow intervals to allow of the fire ascending from the flues. The clamps were finished with alternate layers of brick and fuel, the bricks being laid touching each other throughout, the interstices formed by their contraction under the great heat being sufficient to ensure the firing of the upper layers of fuel. The sides of the clamp were then built up with mud and broken bricks, well plastered with mud to exclude the air.

Besides the advantage of cheapness, coal is shown to be in many other respects superior, as fuel, to wood; the space occupied by it between the layers of brick is so much smaller, that the clamp sinks much less, and its outer casing is less deranged. The wind which interferes with the gradual and equable process of the fire is thus better kept out. The loss by breakage is likewise much less, and the bricks from being burnt more slowly are more compact. The coal should be broken into pieces not exceeding 1 in. in diameter. In kilns, likewise, coal must have like advantages over wood except as regards the greater displacement of the casing of the clamps; the permanent walls of kilns not being liable to this contingency. Kiln walls may be built of bricks plastered with mud, and repaired with the same material from time to time; they should slope on the outside about 1 ft. in 5.

Another construction, by Capt. Bell, Figs. 1345, 1346, seems well adapted to prevent the sinking of kilns when wood is used as fuel. The wood is everywhere contained in flues, crossing each other at right angles, the walls of which are supported by layers of bricks on edge, completely covering the area of the kiln.

The ground layer of four flat bricks being laid with equidistant flues, they are filled up with light wood and dry chips, over which two bricks are laid flat; on this is formed a second set of flues, running across the ground flues, and, after filling up between the flues with wood, the whole area is built over with three bricks on edge, the length of the bricks running in the same direction with the flues and wood. The full height is formed by an alternation of flues and solid masses of bricks, as shown in Fig. 1346. Two rows of bricks laid flat seem to be requisite above each set of flues, to prevent the bricks on edge from falling into them, whilst the fuel is being consumed.

To close the clamp, extend the flue opening as at *a*, Fig. 1345, one brick in length, and cover

it with two flat bricks. Then build up, with one brick breadth-ways, the outer coating as at *g* (with half-dried bricks, or any kind), over which straw (well wetted) is laid on the slope from the top downwards, giving it a good coat of mud plaster. The mud should not be thickly laid on, but well rubbed into the grass. If thick, the heat of the fire and sun makes it peel off and admit the air, before the fire has gone through the kiln.

One great error appears to consist in putting large masses of wood into the *upper tier* flues: it is thus that so much material becomes vitrified. The ground flues ought to be filled (but not choked) with good dry fuel intermixed with chips, so as to communicate quickly through the whole. The wood of the first tier should be reasonably large, with some small pieces or chips; and in every higher tier in succession they should be less in size as well as in quantity; because, as all the fire and heat rise from below, the higher tier has the advantage of all the foregoing flue fires in addition to its own. Previous to its ignition, too many bricks should not be piled above wood, however great the quantity of the latter, or they will be irregularly burnt and much fuel wasted.

Works and Papers relating to Brick-making:—Brughat, 'L'Art du Briquetier,' 2 vols., 1861. Dobson (E.), 'On Bricks and Tiles,' 1868. Medley (F. G.), 'Roorkee Treatise on Civil Engineering,' Papers by Clift, Fothergill, and others, in the 'Trans. Inst. Mechanical Engineers.'

BRICKWORK. FR., *Maçonnerie de briques*; GER., *Mauerarbeit, Ziegelwerk*; ITAL., *Mattonato*; SPAN., *Enladrillado*.

A term used in the art of construction to denote the combination of bricks with mortar or cement.

Architects and surveyors in the neighbourhood of London adopt as their standard of measurement for brickwork the square rod of 272 ft. superficial, reduced to a thickness of $1\frac{1}{2}$ brick. In the provinces and by civil engineers the cubic yard is more commonly used.

A rod of reduced brickwork of four courses to the foot in height requires 4356 bricks, and a cubic yard requires 384 bricks. When the mortar-joints are limited to $\frac{1}{4}$ of an in. in thickness, the rod of brickwork contains 258 ft. cube of bricks and 48 ft. cube of mortar; the cubic yard contains $22\frac{3}{4}$ ft. cube of bricks and $4\frac{1}{4}$ ft. cube of mortar. When the joints are $\frac{3}{8}$ of an in. in thickness, the rod of brickwork contains 235 ft. cube of bricks and 71 ft. cube of mortar; the cubic yard contains $20\frac{3}{4}$ ft. cube of bricks and $6\frac{1}{4}$ ft. cube of mortar.

The proportions, in general, of bricks and mortar in any given quantity of brickwork vary according to the size of the bricks and the thickness of the mortar-joints. In practice, 3 cubic yards of mortar are allowed to a rod of brickwork, and 36 bushels of Roman cement with an equal quantity of sand; but when Portland cement is used there should be allowed about 38 bushels of cement to an equal quantity of sand. When the proportions of Portland cement to sand are to be as 1 to 2, 25 bushels of the former and 50 of the latter will be required for a rod of brickwork. 126 gallons of water are usually allowed to a rod of brickwork to slake the lime and mix the mortar. Cement requires rather more water, particularly Roman cement, which absorbs it very rapidly.

The weight of bricks varies considerably, some weighing only 5 lbs. and others $7\frac{1}{2}$ lbs., and in some cases as much as 9 lbs. each. For the purpose of calculation, however, the weight of a rod of brickwork just built may be taken at 16 tons, which will probably be reduced to 15 tons when the work becomes thoroughly dry.

Some bricks are very porous, and will absorb more than *one-fifth* of their weight of water, if immersed in it soon after their withdrawal from the kiln. When bricks are exposed to the rain,

which is usually the case when stacked for building, they take up a large quantity of water, which they never entirely part with. Ordinary London stocks absorb about *one-fifteenth* part of their weight of water in the process of building, most if not all of which they lose again by evaporation.

Brickwork built with Portland or Roman cement requires a weight of about 30 tons a superficial foot to produce fracture by compression; and when built with blue lias lime mortar, thoroughly set, it requires about 20 tons. When Portland cement is used, fracture almost invariably takes place in the bricks; but with Roman cement, particularly when used with much sand, fracture sometimes occurs in the cement itself, and still more frequently when mortar is the cementing material—a result naturally to be expected from a consideration of their relative degrees of strength. See CONSTRUCTION.

BRICK-NOGGING. FR., *Remplissage de briques d'un châssis de charpente*; GER., *Füllmauerwerk*; ITAL., *Muratura di riempimento*.

Brick-nogging or brick-nog partition, is a description of walling consisting of brickwork and timber. It is usually made of the width or thickness of a brick, and is framed similar to a wood partition, the quarters or studs being 2 or 3 ft. apart, with brickwork filled in between them; horizontal pieces, called *nogging-pieces*, are also laid in regular tiers between every two courses of bricks. Although brick-nogging does not add to the strength of a partition, it is some little security against fire.

BRICK-TRIMMER. FR., *Enchévêtre de briques d'une cheminée*; GER., *Gurt bogen im Kamin*; ITAL., *Arco di mattoni*.

Brick-trimmer is the term applied to a brick arch abutting against the wood trimming just in front of a fire-place, and used to support the hearth. See Fig. 271, p. 121.

BRIDGE. FR., *Pont*; GER., *Brücke*; ITAL., *Ponte*; SPAN., *Puente*.

Bridges are structures, usually of wood, stone, brick, or iron, erected over rivers or other watercourses, or over ravines or railroads, to make continuous roadways between banks.

A *draw-bridge* is a bridge so constructed that a part of it may be temporarily removed, or drawn aside, to allow the passage of vessels; called also a *swing-bridge*, or *bascule-bridge*, when the part which opens turns laterally on a centre or end pivot. In mathematics and mechanics the terms *laterally*, *lateral*, and *lateral*, or the quality of having distinct sides are often misapplied. *Lateral*, as an adjective, signifies proceeding from, or attached to, the sides; as, the lateral branches of a tree; lateral shoots; or as an adjective this term may signify, directed to the side; as, the lateral view of an object. Sometimes, in mathematics, an equation of the first degree is designated as a *lateral equation*. In mechanics, *lateral pressure or stress* is a pressure or stress at right angles to the length, as of a beam or bridge; distinguished from *longitudinal pressure or stress*. And *lateral strength* is that strength which resists a tendency to fracture arising from lateral pressure.

In the sequel, we treat of the construction and mechanical requirements of *Draw, Girder, Lattice, Truss, Tubular, Flying, Suspension, Skew, and Trestle bridges*; after we have examined the nature and actions of pressures, thrusts, and tensions.

Equilibrium of Pressures, Thrusts, and Tensions;—Forces.—Anything which cannot be presented to the senses must be represented conventionally, or no idea of it can be entertained by the mind. We have no objection to represent the magnitudes and directions of forces, velocities, pressures, thrusts, and tensions by straight lines of different lengths, and in different positions; but we object to the careless manner in which writers on mechanics represent forces, pressures, velocities, &c., by straight lines, triangles, and parallelograms, out of all proportion, and often, too, without the least regard to the action, direction, or nature of the force considered. In the article on **BOILERS**, p. 425, we gave a conventional signification to the areas of plane figures, but in the present article the sides and angles of triangles, parallelograms, and other plane figures are employed to give an idea of mechanical operations and combinations, where the *principle of work* does not apply, as rest and not motion is here principally considered.

When comparing graphically the action of statical forces, it would be convenient to put a split arrow ($\rightleftarrows$) to designate the directions of tensions, the arrow without feathers ($\longrightarrow$) to point out the directions of thrusts, while the complete arrow ($\rightleftarrows$) might be applied to forces in general. If three forces P, Q, R, Fig. 1347, be represented by the abstract numbers, 6, 4, 3, respectively, then if A B C be a triangle whose side A C = 6, A B = 4, B C = 3, equal parts taken from any scale of equal parts; let P O be a tension equal and parallel to A C, Q O a tension equal and parallel to A B, R O a tension equal and parallel to B C; these three tensions will keep the point O at rest. Three thrusts represented by three lines P O, O Q, O R, whose lengths are as 6, 4, and 3, respectively, and parallel to the sides of the triangle A B C, will also keep the point O at rest. Take A T equal and parallel to B C, then the two thrusts represented in magnitude and direction by the lines T A, B A, and the tension represented in magnitude and direction by the line A C, will keep the point A at rest. Again, if B S be equal and parallel to A C, tensions represented by A B, B S, and a thrust, C B, will keep the point B at rest.

Let P A, Q R, Fig. 1348, be a parallelogram, if P A, Q A, represent the magnitudes and directions of two forces, two pressures, two thrusts, or two velocities acting on the material point A; then the diagonal R A will represent the magnitude and direction of a single force, pressure, thrust, or tension, equivalent to the operations represented by the lengths and directions

of P A and Q A. Such imaginary parallelograms form a great portion of the stock-in-trade of writers on mechanics. We have introduced Figs. 1347 to 1351 to illustrate the manner in which the different forms of arrows may be applied with advantage. The properties pointed out in Fig. 1347 depend upon the truth asserted of the parallelogram P A Q R, Fig. 1348, which we will prove presently.

The principle of sufficient reason; first employed by Archimedes in demonstrating the fundamental propositions of mechanics.—Let P and Q, Fig. 1349, be two equal forces acting in the same plane on the rigid perpendicular prop A R, the point R fixed; further, let these forces P, Q, make equal angles, S A D, S A B, with the prop A R, which may turn to the right or left round the fixed point R. But as the forces P and Q and the angles B A S and D A S are also equal, there is no reason why the post A R will turn to the right or left; hence it will stand, and the two tensions will be neutralized by the perpendicular thrust of the post A R. This we call a mechanical demonstration, and the principle applied the *principle of sufficient reason*. For there is no reason why the post under consideration should fall to one side more than another, hence we conclude it will fall to neither side. Let A B C D be a parallelogram whose sides are all equal; if the length of the line A B be taken to represent the magnitude of the force Q, then A D will truly represent the force P; and two other equal forces, V and U, applied to the point C, represented in magnitude and direction by the lines C D, C B, will counteract the forces P and Q the same as the post A R, the diagonal A C being rigid. The principle of sufficient reason applies here as in the former case. It is evident that any number of equal forces may be applied in the directions of the arrows, $P = Q = V = U$, without disturbing the form of the equal-sided parallelogram A B C D, or the position of the rigid diagonal A. The abstract truth of the parallelogram of forces, thrusts, tensions, pressures, or velocities may be established by reasoning as follows: Let A B C O be a parallelogram; when its sides can be expressed by numbers, it may be divided into small parallelograms, the sides of which are all equal to one another. We have selected a very simple case, and taken O C = 4 equal parts and A O = 3 of the same parts. Let the force P be to the force Q as m to n ; in the present example, $P : Q :: 4 : 3$.

The forces P and Q applied to the material point O in the direction O C, O A, may evidently be represented by the lines O C, O A; if a new set of forces, represented by the small parallelograms, be introduced as represented by the arrows in the figure, the combined action of the forces P and Q will not be interfered with, nor will the equilibrium of the figure be disturbed. Take, for example, the small equal-sided parallelogram D E T L, and for a moment suppose the diagonal D T rigid; then the *principle of sufficient reason* applies to the forces introduced, and no disturbance takes place. Let us now view these forces under another aspect. The forces along the sides of the small parallelograms on the line C O are equal to the force P, but in a contrary direction, and hence destroys it. The forces represented on the line 9, 10, also destroy one another. This may be said of the forces on the line 7, 8; but the forces on the line A B are not neutralized, and are exactly equal to the force P, but applied to the point B in the diagonal O B. Again, the forces along the sides of the small parallelograms on the line A O are equal to the force Q, but in a contrary direction, and hence may be said to destroy it. The forces pointed out by the arrows on the line 1, 2, also neutralize one another; the same may be said of the forces supposed to be introduced on the line 3, 4, and so on, until we arrive at the forces pointed out on the last line B C, which, together, are exactly equal to the force Q, but applied to the point B in the diagonal O B. According as the equal parts be long or short, the point B will change its position; but it will always be in the diagonal O Z, and the forces $a + b + c + d = P$ and $g + f + e = Q$ will in all cases have their resultant position in the diagonal O Z. Had we supposed the force P to be divided into 1000 equal forces, O C would be represented by 1000 equal parts, and O A = Q would then be composed of 750 such parts, and our reasoning on the 750000 equilateral small parallelograms of forces would result in the same conclusion. The equilibrium of forces and pressures may be illustrated in a practical way by a simple mechanical contrivance, represented in Fig. 1351, easily constructed. Suppose P Q R to be a slate or board rolling freely upon three equal spherical balls placed on a horizontal table A B C. If any three points, P, Q, R, be taken in the surface of the plane movable on the balls, and cords, A P, B Q, C R, be attached, passing over the pulleys,

with a different amount of weight attached to the other ends—the ends with the weights attached are not represented in the cut—the board P Q R will roll upon the balls, and ultimately come to rest upon the table A B C, where the three forces destroy each other. When this experiment is carefully made, it will be found that the directions of the forces A P, B Q, C R, meet in the same point O. Again, from any scale of equal parts take $O r =$ the pounds in the force drawing the cord Q B, and from the same scale of equal parts lay off $O a =$ the pounds drawing the cord R C; then, if the parallelogram $O r s a$ be constructed, the diagonal O s will be in the direction of the third force acting over the pulley A. It will be further found that the units of length in O s, the diagonal, will = the weight or force acting by the cord A P.

If $O a = 22$ equal parts, $O r = 28$, and $O s = 26$, all measured on the same scale of equal parts, then, if 7 lbs. be attached to the cord Q B, and $5\frac{1}{2}$ lbs. to the cord R C, a weight of $6\frac{1}{2}$ lbs. must be attached to the cord A B to maintain this equilibrium. When forces are thus represented by a parallelogram, as $O r s a$, the forces represented by the sides are called the component forces, while the force represented by the diagonal is denominated the resultant. Another experiment may be instituted to determine the intensity of forces by this simple apparatus. Instead of three forces being applied to the board, let there be any number; and suppose H to be any point taken in the movable plane P Q R, and from H let fall perpendiculars H n, H m, H f, and so on, in the directions, or directions produced, of the forces; then the units of length, taken from any scale of equal parts, multiplied by the pounds in the corresponding force, will be what is termed the *moment* of that force tending to turn the board or movable plane upon the point H. This being done, the principle denominated *the principle of the equality of moments* may be verified by experiment. Here but three forces are applied, but any given number may be introduced; in the present case,

$$H f \times B \text{ lbs.} + H m \times C \text{ lbs.} = H \times n \text{ A lbs.}$$

The student must not confound *the principle of the equality of moments*, just defined, with the intensity of forces usually considered by examining the motions they produce, or the spaces passed over when the motions are uniformly accelerated. It has been before shown that, generally,

$$(\text{Force}) = \frac{W}{g} \frac{v}{t}; \quad [1]$$

t being an extremely small portion of time, denominated an element, during which the velocity v is generated. The above formula shows that if, by observing the laws of motion, we know for each instant the value of the ratio $\frac{v}{t}$, we shall then have that of the corresponding effort designated (Force) in the above formula. Suppose we know, from experiment, that the motion is uniformly accelerated, we have, for the space S, $S = \frac{1}{2} V_1 \times T^2$, in which

$$V_1 = \frac{V}{T} = \frac{v}{t}, \text{ as in [1];}$$

$$(\text{Force}) = \frac{W}{g} \frac{2S}{T^2}. \quad [2]$$

Suppose a locomotive weighing 10 tons (22400 lbs.) runs, with a uniform accelerated motion, a distance of 154.4 ft. in four seconds; require the force in lbs. capable of imparting this accelerated motion, the friction of the rail not being considered?

From [2] (Force) = $\frac{22400 \times 2 \times (154.4)}{32.2 \times 4^2} = 13440$ lbs. (See pp. 93, 94, 116 Byrne's 'Essential Elements of Mechanics'.)

Definition.—A bar is called a *strut*, or a *tie*, according as a thrust or a pull is exerted along its line of resistance.

Let CHBA, Fig. 1352, be a *skeleton diagram* representing centres and lines of resistances, H B a platform with a load $W = 47$ cwt. upon it, C B a chain supporting both load and platform; find, by construction, the tension of the chain and the amount and direction of the pressure upon H, the point about which the platform turns, the weight of which being neglected?

Draw W A perpendicular to H B, intersecting the chain in A; join A and H, and, from a scale of equal parts, lay off $A p = 47$, a part for each lb. in W, which acts in the direction A W. Draw $p r$ parallel to C B, and $r n$ parallel to A W; the parallelogram $A n r p$ gives the required tension and thrust. In the diagram $A r = 37$ equal parts, answering to 37 cwt., the pressure on the hinge H; $A n = 26$ equal parts, answering to 26 cwt., the pressure tending to break the chain. Take $H s = A r$, draw $s m$ parallel to W H, and $s t$ parallel to H C; then H t gives the thrust of W against the wall, which is represented by H C, and H m shows the pressure in the direction of the stationary wall H C.

Given a triangular frame, A B C, Fig. 1353, loaded and supported both in the direction of the vertical line D E; find the relative proportions of the forces?

Put A, B, C, for the three joints, and a, b, c , for the three bars. These things being premised, from any point, P, draw P R, P Q, P S, parallel to the lines of resistance a, b, c , respectively; across these lines the vertical line Q R S, then the following proportions apply to the forces:—

Load on A : supporting force at B : supporting force at C : stress along c : stress along a : stress along b ; so stand in order and proportion the lines Q S : S R : Q R : P S : P R : P Q.

1351.

1352.

Out of the six proportions thus succinctly stated, to illustrate, we shall single out one :
Load on A : supporting force at B :: QS : SR.

Let a pole, A B, Fig. 1354, be supported by a cord, C B, and carry a weight, W; required the tension of the cord, and the pressure on the pole?

From B to *n* lay off equal parts, equal to the units of weight in W; draw *mn* parallel to CB, intersecting BA in *m*; draw *mp* parallel to Bn; therefore the units in Bp will give the tension of the cord CB, and the units, measured on the same scale of equal parts, in the diagonal Bm, will give the thrust on the pole AB.

Struts may be distinguished from ties thus:—In Fig. 1355, P Q, Q R, represent two bars of a frame meeting at the joint Q; produce the lines of resistance beyond Q to S and T. Then a force in the direction of the arrow A, between the angle P Q R, both bars are struts; if the force be in the direction of the arrow B, in the angle T Q P, then P Q is a strut, and Q R a tie. Again, when the force is applied in the direction of the arrow C, both bars are ties; and, lastly, when the force is in the direction of the arrow D, in the angle S Q R, then P Q is a tie, and Q R is a strut.

A beam, A B, Fig. 1356, resting on a wall, C, and supported by a cord, Q A; it is required to determine the direction and tension of the cord B P, so that the beam may not change its position when the wall C is removed, the point B being also given?

Let G be the centre of gravity of the beam, through which draw the vertical line G s in the direction of the plumb line, to meet Q A produced in s, join s B, and produce it; B P in the direction of s B shows the direction a cord fastened at B must take so that the beam will not change its position when the wall C is removed.

To find whether a pier, or other support, S T, Fig. 1357, will overturn by the action of a force P, or the resultant of several forces operating in a given direction, P C A. Produce the direction of the force P, and let fall the perpendicular O A; then, in order that the structure may not turn on the point O, we must have, G being the centre of gravity, weight of the structure S T $\times$ O B greater than P $\times$ O A. When (weight S T) $\times$ O B = P $\times$ O A, the pier will be on the point of turning on the edge, O.

By Construction.—Let B C be the vertical line passing through the centre of gravity of the pier or pillar, intersecting the direction of the force P in the point C; from a scale of equal parts take C F = the units in the pressure P, and from the same scale take C E = the units in the weight of the structure, S T; complete the parallelogram of forces, C D E F, then C D will give the amount and direction of the single force tending to overturn the structure or support, S T. When C D produced intersect the base within the edge O, the structure will stand; but should the point of intersection, R, fall without the base, the structure must fall.

A T, Fig. 1358, is a pier, or buttress, weighing 860000 lbs., P a pressure of 320000 lbs.; A B = O T = 6.6 ft.; O A = B T = 15 ft.; the cross-section A B T O is a rectangular parallelogram, of which G is the centre of gravity. The direction of the force P tending to overturn the structure cuts A B 4 ft. from A, and A O at C, 7 ft. from A.

It is required to find whether the structure will stand or fall, and what will be the amount of the pressure, P , just sufficient to overturn the solid mass of which $ABTO$ is a cross-section?

$$CP = \sqrt{AC^2 + AP^2} = \sqrt{7^2 + 4^2} = 8.0622577,$$

$$CP : PA :: CO : OQ,$$

$$\text{or, } 8.0622577 : 4 :: 8 : 3.969 = OQ.$$

Since AT is a rectangular parallelogram, a vertical line, SGm , passing through the centre of gravity, G , divides the base OT into two equal parts. $\therefore OS = ST = 3.3$ ft.; then we can compare moment of the wall = $860000 \times OS = 2838000$. Moment of the pressure = $320000 \times OQ = 1270080$; 2838000 being greater than 1270080 , the structure will stand.

Putting x for the pressure that will just overturn it, acting in the direction of P , then,

$$x \times OQ = 2838000. \quad \therefore x = \frac{2838000}{3.969} = 715022 \text{ lbs.}$$

If $P = 715022$ lbs., the point R will coincide with the point O on the outer edge of the structure.

Geometrical Proposition.—If the sides, or the sides produced, of one triangle, a, b, c , Fig. 1359, be respectively perpendicular to the sides, or sides produced, of another, A, B, C , these triangles are similar. aQ, bP, bR , represent the three perpendiculars, angle $C + CSP =$ a right angle, angle $c + CSQ =$ a right angle; but angle $CSP =$ angle CSQ , $\therefore$ angle $c =$ angle C .

In the same way the angle b may be shown to be equal to the angle B ; and consequently the angle $a = A$.

Funicular Polygon.—Funicular polygon is the term employed to designate a polygon formed of rods, chains, or cords, whose angular points are solicited by any forces whatever. The equilibrium

of such a system of thrusts, tensions, &c., are subject to rules easily determined. First, let us suppose that the polygon has not all its sides in the same plane, and is represented by the contour, $ABCDEF$, Fig. 1360. Let $P, Q, R, S, T, \dots$ be the forces acting upon each of the summits A, B, C, D, E ; the respective tensions of the sides AB, BC, CD, DE, EF , represented by $T_1, T_2, T_3, \dots$ respectively. If the entire polygon is in equilibrium, it must be so for all the summits separately, and since T_1 must be equal and opposite to the resultant of T and P , it follows that any two sides uniting at the same summit, and the direction of the force acting upon this summit, must be in the same plane; and the tension T_1 must be equal and opposite to the resultant of the force Q and tension T_2 , and consequently in substituting at the summit C , for the tension T_1 , its two components P and T , the forces P and Q , and the tensions T and T_2 , supposed to be transferred to the point C , parallel to themselves, must be in equilibrium. We see also that the forces P, Q, R , and the tensions T and T_3 , supposed to be transmitted to the summit D in parallel directions, must then produce an equilibrium. By continuing this process, we arrive at the conclusion, for the equilibrium of the funicular polygon, that when all the external forces and the tensions of the extreme sides are regarded as transferred parallel to themselves to any summit, they must necessarily produce an equilibrium there. These remarks are independent of the direction of the forces and the nature of the sides, and are applicable when the sides are subjected to efforts of compression instead of tension, with the reservation solely that the sides be sufficiently rigid to resist the compressions, without a change of form. Where the forces soliciting the funicular polygon are weights, in which case the forces $P, Q, R, S, \dots$ are all vertical and parallel, and the polygon necessarily in one plane; for, the direction of each force, and those of the two sides meeting at the summit, are in the same vertical plane; and, as through one side we can draw but one vertical plane, it follows that the two vertical planes, containing the same side of the polygon, are coincident, and so for the other sides. Again, since all the external forces $P, Q, R, \dots$ and the tensions T, T_1 , of the first and last sides are in equilibrium, T and T_1 must also be in equilibrium with the single resultant of all the parallel forces.

Determination of the Tensions by a Graphical Construction.—If, in accordance with the preceding views, we describe upon the side AB , produced from any convenient scale of equal parts, a length equal to the tension T , and construct the parallelogram $Babd$, Fig. 1361, the side Ba , measured on the same scale of equal parts, will represent their tension, T_1 of the side BC , and the side Bd , the external force P . Then, if we draw through the point B , for example, a line BG^1 perpendicular to the directions of the forces $P, Q, R, \dots$ upon which lay off $B^1C^1, C^1D^1, D^1E^1, E^1F^1, F^1G^1$, proportional to the forces P, Q, R, S, U , and from the same point erect the line BO perpendicular to AB with a length proportioned to the tension T , or to Bb , the triangle BOC^1 having two sides, BO, B^1C^1 , respectively perpendicular and proportional to the sides Bb and Bd of the triangle Bbd , must be similar to it by the geometrical proposition preceding. Then the third side, OC^1 , of the first will be proportional to the third side, bd or Ba , or to the tension T_1 , and will be perpendicular to the side BC of the polygon; the following triangle will be in the same condition, in relation to the side CD , to the force Q , and the tension T_2 , which will be proportional to the side OD , and so on. Then, if the weight soliciting the different summits of the contour $A, B, C, \dots$ are in equilibrium, and we lay off upon a horizontal line lengths respectively proportional to these weights, and then from points of this line corresponding to each summit draw straight lines perpendicular to the directions of the sides of the polygon, all these right lines will intersect at the same point, and their lengths will be proportional to the tensions of the sides of the polygon, which will thus be determined. If a line VZ be drawn parallel to

1359.

1360.

$B G^1$, the triangle $V O Z$ answers the same purpose as the triangle $B O G^1$. The triangle $B O G^1$, Fig. 1362, expresses the same relations as the triangle $B O G^1$, Fig. 1361, $B G^1$ being taken equal to the sum and in the direction of the forces $P, Q, R, \dots$. $B O$ is drawn parallel to the direction of T , and $B X$ parallel to the direction of T_1 ; $G^1 X$ gives the tension of T , and $G^1 O$ the tension of T_1 , both measured on the same scale of equal parts as $B G^1$. $O B$ is parallel to T or $A B$; $O C^1$ is drawn parallel to $B C$; $O D^1$ to $C D$; $O E^1$ to $D E$; $O F^1$ to $E F$.

We have been very particular to pass nothing over that might make the proper relations and actions of forces, thus circumstanced, clear to the mind of the student, since the proper arrangement of thrusts and tensions, the action of braces, struts, and ties, in bridge-building, roofing, and in all sorts of lattice-work, designed to combine strength with lightness, depend upon the extension of the simple principles here presented.

If the same Fig. 1362 be inverted, then such frame, Fig. 1363, consists chiefly of struts, and is, therefore, unstable unless their ends are made fast by suitable stays. In a polygonal frame loaded and suspended vertically, represented by the skeleton diagram, Fig. 1362, the bars which are struts in Fig. 1363 become ties, and the frame is stable and yet flexible.

The diagram of forces for Fig. 1363 may be constructed as follows:—Suppose the polygonal frame loaded vertically and supported vertically, let $A, B, C, D, \dots$ be the bars; $a, b, c, d, \dots$ the joints of which b, c, d, e, f , are loaded, a and g are supported. Take any convenient point, as O , draw $O A^1$ parallel to A ; $O B^1$ parallel to B ; $O C^1$ parallel to C ; $O D^1$ parallel to D ; $O E^1$ parallel to E ; $O F^1$ parallel to F ; and $O G^1$ parallel to G . Then draw the vertical line $A^1 F^1$ crossing the lines $O A^1, O B^1, O C^1, \dots$. Then if the whole load on the frame be represented by $A^1 F^1$, the parts into which $A^1 F^1$ is cut by the lines $O A^1, O B^1, O C^1, \dots$ will represent the fractional parts of the load that must rest on each of the joints to secure equilibrium.

$A_1 B_1$ represents the part of the load to be applied at the joint b ; $B_1 C_1$ the part to be applied at c ; $C_1 D_1$ the part to be applied at d ; and so on. The lengths of the lines $O A_1, O B_1, O C_1, \dots$ represent the resistances along the lines $A, B, C, \dots$ to which they are respectively parallel. The two parts $F_1 G_1, G_1 A_1$, into which $F_1 A_1$ is divided by the line $O G_1$ parallel to G represent the supporting forces at a and g , that is, $F_1 G_1$ represents the supporting force at g , and $G_1 A_1$ the supporting force at a . The horizontal stress of the frame is represented by the length of the perpendicular $O G_2$ let fall from O on $F_1 A_1$. If the angles of the polygonal figure $A B C D \dots$ be given, the angles of the diagram of forces $O A_1 F_1$ are also given; hence, when the length of any one of the lines in $C A_1 F_1$ is also given, the lengths of the other lines are readily found by plane trigonometry, to any required degree of accuracy.

If the skeleton diagram $A B C D \dots$, Fig. 1363, represent an open frame, the bar G is omitted; in this case the stress along the outer bars, represented in the diagram of forces by the lines $O A_1, O F_1$, must be met by oblique forces as abutments; for vertical supports would not be sufficient. This frame, being, as before observed, composed of struts, is unstable, and must be connected with suitable stays.

Let $A B$ and $B C$, Fig. 1364, be a roof resting on the side walls A and C ; a uniform section of this roof weighs 6000 lbs., the angle $B A C = 34^\circ$, $B C A = 44^\circ$; it is required to find the thrust on the points A, C , the roof being without a tie-beam; what would be the tension of a tie-beam, $A C$, or of a rod connecting the feet of the rafters; and also find the direction and amount of the pressure of the roof to overturn the side walls?

To construct the diagram of forces, draw $O a$, Fig. 1365, parallel to $A B$; $O c$ parallel to $C B$; and $O b$ parallel to $A C$, Fig. 1364.

Draw the vertical line $a b c = 6000$ equal parts to represent 6000 lbs.

Let $W = 6000$ lbs. applied, suppose, at the centre of gravity, G , of the section.

$\therefore$ angle $a O b = 34^\circ$; $b O c = 44^\circ$. $O a b = 90 - 34 = 56^\circ$; $O c b = 90 - 44 = 46^\circ$.

Sin. $78^{\circ} : 6000 :: \sin. 56^{\circ} : Oa = 5085.35$. Natural sine of $78^{\circ} = .9781476$; natural sine of $56^{\circ} = .8290376$. Sin. $78^{\circ} : 6000 :: \sin. 46^{\circ} : Oa = 4411.44$. Natural sine of $46^{\circ} = .7193398$.
 $\therefore$ The thrust on the point C = 5085 lbs., and the thrust on the point A = 4411 lbs. As sine of $90^{\circ} : Oa :: \sin. aOb : ab = 2466.8$. $\therefore bc = 6000 - 2466.8 = 3533.2$. $\therefore$ The side wall at C supports 3533 lbs. of the weight W, and the side wall at A, 2467 lbs. nearly. As sin. $90^{\circ} : Oa :: \cos. aOb : Ob = 3657.3$. $\therefore$ The horizontal thrust along the side A C = 3657 lbs.

Draw $A p$ perpendicular to AC , and $= ab$, the vertical weight at A , Fig. 1364; make $An = Oa$, the thrust along the rafter AB ; complete the parallelogram $Apmn$, and draw the diagonal mA , $=$ the amount and direction of the pressure of the roof tending to overturn the wall A . Or, to avoid complicating the figure, we reproduce the diagram of forces, Fig. 1366; taking the lines Oa , ab , complete the parallelogram $Ooba$, then the diagonal ar gives the amount and direction of the pressure as well as the parallelogram $Anmp$, Fig. 1364. On the lines Oc , cb , construct the parallelogram $Osb c$, draw $Sc =$ the amount and direction of the pressure of the roof applied to overturn the wall C , when the tie AC is omitted.

Given the skeleton diagram A B C D E, Fig. 1367, of a frame loaded and supported vertically ; A E being horizontal. O B₁ Fig. 1368, is parallel to A B ; O C₁ parallel to B C ; O D₁ parallel to C D ; O E₁ parallel to D E ; and O F₁ is drawn parallel to A E ; B₁ E₁ represents the whole load, and, being vertical, is perpendicular to O F₁. Now suppose the angle F₁ O C₁ = 12°, the natural tangent of which is .21255 = F₁ C₁, when O F₁ = 1 ; the secant of this angle is 1.0223 = O C₁. F₁ O B₁ = 37° ; F₁ O D₁ = 25° ; F₁ O E₁ = 50° ; then the comparative lengths of the lines in the diagram of forces will stand thus :—

	Tangent.		Secant.
$O F_1 = 1;$	$F_1 C_1 = \cdot 21255$		$O C_1 = 1\cdot 0223$
	$F_1 B_1 = \cdot 75355$		$O B_1 = 1\cdot 2521$
	$F_1 D_1 = \cdot 46630$		$O D_1 = 1\cdot 1033$
	$F_1 E_1 = 1\cdot 1917$		$O E_1 = 1\cdot 5557$

The frame is vertically loaded, with 5000 lbs; how is it distributed, and what are the particulars of its action when the forces balance each other?

$$F_1 B_1 + F_1 E_1 = 1.94525 = 5000 \text{ lbs.}$$

$$1.94525 : 5000 :: 1.0223 : 2628 \text{ lbs. stress along the bar } b \text{ or } BC.$$

$$1.94525 : 5000 :: 1.2521 : 3218 \text{ lbs. stress along A B or bar } u.$$

$$1.94525 : 5000 :: 1.1033 : 2836 \text{ lbs. stress along bar } c.$$

$$1.94525 : 5000 :: 1.5557 : 3999 \text{ lbs. stress along } d.$$

$$F_1 B_1 - F_1 C_1 = C_1 B_1 = .75355 - .21255 = .541; \quad 1.94525 : 5000 :: .541 : 1391 \text{ lbs. load on the joint B.}$$

$$F_1 C_1 \div F_1 D_1 = C_1 D_1 = \cdot 67885; \quad 1 \cdot 94525 : 5000 :: \cdot 67885 : 1745 \text{ lbs. load on the joint C.}$$

$$F_1 E_1 - F_1 D_1 = .7254; \quad 1.94525 : 5000 :: .7254 : 1864 \text{ lbs. load on the joint } D.$$

$$1.94525 : 5000 :: F_1 E_1 : 3063 \text{ lbs.},$$

the vertical weight falling on the support at E, the remainder of the weight, or $5000 - 3063 = 1937$ lbs., must fall on the support at A. The horizontal stress being represented in the diagram of forces by $O F_1 = 1$, we have $1.94525 : 5000 :: 1 : 2570$ lbs., the horizontal stress of the frame. When the load is properly distributed, the necessary stays, C E, A C, require but little strength: without stays such a frame, however well balanced, would be unstable.

Examples of Bridges in which the actions of combined forces have been applied with more or less success.—The McCullum Inflexible Arched Truss Bridge approaches nearer the standard of perfection than any other wooden bridges that have fallen under the editor's notice; this fact is easily established by comparison and demonstration.

Fig. 1369 is what is known as the *Burr Bridge*. It is composed of lower and upper chords, and posts and braces. The posts are framed into the chords, and the braces are framed into the posts. Arches are placed on each side of the truss, securely fastened thereto, and, extending below the lower chords, abut against the masonry. This form of truss was extensively used throughout Europe and the United States previous to the introduction of railroads. Many spans were of great length, and in cases where the arches were large, and the masonry sufficiently permanent, this bridge was comparatively successful. Much difficulty was, however, experienced, by reason

of the absence of counter-braces. A moving load produced a vibratory and undulating motion, tending to loosen the connection of the timbers, which generally resulted in failure. Many of the first railroad bridges, both in Europe and America, were built upon this plan; but much greater difficulty was found in adapting it to the use of railroads than had been previously experienced in its use upon common roads. This difficulty arose from, first, the practical impossibility of perfectly combining the action of the arch and the truss (each system, of itself, being insufficient to carry the whole load); and, second, the absence of counter-braces. These defects, clearly apparent in their use on common roads, were greatly aggravated under the increased and concentrated nature of the weight, and the rapid transit of trains on railroads.

It is true they were obviated in part by adding largely to the amount of material in the structures; but as the difficulty was inherent in the plan, violent contortions in shape could not be prevented, and these in time caused failures. These remarks are intended to apply to spans of considerable length, as experience has proved that plans of even an inferior grade may be measurably successful in spans of ordinary length; whereas nothing short of the most judicious distribution of material will ensure permanency in cases where long spans are indispensable, and any arrangement which can be made permanent in the latter case must certainly prove so in the former. It is worthy of remark here, that this particular combination of the arch with the truss is even now, with some, a favourite idea, but it is believed that its warmest advocates will be generally found among those whose opportunities for practical investigations have been limited, and that it is only necessary that the question be properly presented to them, to produce a change of views in respect to it. This partiality for the combination of the arch and the truss is attributable partly to the fact that the simple truss has in many instances failed, and, as a last resort, the arch has been added, of such dimensions and strength as to be competent to carry the truss and load: the truss serving only as a stiffener to the arch, while the latter, thrusting upon the masonry, has sustained the whole weight. Besides, to the casual observer who has never studied bridge construction, this combination presents at least an appearance of great strength and solidity, which do not in fact exist. That the simple truss without the arch has failed in some instances is unquestionably true; but while many of these failures have been caused from inattention to, or ignorance of, the laws regulating the composition and resolution of forces, by far the greater number have arisen from the inferior quality, or lack of the requisite amount of material, or from inferior workmanship. The acknowledged failure of the *Burr Truss*, as applied to railroad purposes, led to the invention of several other plans, all of which were based upon the abandonment of the arch, and were aimed at perfecting a truss, which of itself would be sufficient to meet the emergencies of the case. This was in pursuance of what was considered a very reasonable hypothesis, namely, that one system properly proportioned must prove much superior to any method or arrangement in which the attempt was made to combine two distinct principles, in their nature heterogeneous. Among the most prominent plans presented to remedy existing defects was one invented by Stephen H. Long. This plan of bridge was composed of lower and upper chords, posts, and braces, similar in outline and general arrangements to the Burr Truss, but differing from it in detail. An efficient system of counter-braces was introduced; these were made adjustable by wooden wedges, as were also the sustaining braces, by means of which any desirable elevation or deflection might be given to the truss. This plan of truss was rigid to a degree not previously attained; and to such an extent was this true, that, when properly adjusted, no perceptible deflection was produced by the passage of the load. It was, however, found difficult to keep it in adjustment, in consequence of the great shrinkage of the wedges and other timbers of the truss.

The bridge from which this example, Figs. 1370 to 1373, of Long's framing is taken consists of seven equal openings of 180 ft., measuring from centre to centre of the piers. The bottom string course is a beam built of six planks, each a foot in depth, four of the planks being 5 in. in breadth; and the two outside planks each 4 in. When put together these planks form a beam 12 in. in depth and 28 in. in breadth. The planks are bolted together by screw bolts, placed about 2 ft. apart and alternately near the top and bottom of the beam, as shown in the vertical section, Fig. 1372. Short wedges of wood are let into the bottom string to the depth of about 1 in., and into the sides of these wedges are mortised the ends of the diagonal braces, Fig. 1371. These diagonal braces abut against similar wedges which are let into the top string beam. The top string consists of three lines of 8 in. square timber, placed with a small space between each, so as to make the whole breadth of the beam 28 in., the same as that of the lower string. The pieces composing this beam are bolted together at intervals of 7 ft. All the braces are 8 in. square, and the number of braces abutting on each block, both at the top and bottom string courses, is always three, arranged two on one side and one on the other. Along the top string beam are fixed short cross pieces, 5 in. by 7 in., one above each of the abutting wedges. These cross pieces receive the tops of the vertical ties, which pass entirely through the framing from top to bottom, and are secured above the top string and below the bottom one by screw-bolts and nuts. Similar cross pieces below the lower string receive the extremities of the vertical ties. Two of these vertical ties pass through each of the abutting wedges, so that for the two sides of the bridge there are four vertical ties in each length of 7 ft. The frames are connected at the top by cross beams, and

the lateral stiffness of the bridge is further increased by wrought-iron ties at each of the piers, these ties being carried into the masonry at some depth below the platform of the roadway. The longitudinal sleepers for the railway, which has only a single track over this bridge, are laid upon transverse beams, which rest upon the bottom string pieces and are placed one on each side of each of the abutting wedges throughout the whole length of the bridge. The platform is further strengthened by diagonal horizontal beams framed between the bottom strings, Fig. 1373.

The invention of what is known as the *Howe Bridge* followed. In this, as in Col. Long's bridge, the idea of combining the arch with the truss was *originally* abandoned for reasons heretofore given, and it was believed that this simple form of truss would prove equal to any reasonable requirement. In the *Howe Bridge*, the posts used in the Burr and Long bridges are dispensed with, and iron rods substituted, by means of which any desirable *camber* may be given to the truss, thus overcoming the practical difficulty previously experienced in the adjustment of Col. Long's bridge, by the use of wooden wedges. This method of producing *camber* is certainly an improvement upon the means adopted in the Long Bridge for that purpose, but is much inferior to the latter in its method of counter-bracing, in that they are not adjustable, and perform a *negative* rather than a *positive* duty.

The Improved Burr Truss, introduced by Thomas Steele, is shown in elevation, Fig. 1374; Fig. 1375 is part of the plan of the same; and Figs. 1376, 1377, the detail to a larger scale of the tension-posts, braces, and counter-braces, upper and lower chords, and their iron fastenings.

In this method of combining an arch with a trussed frame the arches are connected with the tension-posts, and the posts with the chords by screw fastenings, as seen in Figs. 1376, 1377; and all is so arranged as to admit of changing the position of the arches relatively to the chords, or of drawing together the chords without changing the position of the arches, and thus regulating and distributing the strain over the different parts of the bridge at pleasure. This adjustment must take place once or twice in each year until the timber becomes perfectly seasoned; after which, in a well-constructed bridge, but little attention will be required. Plates of iron should in all cases be introduced between the abutting surfaces of the top chords and arches, and all possible care taken to prevent two pieces of timber from coming in contact, by which decay is hastened. Care should also be taken to obtain the curve of the parabola for the arches, as it is a curve of equilibrium and of greatest strength.

The parabola is the curve of equilibrium when no load is upon the bridge, and also when the load is uniform; but there can be no curve of equilibrium for the variable load of a passing train. Stiffness can be secured in this case only by an efficient system of counter-bracing. The Improved Burr Truss, of Steele, Fig. 1374, presents an example of one of the systems to produce the required stiffness.

Bridges constructed on this plan will be found to possess an unusual amount of strength for the quantity of material contained in them, and, if well built and protected, great durability.

The following are the points to be attended to in erecting one of these bridges, as given by the inventor in Haupt's Treatise on Bridges:—The truss must first be raised, provided with suitable cast-iron skew-backs to receive the braces and tension-posts; and the several parts of the chords should be connected with cast-iron gibs. Wedging under the counter-braces must be avoided by extending the distance between the top skew-backs sufficiently to bring the tension-posts on the radii of the curve of camber of the bridge. The tension-posts must be about 8 in. shorter than the distance between the chords; and in screwing up the truss care must be taken not to bring their ends in contact with the chords; but they must be equidistant, and about 4 in. from them. When the truss is thus finished it must be thrown on its final bearings; and it is then ready to receive the arches which should be constructed on the curve of the parabola, with the ordinates so calculated as to be measured along the central line of the tension-posts. They must be firmly fastened to the posts and bottom chords by means of strong screw-bolts and connecting-plates, as shown at *dd*, and should abut on the masonry some distance below the truss, which can be effected with safety, as the attachment to the posts and chords will relieve the masonry of much of their horizontal thrust. When a bridge thus constructed is put into use, it will be found that, as the timber becomes seasoned, the weight will be gradually thrown upon the arches, which will ultimately bear an undue portion of the load. To avoid this, the camber must be restored and the posts moved up, so as again to divide the strain between the truss and the arches.

The *Howe Bridge* is composed of lower and upper chords, braces, and counter-braces, vertical rods, and cast-iron *bearing-blocks*. The braces abut on the *bearing-blocks*, which pass through the chords in such a manner as to permit the rods to bear directly upon them. Spans of considerable length were built upon this plan, but experience proved that even this truss—like all others—had its limit, beyond which it could not be safely extended.

In the progress of railroad enterprises, in order to save large expenditures of money for masonry, longer spans than had been previously used became desirable, and in certain locations absolutely indispensable; besides this, locomotives were largely increased in weight, to meet the demands of traffic, and furnish a more economical mode of working; and thus arose the necessity for the adoption of some other expedient to meet the increased requirements of bridges. As all had been done by way of improving this truss that mechanical skill could devise, and which an extensive practice had amply afforded, it became evident that some *radical* change must be made in its arrangement, to enable it to meet the exigencies of the case. In this emergency the *arch*, heretofore condemned in the *Burr Truss*, was again resorted to; for it had been proved, from the experience which its use in that truss had afforded, that an *arch* of sufficient size, abutting against permanent masonry, would place the truss in a position of secondary importance.

It will be observed that the arch of the Burr Bridge, Fig. 1369, abuts upon the masonry in precisely the same manner as the arch of what is denominated the *Improved Howe Truss*, Fig. 1378, and the difference between the two consists simply in the mode of connection with the truss, and not in any change of principle or method of action.

It will be seen that the Burr Arch is securely fastened to the posts and braces of the truss, forming a solid adjustable mass. In Fig. 1378 the arches are not fastened to the braces or rods, but have an independent connection with the lower chord of the truss, by means of rods radiating from the former to the latter. By this method it was supposed that any desirable adjustment could be effected, and that the strain could be put upon either system, or equally upon each.

This new arrangement, although plausible in theory, is found impossible in practice, for the following reasons:—

1st. The rods from the arch to the lower chord are of various lengths, consequently the contractions and expansions must vary proportionately.

2nd. Not a single rod in the arch is of the same length as those in the truss, hence the expansion and contraction of the rods in the truss will vary from that in each, and all the rods connecting the arch with the lower chord.

3rd. This combination is exceedingly liable to maltreatment from the careless or ignorant.

4th. And even if it were everything in practice that is claimed for it in theory (which is not the fact), it involves a constant expenditure for adjustment, which must continue during the existence of the bridge itself.

The Burr Truss, Fig. 1369, with all its defects, *can be made superior by far to the Improved Howe Truss*, Fig. 1378. For, in the former, there may sometimes be a yielding and compression between the parts of the truss and those of the arch, producing a certain degree of united action; while in the Howe Truss everything depends upon the length of the rods, which must always change with the temperature, and thus render an approach even to perfect adjustment a matter of extreme delicacy. But, in either Fig. 1369 or Fig. 1378, it is clearly evident that, in order to have a structure absolutely safe, the arch and the truss—each of itself, independently of the other—should be of sufficient strength to sustain the whole load, that the strain may be borne alternately by each separate system.

Fig. 1379 shows an elevation of a bridge erected upon Howe's plan over Sherman's Creek, on

1379.

the Pennsylvania Central Railroad. Fig. 1380 is a plan, and Fig. 1381 a vertical section. The bridge has two spans, each 148 ft. 3 in. from end to end of the bow, or 154 ft. 6 in. from the

centre of the pier to the end of the truss. The pier is 3 ft. 2 in. wide at top and 6 ft. at the skew-backs. The truss is formed of three rows of top and bottom chords, and two sets of posts

and braces. It is counter-braced by rods of 1 in. iron between the braces. The panels increase in width from the end towards the middle of the span. The first panels are 9 ft. 1½ in. from centre to centre of posts, and the middle ones 12 ft. 1½ in.

In order to simplify and make clear the real points of difference existing in the combinations of the various plans of trusses of the same general outline, it may be stated that the material composing *any bridge truss*, whether of wood or iron, or of both, is subjected either to *tension* or *thrust*, and it is upon the proper application of these elements, together with a judicious distribution of the material, rather than upon any difference in detail that the perfection of any bridge structure depends; this may be illustrated by reference to Figs. 1382 to 1385.

Fig. 1382 is the truss of the Burr Bridge; in this the upper chord and braces are acted upon by thrust, and the lower chord and posts by tension.

Fig. 1383 is the Howe Truss, without the counter-braces; in this also the upper chord and braces are subjected to thrust, and the lower chord and vertical rods are acted upon by tension.

Fig. 1384 is a plan of truss sometimes used, the counter-rods being omitted; in this the upper chord and vertical struts are subjected to thrusts, and the lower chords and diagonal rods are acted upon by tension.

Upon a comparison of these plans it will be discovered that the variations between the Burr Truss, Fig. 1382, and the Howe Truss, Fig. 1383, consist in the use of vertical rods and bearing-blocks in the latter, instead of vertical posts in the former, both having precisely the same duty to perform. It will also be seen that Fig. 1384 varies from Fig. 1383, in that the rods are placed diagonally instead of vertically, changing the element of thrust from the diagonal braces in the latter to the vertical struts in the former, and transferring the element of tension from the vertical to the diagonal line.

Much importance is sometimes attached to just such modifications in detail as exist in Figs. 1382 to 1384, while the nature and intensity of the destroying forces are the same and equal in each. This has been proved by actual experiment, by the celebrated engineer and bridge-builder, D. C. McCallum, as follows:—Models were built, one on each plan, of equal length and height of trusses, containing the same sectional area and kind of material in chords and braces, and of equal perfection in details and workmanship, when it was found that the real difference in strength was unappreciable; and it may be well to add, that any given amount placed upon each, in progress of the experiments, presented precisely the same characteristics and contortions in shape, until final failure took place. All bridges having their chords parallel, irrespective of the particular method adopted in combining them, and regardless of the amount of material used in their construction,

when loaded to nearly the point of fracture, present somewhat the same appearance, the greatest deflection being invariably at points near the abutments. This will be understood by the statement, that the vertical strain is increased, as the distance from the centre, to the ends of the truss; at the centre the vertical strain is nothing, and at each end of the truss it is equal to one-half the weight of the structure and its load.

In point of strength, the arrangements, Figs. 1382 to 1384, are not superior to the simple combination, Fig. 1385.

All bridges having their chords parallel exhibit the same uniformity of action, and may be illustrated by reference to Fig. 1386, in which A A is the upper chord; B B, the lower chord; C C, tension-rods; D D, braces.

When a sufficient weight is applied to any truss of this outline, to cause deflection below the straight line, the upper ends of the braces, D D, are made to approach each other, and the distance between the ends is diminished; and as the deflection increases, the upper ends of the braces, D D, will describe arcs, *a b*, of a circle downwards, the radius of which being the length of the braces, D D. But when the upper chord is arched, as in Fig. 1387, a sufficient weight will cause the braces, D D, to describe an arc upwards, represented by *cd*, Fig. 1387. When the chord, *ce*, becomes straight, the arc will then be described downwards, as shown in Fig. 1386. As an illustration of the McCallum Inflexible Arched Truss, see Fig. 1388, in which A A is the lower chord; B B, the upper chord; C C, tension-rods; D D, braces; E E, struts; and W, weight.

Upon an inspection of this figure, it will be seen that any deflection produced upon the centre of the arch, by means of the weight W, will cause the points B B to separate, by thrusting outward, and in the direction of the ends of the truss, producing an upward movement of the upper chord, at the ends of the braces D D, the latter describing arcs of a circle upward, and from thence will be communicated, by means of the tension-rods C C, to the centre of the lower chord, raising the latter at the point where the rods, C C, meet. By removing the weight W, and inserting a vertical strut at F, the upward movement of the chords will be arrested by the weight W. This peculiar action may be described as follows:—

Any deflection produced in the centre of the arch will cause an outward and, consequently, an upward force at the upper ends of the braces, which, by means of the tension-rods and strut, is transferred directly back to the under-side of the arch, producing an upward force at the latter point, equal to the original downward force applied on top of the same. This combination of forces is in agreement with a well-known law, namely, when two forces of equal powers of resistance are opposed to each other, a state of rest is produced.

For a further illustration of the action of this truss, see Fig. 1389, in which A A are pieces of the lower chord, the centre being removed; B B, upper chord, deflected by the weight W. C C are braces which pass through the lower chord and rest upon the masonry. D D are tension-rods. It will be seen that the ends of the pieces of the lower chord at E E are raised considerably above a horizontal line. This upward tendency will continue until the upper chord between B B is deflected below a straight line, when the action will be reversed.

Fig. 1390 exhibits the forces at a state of rest, in which A A are portions of the lower chord; B B, upper chord; C C, arch-braces, which pass through the lower chord, and rest in the masonry; D D, tension-rods; E E, braces; W, weight. It will be seen that the strain produced by the weight W is transferred to the lower chord by means of thrust upon the braces E E, to the points F F, and, by means of tension on the rods D D, to the points B B, and from thence it is brought upon the arch-braces C C, which rest upon the masonry. In this manner a perfect equilibrium of forces is effected, as it is evident that the point G cannot change position, unless the points B B are thrust outward towards the ends of the truss, which must raise these points, this being prevented by the strain upon the points F F, communicated by the weight W, through the braces E E.

For a full plan of McCallum's Inflexible Arched Truss is referred to Figs. 1391 to 1395. Upon inspection, it will be observed that the sustaining principle is very much increased

1391.

PLAN
1392.

WHOLE PLAN OF LOWER CHORD.

1393.

1394.

1396.

toward the ends of the truss, not only by the addition to the amount of material at these points, but it will be seen also that the panels become shorter as the vertical strain increases. The posts are placed upon lines radiating with the arch; the braces form equal angles with the posts; and in this way the latter are made to approach more nearly together toward the ends of the truss. The student has already had sufficient evidence of the great strength of this form of truss, and it has also been shown that the tensile strain upon the lower chord is much less than in any other known plan. In fact, the latter may be *entirely severed*, and the structure will still be competent to sustain a heavy load. In this, it differs from all other combinations.

In Fig. 1394, U is the upper chord; S, straining beam; A, arch-brace; M, main-brace; C, counter-brace.

Upon referring to Fig. 1391, which represents a clear span of 180 feet, it will be seen that the arch-braces which rest upon the abutments are extended to points on the arch about 47 ft. from the abutments. From the top of each set of arch-braces, running diagonally on each side of the truss, are placed heavy suspension-rods, which are connected with the lower chords 12 ft. farther from the masonry. Thus the bridge seat is substantially transferred to a point 47 ft. towards the centre of the bridge, reducing a span of 180 to 86 ft., so far as the *tensile strain* upon the lower chord is concerned. For this intermediate space of 86 ft., the arch-beam is of sufficient strength to sustain the whole load, if required. *Strength*, however, is not all that is required, for a railroad bridge especially, subject as it is to a *moving load*; there must also be *rigidity, stiffness*, and freedom from vibration. A bridge *may* be strong yet flexible, rigid yet weak; in fact, flexibility is incompatible with durability; the structure should be prepared at all times to receive its load, and should not be permitted to change shape in the slightest degree by its passage over it. To produce this result, an effective system of counter-braces is indispensable.

The proper office of counter-braces is frequently misunderstood, as is evident from the manner of their application in many cases in which they are used as *check-braces only*, having a *negative* rather than a *positive* action; this may be readily shown. When the load is applied, the truss is deflected in consequence of the yielding of the braces; this has the effect of *shortening* the diagonals in the direction of their length, while the diagonals in the direction of the counter-braces are correspondingly *lengthened*; this will leave a space between the ends of the latter, and the *bearing-block* in the lower chord. When the truss is in this condition, if wedges are inserted between the ends of the counter-braces and the lower chord, in such a manner as to fill up the whole space, it is evident that the weight may be removed without at all affecting the shape of the truss, the deflection originally produced by the weight being maintained by the counter-braces, the strain upon the sustaining braces and other portions of the truss remaining precisely the same as when the weight was suspended.

Now suppose the original weight to have been 200 tons, it is evident that, as soon as it is removed, each counter-brace will be subjected to an upward thrust, easily found from its position; the sum of all the thrusts making 200 tons. Now let there be a smaller load applied, this load will not produce any additional strain upon any portion of the truss, nor will the deflection be increased in the slightest degree; the only effect produced by suspending the latter weight will be the relief of the counter-braces, equal to the difference between the first and second weights.

The inventor has found it very difficult to explain this clearly in the course of conversation with some individuals, from the fact that *weight* and *strain* were confounded. Now it is true, when the original weight was applied of 200 tons, the abutments were loaded with just 200 tons more than previously, and the truss was also loaded with 10 tons more; but when the wedges were driven, and the weight removed, while the abutments were relieved of 200 tons pressure, the truss still retained the original strain produced, the weight being required to *produce the strain*, the latter remaining after the former has been removed.

In order to make a practical application of the above, the following method of adjusting the *Inflexible Arched Truss* is submitted. When these bridges are raised, it is usual to load them with a train of locomotive engines, attached closely to each other, and that greater weight may be obtained, the tenders are sometimes detached, and the bridge covered with engines only; with this load, the latter is strained down to a perfect bearing in all its parts; by this means the whole structure is more or less deflected, while the counter-braces are hanging loosely in their places; if, therefore, when the bridge is in this condition with its load, the counter-braces could be lengthened with considerable force, it would not recover its original shape upon removal of the load, but would be held down by the action of the counter-braces to very nearly the same position as when loaded. In this plan of bridge, the lower ends of the counter-braces rest in *iron stirrups*, which are attached to the vertical ties or posts at a point near the lower chord by means of castings and nuts, by which they may be lengthened several inches; in this manner they are made to perform a *positive* duty. When the bridge is adjusted as above, it is clear that a *less* load than that originally applied cannot produce any deflection whatever; the only effect of the passage of a train over it will be to relieve the counter-braces, and will not add a pound pressure upon any timber of the trusses.

In the arrangement of any bridge truss the attainment of the following requisites is desirable:—

- 1st. Such equilibrium of forces as will produce uniformity of action.
- 2nd. Such quantity and distribution of material as will ensure a *large surplus* of sustaining principle, *thereby guarding the structure against accident*.
- 3rd. *Perfect rigidity*, that the combination in all its parts may have permanency *equal to the durability of the material composing the same*.
- 4th. The arrangement of the parts should be such as to be free, if possible, from the necessity of adjustment.

The McCallum *Inflexible Arched Truss* meets all these requirements.

Problem.—Let it be required to find the equal weights w , w , Fig. 1396, kept in a state of rest by a single weight, W , which has caused the arc $q C a$ to assume the chord $p D b$, the rigidity of

the arc being neglected. Let R = the radius of the arc $q C a$, and put $2c$ = its length; then the chord $q a$ and versine $C D$ are readily calculated. Let the chord $q a = 2d$, and $C D = 2e$. Let $f = A q = A p = B a = B b$ and $g = B m = B n = A s = A r$. Also let $A B = 2h$

$$\frac{2h - 2d}{2} = h - d, \quad \frac{h - a}{f} = \cos. \theta, \text{ putting } \theta \text{ for the}$$

angle $a B n = q A s$.

$$\frac{2h - 2c}{2} = h - c, \quad 2h - 2c = A B - p b.$$

∴ Putting ϕ for the angle $b B n = p A s$, $\frac{h - c}{f} = \cos. \phi$.

$$\therefore \phi - \theta = \text{angle } a B b = n B m = s A r.$$

$$\therefore m n = g \sin. (\phi - \theta).$$

Then, according to the principle of work, $2g \sin. (\phi - \theta) w = 2e W$. ∴ $w = \frac{e W}{g \sin. (\phi - \theta)}$.

Let $A B = 2h = 188$ ft.; the length of the arc $q C a$ = the straight line $p D b = 2C = 136$ ft.; $R = 200$ ft.; $m B = g = 60$ ft.; $b B = f = 50$ ft.

It will be found that the arc $q C a$ before being disturbed contains $38^\circ 57' 40''$; the versine of this arc = 11.449 ft. = $2e$; the chord = 133.39576 ft. = $2d$.

$$\frac{h - d}{f} = .5460424 = \cos. 56^\circ 54' 15''; (\theta). \quad \frac{h - c}{f} = .5200000 = \cos. 58^\circ 40' 4''; (\phi).$$

$$\therefore \phi - \theta = 1^\circ 45' 49''.$$

$$\therefore \frac{e}{g \sin. (\phi - \theta)} = \frac{5.7245}{60 \sin. (1^\circ 45' 49'')} = 3.100092. \quad \therefore w = \text{more than 3 times } W.$$

Consequently, the weight W before reducing the arc $q C a$ to the straight line $p D b$ must raise more than six times its own weight if posited at s and n .

Description of an Iron Bridge, in which the Forces are well combined to meet the demands of Railway Traffic.—The bridge we now propose to describe is one belonging to a system of bridge-building introduced by Wendel Bollman; it was erected at Harper's Ferry, U.S., the practical working of which was carefully observed by the editor of the present work. This iron suspension trussed bridge was 124 ft. between the abutments. The length of the cast iron in the stretcher was 128 ft. The weight of the cast iron, 65,137 lbs.; weight of wrought iron, 33,527 lbs.; making the total weight of cast and wrought iron, 98,664 lbs.

Fig. 1398 is an elevation of part of the side, showing one pier and part of the cast-iron stretcher. The cap is removed from the pier to show how the rods are secured.

Fig. 1397 is an elevation of both piers and of the eight panels of which the bridge is composed. The system of arranging the braces and connecting-rods is exhibited in this figure.

Fig. 1401 is a cross-section, showing the floor-bracing and the position of the rails. Fig. 1401 also shows, in section, the roof and posts.

Fig. 1400 shows a plan of the flooring of the bridge, the positions of the rails, and floor-bracing.

Fig. 1399 shows two posts, part of the stretcher, and the diagonal rods in one of the panels.

The wrought iron requires little workmanship, the rods from the centre to abutments having but an eye at one and a screw at the other end; with a weld or two between, according to length. The long counter-rods have two knuckles and one swivel for adjustment of strain, and convenience in welding, as well as in raising the whole.

The cast-iron stretcher is octagonal without, circular within, and averages 1 in. of metal. It is cast in lengths according to the length of panel, and jointed in the simplest manner,—at one end of each length is a tenon, at the other a socket. The latter is bored out, and the tenon and its shoulder turned off in a lathe to fit the socket; thus, when thoroughly joined, to form one continuous pipe between abutments. The ends of the sections of cylinders, inserted into those contiguous, are slightly rounded, to allow a small angular movement without risk of joint fracture. A cast-iron plate or washer sets on a bracket cast with each abutment end of stretcher, and at right angles to the centre acting-rods. The tension-bars are passed through this washer to receive a screw-nut for the erection and adjustment of the system. The stretcher or straining beam, the vertical posts, and suspension-bars, compose the essential features of the bridge; each post being hung by two bars from both ends of the stretcher independently of all the others; and each post and pair of tension-bars forming with the stretcher a separate truss. This system, perfect in itself, is additionally connected by diagonal rods in each panel; also by light hollow castings, acting as struts. The diagonal side rods might be safely dispensed with; for the peculiar merit of the truss is its perfect independence of such provision. They are therefore used as a safeguard only in case of the fracture of any of the principal suspension-rods.

By this combination of cast and wrought iron, the former is in a state of compression, the latter in that of tension; the proper condition of the two metals. It unites the principles of the Suspension and of the Truss bridges. Each bar performs its own part in supporting the load in proportion to its distance from the abutment; so that the entire series of suspending-rods transmits the same tension to the points of support as would be equally transmitted from thence to the centre of the bridge.

This bridge, it will be seen, is composed of seven independent trusses, which transfer the weight concentrated on each floor beam directly to the abutments, without aid from any other connection; and not from panel to panel, as in general use. The strain on cast and wrought iron is wholly in direct line; and the result, the least quantity of metal is required to carry a given weight. The weight of bridge and load has a vertical pressure on the piers, towers, &c., the only horizontal thrust being from the expansion of iron, which may be accommodated by rollers, sliding on an abutment bracket placed over the pedestal, or by other means: the necessary dimensions of masonry therefore become moderate.

1

It is evident, from an inspection of the cuts, that no chord is requisite at the bottom of the truss to resist tension; the only advantage of that employed is to regulate the movement produced by expansion, in the performance of which agency the resistance is one to compression. Although the abutment-bracket casting and its pedestal were so constructed as to admit of accommodation to expansion, by rollers, yet such contrivance was omitted with the view of fully testing the effect of greatest expansion throughout the system.

This bridge was inspected by the writer, ten months after it was erected at Harper's Ferry; during which time it had been exposed to extremes of cold and heat, and to an average run of twenty trains daily. From the closest inspection, we find that the extreme expansion measures, as near as possible, $\frac{5}{16}$ in. on each tower, or $\frac{5}{8}$ in. in the entire length, 128 ft. of stretcher; and without the slightest perceptible derangement of masonry; the dimensions of which are 4 ft. square of base, 12 ft. high, and 2 ft. 9 in. at top.

While on the subject of expansion, it may be well to notice the effect from difference in expansion of the rods. At the first point of suspension, or where the longest and shortest rods meet, the counter-rod is about four and a half times longer than the acting-rod; and the expansion of the counter is four and a half times that of the acting-rod. But there is also a proportionate difference in the lengths of stretcher from the point directly over the centre of connection to the extremities of these rods. This has been practically proved in this bridge. The suspender bolt, when the expansion is extreme or $\frac{5}{8}$ in. in length of stretcher, exhibits a motive difference of $\frac{3}{16}$ in. toward the short or acting rod; which difference is provided for, as seen by slot, dotted in elevation, where the vertical suspender bolt moves to accommodate any such difference, and to give that proportion of weight to each rod according to the angle. It affords easy access for repairs; for instance, should a new floor beam be required, it is but needed to slacken the horizontal rod and the keys in longitudinal strut, remove the washer under point of suspension, and let down the beam to be replaced: which can be done without trestling up any part of the bridge. In case of fire, the floor may be entirely consumed without any injury to the side truss.

The permanent principle in bridge-building, sustained throughout this mode of structure, and in which there is such gain in competition with every other, namely, the direct transfer of weight to the abutments, renders the calculation simple, the expense certain, and facilitates the erection of secure, economical, and durable structures.

Details.—Resistance of cast-iron stretcher G H to compression, 177,511 lbs., or 4930 lbs. the sq. in. Half weight of bridge and load: weight of iron, 24,000 lbs.; weight of wood, 15,000 lbs.; weight of load, 184,000 lbs.; momentum, 25,000 lbs. = 248,000 lbs..

Size of Acting-rods.

Trial made on the 1st day of June, 1852, to prove the Capability of this Bridge.—Three first-class tonnage engines, with three tenders, were first carefully weighed, and then run upon the bridge, at the same time nearly covering its whole length, and weighing in the aggregate 273,550 lbs., or $136\frac{1550}{20000}$ tons nett, being over a ton for each foot in length of the bridge. This burden was tried at about eight miles an hour, and the deflections, according to gauges properly set and reliable in their action, were at centre post $1\frac{3}{8}$ in., and at the first post from abutment $\frac{9}{16}$ of an in. From this test it is found that the load did not cover the entire length of bridge by about 13 ft., yet the excess of weight in the middle, and at a speed of about eight miles an hour, produced no greater deflection than $1\frac{3}{8}$ of an in. at the centre post, and $\frac{9}{16}$ of an in. at the first point from abutment.

Before proceeding farther, it is necessary to point out some serious mistakes made by experimenters and writers on the strength of materials. When discussing the strength of girders resting on supports, the editor of the present work, in his new theory of the strength of materials, first pointed out fallacies involved through introducing an imaginary line, termed the neutral axis, and merely investigating the upright laminæ of the material. We do not propose to discuss this subject thoroughly here, but to show how errors may be involved when the strength of girders is considered with respect to forces supposed to act only in parallel upright planes. See 'Civil Engineer and Architect's Journal,' June, 1846.

If a beam, *Q R*, Fig. 1402, rests loosely on two supports, *A* and *B*, and is loaded in the middle with a weight, *W*, which deflects it ; before the weight is placed on the beam $ab = pq = cd$; and $ef = rs = nm$; but when the beam is deflected by *W*, *p q* is greater than *a b* or *c d*, and *r s* is less than either *e f* or *m n*. Before the beam is loaded it is supposed to be rectangular ; in most cases this change of form may be detected by experiment. Although the nature of the material and amount of pressure may render this change of form imperceptible, yet these forces acting across the girder, in the directions of *p q r s*, are in operation, loosening bolts, buckling and puckering upright sheets, and so on. This action should be carefully attended to by engineers in constructing girders, whether solid, hollow, or composed of skeleton frames.

The material at *r s* is wire-drawn and compressed, while at *p q* the material becomes upset, extended, and loosened, according to the elastic limit and nature of the girder. The current erroneous theory of the strength of materials supposes, when the beam is bent by a weight, *W*, the fibres are compressed at *p q* and extended at *r s*, without alteration of breadth ; that is, *p q* remains $= ab$ or cd , and also $= rs$ or ef . A portion of the body will often be forced out near the line *p q* ; but when the substance supporting the weight is tough, the separation may take place irregularly and diagonally, with a sliding cutting motion, and not directly through the plane *p q r s*, in the middle.

Stone Bridges.—The art of constructing stone bridges has always been and still is as much the domain of practice as of theory. The long and intricate calculations which it is necessary to go through in determining the principal dimensions of a stone bridge, though these calculations are always, with a wise precaution, subordinated to practice ; the little time which those upon whom the guidance of engineering works devolves have to devote to the calculations, and the dispatch with which projects have to be designed and executed ; and other considerations affecting skilful builders who, for want of time or opportunity, have failed to gain sufficient theoretical knowledge, the absence of which might be compensated for by their long practice aided by a few simple and precise principles—all this has induced Edmond Roy, the experienced French engineer, to compress into a few pages some practical information and formulæ, into which enter only the simplest elements of arithmetic and geometry, and by means of which may be readily determined the dimensions of aqueducts, bridges, viaducts, and retaining walls.

Before proceeding further, we give this practical epitome of Roy : it speaks for itself.

EMPIRICAL FORMULÆ SERVING TO DETERMINE THE PRINCIPAL DIMENSIONS OF BRIDGES IN MASONRY OF SEMICIRCULAR, ELLIPTICAL, SEGMENTAL, AND GOTHIC FORMS.

Depth of Masonry at the Crown and Form of the Curve of the Intrados.—Up to the present time the greater number of empirical formulæ giving the depth of masonry at the crown determine this depth in consideration of the span alone. In this way a bridge having a semicircular or an elliptical arch, even if the latter be depressed to the degree of $\frac{1}{16}$, ought, in accordance with these formulæ, to possess an equal depth at the crown. Such are the formulæ of Perronet, of Gauthey, and of Rondelet.

These formulæ appear to us defective ; in proof of which we might point out the great difference

which exists between the dimensions of the masterpieces of the celebrated Perronet and those which they would have had if his formula had been applied.

In determining the thickness at the crown, we ought evidently to take into consideration :—

1. The span of the arch.

2. The degree of depression.

The greatest radius of the curve of the intrados and the magnitude of the arc of the intrados alone corresponding with these two conditions, the depth at the crown in segmental bridges must be determined by the former of these two quantities or by the two combined. It is also obvious that the lateral thrust upon the abutments with the depression given to the arch, and the dimensions of the abutments at the springing, will therefore be determined by the radii of the curves of the intrados. All other dimensions will follow, generally, from the depth at the crown.

Signification of the Letters employed in the Formula.

Q = the span of the arch.

R = the longest radius serving to determine the depth at the crown.

F = the rise, or distance between the level of the impost and the summit of the intrados.

C = the depth at the crown.

Semicircular Arches.

We have

$$R = \frac{Q}{2}; \quad [1]$$

$$F = R = \frac{Q}{2}; \quad [2]$$

$$\text{General values} \dots \begin{cases} C = 0.30 + 0.07 R; \\ C = 0.30 + 0.08. \end{cases} \quad \begin{matrix} [3] \\ [4] \end{matrix}$$

Formula [3] is applied by us to any span, with ordinary materials.

Formula [4] is applicable to cases in which materials of feeble resistance are employed, such as certain kinds of freestone. The dimensions denoted by this formula are not excessive for spans of less than 12 or 15 metres, and it may with propriety be employed.

Arches heavily banked.—In the case of arches supporting thick masses of embankment, it will be necessary to add to the depth at the crown in the proportion of 0.02 for each metre of embankment above the extrados.

Elliptical Arches.—In the elliptical arch the radius of the upper segment, which is the longest radius, may, in accordance with the various conditions according to which we wish to construct the curve of the arch, have many dimensions for the same span and the same rise. We shall therefore, in order to have a uniform formula for elliptical arches, always consider as a basis of calculation that the curve is of 3 centres only, with segments of 60°. It will not, however, be necessary always to construct the curve of the intrados with 3 centres; it may be of 3, 5, 7, or 9, as may be deemed expedient; we have chosen 3 merely as a uniform basis of calculation. It is plain that a curve of 5, 7, or 9 centres, substituted for one of 3 which has served as a basis of calculation, must have the same rise as the latter. Our opinion is that the curve of 3 centres should never be employed, as it must of necessity be angular.

2. The mode of calculation which we have adopted fixes *a priori* the utmost limit of depression which it is proper to give to elliptical arches, and consequently indicates the moment when we should begin to employ the segment.

The general value of R in cases of curves with 3 centres, the arcs of which are of 60°, is

$$R = Q \times 1.183 - 1.366 F. \quad [5]$$

Let r represent the radius of the lesser arcs, then $r = Q - R$ [6]. If we make $F = 0.134 \times Q$ or $\frac{Q}{7.46}$, we have $R = Q \times 1.183 - 1.366 \times 0.134 \times Q$; whence $R = Q \times 1$, and

$$r = Q - R = 0.$$

This result agrees with the geometrical principle, that the chord of an arc of 60° is equal to the radius.

Thus, according to our principles, the employment of arches of the elliptical form is limited between $F = \frac{1}{2} Q$ and $F = \frac{Q}{7.46}$.

On the other hand, if we compare the section of the ellipse, Fig. 1407, which is depressed to $\frac{F}{Q} = 0.20$ with the segment of 60° or $0.134 \times Q = F$, drawn in a dotted line near it, we shall see that the aperture, or vent, which would result from the employment of each of these two curves would be the same, or nearly so; the difference will be still less on comparing the segment before mentioned with the curve of Fig. 1404. In this latter case it is indeed nothing. Practically, then, there would be no advantage whatever in employing an elliptical arch having a rise of less than $\frac{1}{2}$ of the span, because in such a case we should have a curve too much depressed at the summit, and because this ellipse might be advantageously replaced by a segment with a rise of $\frac{1}{7.46}$ affording a vent equal to that of the ellipse.

In practice elliptical arches having a rise of less than $\frac{1}{2}$ of the span have never been employed.

General Values of the Elements serving to determine the depth at the crown of elliptical arches :—

$$\begin{aligned} R &= 0 \times 1.183 - 1.366 F; \\ C &= 0.30 + 0.05 R. \end{aligned} \quad [7]$$

Plan of Curves with several Centres.—Let A B, Fig. 1403, be the span of the arch, and I F the perpendicular on the middle of A B = the rise.

Describe the half-circumference A F' B with $\frac{1}{2}$ A B for a radius.

Divide the half-circumference A F' B into as many equal parts as there are to be centres.

Produce the perpendicular I F as far as F', the point where it cuts the half-circumference and divides the top segment into two equal parts.

Draw the chords B 1, 1 2, 2 F', F' 3, 3 4, 4 A. Take upon A B any two points r , at equal distances from the extremities A and B, which will be the centres of the first arc of the curve and the radius of which will be B r . Through the point r draw $r o$ parallel to the radius I I, which will cut the chord B 1 in o and B o , and be the chord of the first arc. Through the point o draw $o p$ parallel to the chord 1 2; through the point F draw F p parallel to the chord 2 F': the point of intersection p of the latter two parallels will determine the chord $o p$ of the second arc and the chord $p F$ of the half arc of the summit. Through the point p drawing $p R$ parallel to 1 2, which will cut in r the radius $o r$ produced, and in R the perpendicular I F produced, the axis of the arch: the points r' and R will be the centres of the second arc and of the arc of the summit. Figs. 1404, 1405, give illustrations of curves with 7 centres. It will be seen that the construction is exactly the same; but the first two radii may be taken at pleasure, and the third, that of the arc of the summit, may be determined as for Fig. 1403, which is the case of a curve with 5 centres only.

It follows from the means which we have pointed out that it would be necessary to proceed cautiously, in order to give the proper dimensions to the smaller radii necessary to produce a regular and graceful curve approaching as near as possible to the ellipse. To avoid this we have drawn up Tables applicable to the describing of curves with 5 and 7 centres, and by means of which we may determine by a simple multiplication the length to be given to the first lesser radii of the curves.

There are only two distinct conditions according to which elliptical curves may be traced:—

1. Supposing that the angles in the centre of each of the arcs are equal to each other.

2. That the magnitudes of the arcs are equal.

We give Tables Nos. I. and II., which satisfy the former condition, and Nos. III. and IV., which satisfy the latter for curves with 5 and 7 centres.

NOTE.—The horizontal columns marked by the figures (1), (2), (3), correspond to the examples given in Figs. 1403 to 1405.

The rise and span of an arch being given, divide the rise by the span; the quotient $\frac{F}{Q}$ will be one of the numbers of the first column on the left, or near it: the products of the span by the proportions corresponding to this quotient, situated on the same horizontal line, will give the length of the first radii. The radii near the summit of the curve must be determined from the diagram.

It is necessary to remark that in the application of Tables Nos. III. and IV., in which the angles in the centre are not equal to each other, the divisions of the half-circumference must be made according to the angles indicated in these Tables. See application, Fig. 1405.

The principles of our Tables have nothing absolute about them; they may be varied on the plan and the number of centres increased, if it be found that the limits are too restricted; for the construction employed for 5 and 7 centres is analogous to that to be employed for 9, 11, or 13 centres. Only the flatness of the curve at the summit is proportional to the increase in the number of centres, and greater care is needed in the construction of the plan. Our Tables are designed only to give, within practical limits, the means of avoiding the necessity of making

experiments, and of obtaining *a priori* the required curves. Our general formula [5] gives the values of the radii for a curve of 3 centres with angles in the centres equal.

We do not advise the adoption of the curve of 3 centres for a depression of less than 0.36, for in the two viaducts of Port-de-Piles and of Auzon (railway from Tours to Bordeaux), in the construction of which Roy took part, the former having three arches of 31 metres, and the latter five arches of 20 metres. The designs for elliptical arches of 3 centres with angles in the centres equal, gave a depression of 0.33. In the execution of these works, recourse was obliged to be had to curves of 5 centres, because with 3 centres only there was a very distinct angle at each change of curvature.

Tracing the Ellipsis.—1. Gardener's ellipsis.

Let AB , Fig. 1406, be the span of the arch and major axis of the ellipsis. Upon the middle of AB raise the perpendicular IF equal to the rise of the arch, which will be half the minor axis of the ellipsis. From the point F , as a centre with $\frac{1}{2} AB$ or IF as a radius, describe an arc cutting the line AB in two points, m and m' , which will be the foci of the ellipsis. If at the foci m and m' we fix the ends of a thread, the whole length of which is equal to AB , the major axis of the ellipsis, and with a style keeping the thread equally tense, we move it round from B to F and A , the style will trace a curve which will be an ellipsis, and the right lines ma , $m'a$; and ma' , $m'a'$, drawn from the points a and a' to the foci m and m' , are radii vectores, and they show the positions of the thread as the style moves round.

1. The line bisecting the angle formed by the two radii vectores from the same point in the ellipsis is a normal to the curve in this point. This property of the ellipsis will furnish us with a ready means of determining the joints of the voussoirs. We will return to this subject presently.

2. The plan of describing an ellipsis by means of a thread is applicable only to the laying out of gardens, from which its name is derived. For plans of arches where a very exact curve is required, we propose the following method:—

Substitute for the ordinary thread a piece of wire, the diameter of which should be from $\frac{1}{8}$ to $\frac{1}{4}$ of a millimetre; at the foci m and m' , Figs. 1408, 1409, fix two pins, which will serve as points of rotation; one of these pins passes through a hole in the middle of a pair of pincers, closing with a screw, the use of which is to hold firmly one end of the wire; the other pin has a ring attached to it, to which the other end of the wire is fixed. The part d of the pincers is intended to balance the part c . Instead of pincers, the part c might have a small cylinder with a ratchet wheel. m is a small flat piece of board, mounted on three rollers turning on their centres; b is a horizontal pulley of 0.05 in. diameter turning on a vertical axis fixed in the board m ; around this pulley passes the wire which guides the elliptic track that must be followed by the board m ; through a hole in the board at q passes a style, loaded a little, if necessary, to render its trace upon the plan plainly visible. The board m must always be moved, so that the hole q is on the bisecting line of the angle formed by the radii vectores. The curve thus described will be yet more exact if the pin of the pulley be made hollow to enable the style to pass through it.

Tracing an Ellipsis through Points.—Let AB , Fig. 1410, = Q , i the middle of AB , and the perpendicular $iF = F$. The foci m and m' will be determined in the manner shown, Figs. 1408 to

1410. From the point i as a centre with Ai or $\frac{AB}{2}$ as a radius, describe the part of the circle AD .

At the point A , the extremity of the major axis, erect the perpendicular AN upon AB , equal to $A'm'$, the distance from the focus to the extremity of the major axis. Joining the points D and N , the straight line DN produced will meet the major axis AB produced to a point K ; the straight line DN possesses properties which form the basis of the method we are about to point out.

1. It will be a tangent to the ellipsis at the point where it is met by a perpendicular to the major axis, erected from the focus m' .

2. All the perpendiculars to AB , erected from any points between A and i and included between AB and DN , will be equal to the radius vector passing through the point in which the ellipsis would be met by each of these perpendiculars respectively.

If, then, we take upon AB any points 1, 2, 3, &c., and erect the perpendiculars to AB $11'$, $-m'n'$, $-22'$, $-33'$, which will meet the straight line DN in the points $1'$, $-n'$, $-2'$, $-3'$, by describing arcs of circles with the focus m' as a centre and radii equal to the perpendiculars $11'$, $-m'n'$, $-22'$, $-33'$, between AB and DN , the point in which each of the arcs cuts the perpendicular which has determined its radius will be a point in the ellipsis n , n' , n'' , n''' .

If we now trace a curve passing through all the points thus obtained, we shall have the quarter of an ellipsis, and the other half of the arch may be formed in the same way.

3. Numerical value of the position of the foci.

We have as the value of the distance from the middle of the major axis to the foci:—

$$I m' = \sqrt{\frac{Q^2}{4} - F^2}, \text{ because of the rectangular triangle } m' i F.$$

4. Numerical value of the position of the line D K.

We have as the value of the distance from the middle of the major axis to the point K where the line D N meets the major axis $i k = \frac{Q^2}{4\sqrt{\frac{Q^2}{4} - F^2}}$, because of the similar triangles D i K and

$$D N i', \text{ whence } D i' = \frac{Q}{2}.$$

5. Values of the ordinates of the ellipsis.

The perpendiculars $1 n$, $-m' n'$, $-2 n''$, $-3 n'''$, included between the major axis and the curve, are the ordinates of the ellipsis. The parts of the major axis measured from its extremity A : A 1, $-A m'$, $-A 2$, $-A 3$, are the abscissæ of the above-mentioned ordinates. Representing the abscissæ by x and the ordinates by y .

Section of Elliptical Arches.—We have $y = \frac{2F}{Q} \sqrt{\frac{Q^2}{4} - x^2}$; the area of an ellipsis being equal to π , multiplied by the product of the two half-axes, and representing the section of the arch by S, we have $S = \frac{\pi Q F}{4}$.

Determining the Joints of the Voussoirs.—When the thickness at the crown and at the springing has been decided upon, the thickness at the springing being greater than that at the crown, it will be necessary to trace the mean ellipsis, having just determined its foci: upon this ellipsis must be marked the divisions of the course of voussoirs. In each of these joints of division will be determined the bisecting line $y p$ of the angle formed by the two radii vectores drawn from each point of division, Fig. 1410.

Segmental Arches.—General values of the radius, rise and magnitude.

The chord of an arc or the span of a segmental arch being given, the radius of this arc is determined according to two different conditions, see Fig. 1411.

1. The rise required.

2. The magnitude in degrees and minutes which it is necessary to give to this arc.

The rise being $= F$, and the magnitude equal A, we shall have for R and F the following values:—

$$R = \frac{F^2 + \frac{Q^2}{4}}{2F}; \quad [8]$$

$$F = R - \sqrt{R^2 - \frac{Q^2}{4}}; \quad [9]$$

$$R = \frac{Q}{2 \sin. a}; \quad [10]$$

$$\sin. a = \frac{Q}{2R}; \quad [11]$$

$$F = R - \cos. a \times R. \quad [12]$$

Note on Trigonometry.—It will be necessary to give a few explanations of the chief terms used in trigonometry, to enable those of our readers who have not studied that science to employ the formulæ we have just adduced. The sine of an angle $a b c$, Fig. 1412, which we will call α , is the perpendicular $m n$ let fall upon $c b$ from the point m , where one of the sides meets an arc described from the summit b , as a centre with a radius of 1. The cosine of an angle is the portion of the side $c b$ included between the point n , the bottom of the perpendicular, and the summit b of the angle, the centre of the arc. The sine of an arc is the perpendicular $a d$ let fall from one of the extremities, a , of the arc upon the radius $c b$, passing through the other extremity, c , of the arc. The cosine of an arc is that portion of the radius included between the end of the sinus d and the centre b of the arc. The portion $c d$ is called the versed sine, and is equal to the radius $c b$ of the arc, minus the cosine $d b$. The tangent of an arc, $a c$, is the perpendicular $c t$ erected from the extremity of one of its extreme radii, $c b$, and included between its point of contact, c , and the point, t , where it is met by the other extreme radius, $a b$, produced. The cotangent is the tangent of the complement of the arc.

Chief Relations of the Trigonometrical Lines.—The sinus of an angle or of an arc is equal to the cosinus of its complement. The tangent of an angle or of an arc is equal to the cotangent of its complement, hence the formulæ:— $\sin. a = \cos. (90^\circ - a)$; . . . $\tan. a = \cot. (90^\circ - a)$.

There are two kinds of tables giving the values of the trigonometrical lines: those giving the logarithms of the values of these lines, and those giving their natural values. Of the former kind are the tables of Callet and De Lalande; of the latter are the tables of Richard, and those contained

in the works of Claudel and Chevallot. All tables are calculated for arcs having a radius of 1. They are usually arranged in the following manner: the number of degrees is marked at the top of the page from 0 to 45°, and at the bottom from 45° to 90°, because, as we have said, the sine, tangent, cotangent, and cosine of an arc are equal respectively to the cosine, cotangent, tangent, and sine of their complement. The number of minutes for angles or arcs from 0 to 45° are found on the left of the page, and for angles or arcs from 45° to 90° the numbers are on the right of the page. The values which are found in the horizontal line of each number of minutes, in tables of log. sines, cosines, &c., are the logarithms of the natural values of the sine, tangent, cotangent, and cosine of the angle or arc whose magnitude is expressed by the number of degrees at the top or bottom of the page, increased by the number of minutes found in the left column for the degrees which are marked at the top, and in the right column for degrees marked at the bottom. All these values, it must be remembered, are calculated for a radius of 1. In tables of log. sines, &c., the index is increased by 10.

From the fact of the values of the trigonometrical lines being given for a radius of 1, it follows from a comparison of the similar triangles adb and mnb , that the sine, tangent, cotangent, and cosine of arcs of different radii are to each other as their radii. Thus, when the value of a trigonometrical line has been found in the tables, we have to multiply this value by the radius of the arc in question in order to obtain its true value. The operations on the logarithms of the values of these lines are performed in the same way as on ordinary logarithms, and it will be necessary to remember that the characteristic of all these logarithms (Tables of Hutton) is increased by 10 units, and that the decimal part is always positive.

FORMULÆ GIVING THE DEPTH AT THE CROWN, AND THE PROPORTIONS OF THE RADIUS TO THE RISE, FOR ARCS OF GIVEN MAGNITUDES.

ELEMENTS OF THE ARCS.			Depth at the Crown = C.
Magnitude.	Radius = R.	Rise = F.	
0			
120	$Q \times 0.577$	$Q \times 0.289$	$0.30 + 0.07 R$; [13]
90	$Q \times 0.707$	$Q \times 0.207$	$0.30 + 0.05 R$; [14]
60	$Q \times 1.000$	$Q \times 0.134$	$0.30 + 0.04 R$; [15]
50	$Q \times 1.183$	$Q \times 0.111$	$0.30 + 0.03 R$; [16]
40	$Q \times 1.462$	$Q \times 0.092$	$0.30 + 0.02 R$; [17]

Segments having Magnitudes intermediate to those given in the preceding Table.—To determine the depth at the crown of segmental arches having magnitudes intermediate to those given in the Table, find the depth with the radius of the arc to be employed for the two magnitudes between which that of the given arc lies; a fourth proportional to the difference of the extreme magnitudes, to the difference of the depths at the crown corresponding to these magnitudes and to the difference between the given and one of the extreme magnitudes, will be the quantity which must be added to or subtracted from the depth at the crown corresponding to the extreme magnitude which has served to determine the fourth term of the proportion.

Example.—Let it be required to determine the depth at the crown of a segmental arch of 76° with a radius of 10 mètres.

We shall have for 90° and $R = 10^m$; $C = 0.80$
and for 60° and $R = 10^m$; $C = 0.70$

Differences 30° 0.10

Therefore $\frac{30^\circ}{0.10} = \frac{90^\circ - 76^\circ}{x}$; whence $x = \frac{0.10 \times 14}{30} = 0.046$.

Hence for 76° and $R = 10.00$; $C = 0.80 - 0.046 = 0.754$, this arch would have $Q = 12^m.312$, $F = 2^m.12$.

The operation we have indicated will be indispensable only in the case of arcs of magnitudes lying between 120° and 90°, and 90° and 60°, because below 60° the formulæ giving the value of C for variations of 10° and the coefficients of R varying also by 10 thousandths, it will be sufficient to add to the coefficient of the magnitude next smaller, that of the one given, as many thousandths as there are degrees of difference between them.

By performing an analogous operation upon the rise, the calculation of magnitudes may be avoided. The differences obtained will not be exactly the same, but they will be near enough for practice, and the employment of trigonometry may thus be dispensed with.

Referring to the foregoing example, we have: $R = 10^m$; $F = 2^m.12$; $Q = 12^m.312$; whence $\frac{F}{Q} = 0.172$. The proportion of the rise to the span is included between the proportions 0.207 and 0.134 of the formulæ, Nos. 14 and 15. Proceeding in the same way as for magnitudes, we shall have

for $\frac{F}{Q} = 0.207$; $R = 10^m$; $C = 0.80$;

$\frac{F}{Q} = 0.134$; $R = 10^m$; $C = 0.70$;

Differences .. 0.073 0.10

Establishing the proportion $\frac{0.073}{0.10} = \frac{0.207 - 0.172}{x}$, we shall have $x = \frac{0.10 \times 0.35}{0.073} = 0.048$.

Hence for $\frac{F}{Q} = 0.172$ and $R = 10^m.00$, $C = 0^m.752$.

Thus this example proves that the radius and the rise of an arch being given, we may determine the depth at the crown easily by the aid of our formula without first considering magnitudes.

Gothic Arches.—The best form of Gothic arch is that consisting of two segments of 60° , in which $R = Q$. It is for this form only that we give a value for the depth at the crown, measured like all the preceding according to the vertical passing through the summit of the arch.

$$\begin{aligned} \text{In this case } F &= Q \times 0.866; & [18] \\ \text{and } C &= 0.30 + 0.04 R. & [19] \end{aligned}$$

Lateral Thrust of Arches.—The following formula will furnish a means of verifying the depths at the crown, determined according to our formula, and the arrangement of the extrados, which we will discuss later. This formula denoting the horizontal thrust at the key is given regardless of an overweight or an accidental weight.

T = the horizontal thrust for a given length of the arch.

d = the weight per cubic metre of the masonry.

C = the depth at the crown.

r = the radius of the intrados in semicircular arches; the radius of the curve at the summit in arches with any kind of intrados.

$$\text{We have } T = \frac{d}{2} (2 Cr + C^2). \quad [20]$$

Arches of Cellars.—The depth at the crown of arches for cellars of dwelling-houses will be equal to the half of that of an arch of a bridge, of the same form and the same dimensions (span and rise) $\frac{C}{2}$.

Arches of Buildings.—The depth at the crown of arches of buildings, such as arches of churches, will be equal to $\frac{1}{3.5}$ of that of an arch of a bridge, of the same form and the same dimensions (span and rise) $\frac{C}{3.50}$.

MODIFICATION OF THE DEPTH AT THE CROWN ACCORDING TO THE NATURE OF THE MATERIALS EMPLOYED, AND THE GREATEST RADIUS OF CURVATURE.

The Radius of Curvature and the Employment of Material.—The general formulæ for the depth at the crown given in the preceding chapter were composed on the hypothesis that the employment of materials of various kinds, forming the intrados of arches, would be subject to the dimensions *minima* and *maxima* of the greatest radius of curvature of the arches, and which are shown in the following Table:—

Nature of the Materials employed.	Maximum Radius R.	Mean Depth.	Pressure on square 0.01 borne by the Masonry:	
			At the Crown.	At the Base of the Piers.
Rough unhewn stone and concrete	2.00 to (3.00)		1.00	5.00
Unhewn stone, regular in shape, such as calcareous limestones, laminated trachyte, or rough-hewn stone	4.00 to (5.00)	0.25 to 0.30	2.50	8.00
Stone slightly hewn and bevelled	8.00	0.33	4.00	12.00
Hewn or joggled stone and bricks	14.00	0.40	5.50	15.00
Cut or free stone	20.00	0.60	7.00	20.00

Above a radius of 20 the mean depth of the cut stone should be increased by 0.03 for each extra metre of radius.

This Table has been constructed on the supposition that lime only moderately hydraulic will be used. For cases in which lime eminently hydraulic is employed, the values $3^m.00$ and $5^m.00$ are given.

The slightly hewn stone, or ashlar, as we understand it, should have its beds bevelled to the extent of 0.12 , and the remainder of the bed not too much cut away; the joints should be perpendicular to the facing to the extent of 0.08 . Hewn or joggled, stone should have 0.20 of its beds bevelled, the remainder of the bed not too much cut away, and 0.10 of the joints square with the facing. Cut or free stone should have 0.40 of its beds bevelled, and 0.25 of the joints square with the facing. These regulations for the cutting of the stone constitute the utmost allowance which may be made if the work is to be properly executed.

It is easily conceived that if, in the construction of an arch, whose greatest radius of curvature is 14 metres, in which case we might employ hewn stone having a mean depth of $0^m.40$, we use cut stone having a mean depth of 0.60 , this latter having a larger bed, the pressure will be spread

over a larger surface of stone lying well together and of great resisting power. The masonry of rough stone for filling up the haunches might, in such a case, be reduced in proportion to this spread of the pressure over a wider and well-resisting surface.

Modification of Depth at the Crown.—Having regard to the preceding considerations, in order to take into account the various kinds of materials employed, with respect to—1, the radius of curvature to which it is to be applied; 2, the *maxima* to which each of them may be employed according to the resistance it offers, and in accordance with the spirit of the general formula which we have given; we have adopted the following rule for cases in which it is required to substitute for the materials considered in the general formula, as seen in the preceding Table, other materials capable of more or less resistance.

C = depth at the crown according to the general formula.

R = the radius of the intrados serving to determine the depth at the crown.

Let R' = the radius *maxima* for the materials to be substituted for those which might be employed, according to the preceding Table, and C' = the depth at the crown, modified by the materials substituted for those considered in the general formula of the Table.

We shall then have

$$C' = \frac{C}{\sqrt{\frac{R'}{R}}} \quad [21]$$

Example 1.—Let us consider a bridge with an elliptical arch in which $R = 8^m \cdot 00$, and in the construction of which slightly hewn stone might be employed. Supposing that it is wished to substitute for it cut stone, we shall have $R' = 20 \cdot 00$.

General value: $C = 0 \cdot 30 + 0 \cdot 05 R = 0 \cdot 70$, whence $C' = \frac{0 \cdot 70}{\sqrt{\frac{20}{8}}} = 0 \cdot 51$.

The Table shows that for a radius of $20^m \cdot 00$ the cut stone should have a mean depth of $0 \cdot 60$; when the result obtained is below this limit the conditions are changed, and this shows that the radius *maxima* for the materials should be less than 20 mètres. We conclude from this that hewn stone should be substituted for cut stone, in order to keep within the limits assigned to each of these kinds of materials; and we shall have on this last hypothesis:—

$$C' = \frac{0 \cdot 70}{\sqrt{\frac{14^m}{8}}} = 0 \cdot 53.$$

Example 2.—Let us consider the viaduct of St. Germain, inserted under No. 8 in the Comparative Table.

We have $R = 5 \cdot 00$. Being semicircular, $C = 0 \cdot 30 + 0 \cdot 07 R = 0 \cdot 65$.

In this case, according to the Table, slightly hewn stone should have been used; but unhewn millstone grit was employed, for which the Table gives $R' = 2 \cdot 00$;

$$\text{hence} \quad C' = \frac{0 \cdot 65}{\sqrt{\frac{2}{5}}} = 1 \cdot 02.$$

The engineer, M. Flachet, gave $0^m \cdot 95$.

These two examples thus prove that the rule we have established takes into account all the conditions of resistance which result from the employment of different kinds of material.

The first example leads to the following conclusion:—Whenever the thickness at the crown, found for a kind of material that has been substituted for that which, in accordance with the Table, might have been employed, is less than the mean depth of the materials substituted, which depth is fixed in the Table, we ought to consider this substitution as impossible, and, further, to determine the *minimum* thickness at the crown with a kind of material of which the mean depth should not be greater than the thickness found for the crown. By proceeding in this manner, we shall keep within the bounds of safety, and be guided by a spirit of economy, which ought, except in circumstances of an extraordinary nature, to be considered in every undertaking. This *minimum* thickness being thus determined, it is obvious that it will be always allowable to employ cut for hewn stone, and hewn for slightly hewn stone.

Power of Resistance.—It will be advantageous to give the results of experiments made upon various kinds of stone and mortar, in order to obtain a general knowledge of their powers of resistance. It will be necessary, however, to remember that these experiments were made in the laboratory, where time and destructive atmospheric agents could have no effect. All bodies possess more or less elasticity; under the action of compression, or the reverse, their particles approach to or recede from each other; these actions have limits beyond which bodies lose the power of resuming their primitive forms when the pressure is taken off, and other limits beyond which, the force of cohesion being exceeded and overcome, a rupture of the particles takes place: the former is the limit of elasticity, the latter the limit of resistance to a crushing or a tractive power. As compression is, generally speaking, the sole influence to which masonry is subjected, we shall consider its employment only with regard to this. In practice, stone may be considered as incompressible; but when the pressure is exerted to a certain extent the hardest fly to pieces. The softer divide into two pyramids, whose bases are the upper and under surface of the stone, and whose summits are situated towards the centre; the side portions are driven outwards in the form of splinters. It has been remarked that stones begin to crack as soon as the pressure exceeds the half of that required to crush them; it is, therefore, at this moment that the cohesion of the particles is destroyed, and it is evident that this is the point which must not be exceeded in the

case of masonry having a weight to support. Even this limit should not be reached if the supports are isolated.

Experiments have shown that the weight which prismatic stones of the same nature will support increases nearly as their density. The weight which stones of the same form and nature will support is proportional to the areas of the transverse sections. The resisting powers of three prisms of the same weight and the same nature, having equal bases, are to each other as the numbers 703, 806, and 917, according as their bases are respectively rectangular, square, or circular; which shows that with an equal section a stone increases its power of resistance in proportion as it assumes the cylindrical form.

Representing the resisting power of the cube by 1, that of the inscribed cylinder will be 0.08; that of the same cylinder, placed upon a sharp edge, 0.32; and that of the inscribed sphere 0.26.

It is easier to crush several stones placed one upon another than a solid block of the same form, the same dimensions, and the same nature. For three cubes placed one upon another, Rondelet discovered that the resistance was reduced about $\frac{2}{3}$, a result which the interposition of mortar diminishes, and which is explained by the want of perfect contact of the surfaces. According to Vicat, a cube of 0.03 loses $\frac{1}{2}$ of its strength when it is formed of eight small cubes, and $\frac{1}{2}$ when it is composed of four equal prisms with fixed joints.

It follows from these facts that, having regard to the imperfections in the execution of work, in practice the permanent weight should not exceed $\frac{1}{10}$ of that necessary to fracture the stone, and that, further, in structures composed of ordinary stone or of small materials the $\frac{1}{15}$ or even the $\frac{1}{20}$ should not be exceeded. In the slightest structures the $\frac{1}{3}$ is not exceeded.

According to Vicat, a piece of masonry, composed of cut stone, will, after five months, support a weight of 200,000 kilogrammes per sq. metre without any alteration of surface, and an average of 40,000 kilogrammes when constructed of unhewn stone lying well together, with mortar moderately hydraulic. The quality of the mortar employed may increase or diminish the powers of resistance, as is shown in our Table of pressures which the masonry has to support. We give for arches a force of pressure which is about $\frac{1}{2}$ or $\frac{1}{3}$ of that proposed by Vicat, and for perpendicular masonry it is nearly the same.

TABLE OF THE WEIGHT OF A CUBIC MÈTRE OF THE DIFFERENT MATERIALS EMPLOYED IN MASONRY WORKS, WITH THE PRESSURE PER SQUARE CENTIMÈTRE NECESSARY TO CRUSH THEM.

Nature of the Materials.	Weight of a Cubic Mètre.	Crushing Pressure to the Square Centimètre.
	kilos.	kilos.
Basalt and porphyry	2900	2000
Granite generally	2710	620
Sandstone, hard	2570	890
" soft	2490	4
Calcareous, chonchyllious and hard	2500	400
" compact (lithographic, lias)	2500	300
" oolite (globulous)	2100	110
" sandy	2000	100
Bricks, well burnt and hard	1600	140
" ordinary burnt (Belgian)	2160	100
Ordinary plaster, mixed stiff, 30 hours after use	1570	50
" less stiff		40
Concrete with hydraulic lime, 6 months after use	1830	40
Mortar, hydraulic lime, 15 days after use		4
" highly hydraulic lime, 15 days after use		8
" Vassy cement, half sand, 15 days after mixing		150
" highly hydraulic lime, 14 years after use		154
" ordinary hydraulic		80
" strong lime		20
See SPECIFIC GRAVITY.		

NOTE.—These resistances have been determined by experimenting upon cubes having a dimension of 0.03 to 0.05.

Plan of the Curves of the Extrados.—*Tracing the Curves of the Extrados.*—In arches constructed in one of the usual forms the pressure which acts through the curve of the arch, called the curve of pressure, is the resultant of all the forces acting upon this arch; and it is a principle that this pressure should increase from the crown to the springing. Hence it is necessary, to ensure the stability of the arch, that none of the points of this curve be without the section of the arch; for in such a case the pressure would not be directly supported. From this fact, and from the principle alluded to above, it follows that the thickness of an arch, measured normally at the intrados, which serves as a basis for the form of the curve of pressure, should increase from the crown to the springing.

We admit with M. Dujardin, author of 'Routine des Voûtes,' that an extrados constructed so that the vertical projection from the part of the radius of curvature of the curve of the intrados, produced to any point between the intrados and the extrados, be always equal to the depth at the crown, complies sufficiently with the conditions of an increase of pressure, and gives the dimensions of the haunches of an arch in a way to render the disposal of the masonry similar to all points, Fig. 1413.

Let $oA = R$ and $b\delta = C$. Take any radius, om , and at the point m erect a vertical $mh = b\delta = C$; through the point h draw the horizontal, meeting the radius om in the point n , to which the latter has been produced; the point n will be a point of the curve of the extrados, and mn the thickness of the arch at the haunches. Proceed in a like manner for $m'n'$. By joining all the points thus found we shall have the curve of the extrados.

The numerical value of the thickness of the arch at the haunches will be as follows:—

Representing the angle $bo m$, formed by the radius drawn to a point m , at which point it is required to find the thickness of the arch by a ; and the thickness of the arch by e ; we have $b\delta = C$; and $e = \frac{C}{\cos. a}$.

This method of tracing the curve of the extrados is simple and practical. Figs. 1414 to 1416 are examples of arches of 10 metres span.

Fig. 1414 is a semicircular arch; Fig. 1415 a segmental arch of 60° ; and Fig. 1416 an elliptical arch. The slope of the abutments is in each case $\frac{1}{4}$. In the arch, Fig. 1416, the joint of rupture is determined by $\frac{V V'}{F} = \frac{F}{Q}$. In Fig. 1414 the joint of rupture is at an angle of 60° with the vertical.

Depths of the Crown.

Semicircular arches		$C = 0.30 + 0.07 R.$
Elliptical		$C = 0.30 + 0.05 R.$
Segmental of 60°		$C = 0.30 + 0.04 R.$
" of 50°		$C = 0.30 + 0.03 R.$
" of 40°		$C = 0.30 + 0.02 R.$
Gothic		$C = 0.30 + 0.04 R.$

Values of R.

Semicircular arches		$R = \frac{Q}{2}.$
Elliptical		$R = Q \times 1.183 - 1.366 F.$
Segmental		$R = \frac{F^2 + \frac{1}{2} Q^2}{2 F}.$
		$R = \frac{\frac{1}{2} Q}{\sin. a}.$
Gothic		$R = Q.$

Thickness of the Abutments at the Springings.

In all cases		$E = 0.20 + 0.30 (R + 2 C).$
Gothic		$E = 0.20 + 0.15 (R + 2 C).$

Thickness of the Piers at the Springings.

With 1 to 8 ^m span		$P = 2.50 \times C.$
8 ^m and over		$P = 3 \times C.$

Strengthening of the Head-bands at the Springings.

$$\frac{1}{2} Q \times 0.025.$$

Example 1.—Application of the method to a semicircular arch: $AB = Q$; $CD = C$, Fig. 1414. Upon oc perpendicular to the line of the springing AB , erect from the centre o of the curve of the intrados, a line $o'o' = CD = C$ the depth at the crown; and remark that $o'D = oC = R$; from

the point o' draw $o'A'$ parallel to the line of the springing. Producing the radii oc' , oc'' , oc''' , and so on; these radii will cut the line $o'A'$ in the points $1'$, $2'$, $3'$, and so on; if we now continue these radii from the points 1, 2, 3, and so on, where each of them cuts the line AB to the points $1'$, $2'$, $3'$, $4'$, $5'$, $6'$, $7'$, making them equal to $o'D$ and equal also to the radius of the curve of the intrados, we shall obtain a series of points D , $1'$, $2'$, $3'$, $4'$, $5'$, $6'$, $7'$, which will determine the curve of the extrados.

Remarking that each of the portions 01 , 02 , 03 , and so on, is equal to $c'1'$, $c''2'$, $c'''3'$, and that $oo' = C$ is the vertical projection from the portions of the radii 01 , 02 , 03 , we see that this construction exactly fulfils the conditions already mentioned; that the vertical projection from a part of the radius of curvature of the curve of an arch produced to any point within the intrados and the extrados is always equal to the depth at the crown.

We would remark that the curve in question will never descend (in semicircular and elliptical bridges) to the level of the springing; for this curve which is determined by the sliding of the extremity o' of a line $o'D$ along a line $o'A'$, parallel to that of the springing and distant from this latter by a quantity equal to the depth at the crown, the direction of which in this sliding motion is compelled to pass constantly through the point o , the centre of the curve of the intrados, this curve is a conchoid of which $o'A'$ is the asymptote. The point of the curve of the extrados nearest the plane of the springing will therefore be measured by infinity, and its distance from this plane would then be equal to the depth at the crown.

Example 2.—For the segment we have proceeded in the same way as for the semicircle; the determining of the curve of the extrados stopping with the last radius oA , Fig. 1415, it follows that the abutment rises above the plane of the springing by a quantity equal to the depth at the crown. In practice the extrados of the arch must be made to coincide with the top of the abutment according to the dotted line.

Example 3.—For the elliptical arch with five centres, Fig. 1416, we have proceeded for each arc of the ellipse in the same way as for

1416.

the half-circumference of the semicircular. Above each of the centres o , o , o , at a distance from these centres equal to the depth at the crown, draw a horizontal, then at each extreme radius of the arcs of the intrados find the points $1'-2'-x'-y$ by the aid of the portions of the radii of curvature $11' = oc$, $22' = oc'$, $xx' = 22'$, $yy' = o_2A$.

For all elliptical arches, determine by the aid of a diagram the curve with 5 or 7 centres approaching as near as possible the given ellipsis of the intrados, and deduce from it the curve of the extrados as in the third example. In practice the extrados must be made to coincide with the abutment as shown by the dotted line.

Abutments and Piers.—*Thickness of the Abutments at the Plane of the Springing.*—Let E = the thickness of the abutments at the plane of the springing for arches of all forms, and H = the height of the abutments or piers. We have already R = the radius of the intrados serving to determine the depth at the crown, and C = the depth at the crown.

For any span and any form of arch we shall have

$$E = 0.20 + 0.30 (R + 2 C); \quad [22]$$

except for the Gothic arch of two segments of 60, when

$$E = 0.20 + 0.30 \left(\frac{R}{2} + Q 2 C \right).$$

The height of the abutments should not exceed

$$H = Q \times 1.50. \quad [23]$$

Except in cases of absolute necessity, the height should never exceed

$$H = Q \times 2. \quad [24]$$

The first value of H will give to bridges of one arch the most solid appearance, a quality which public works ought to possess; it is also the limit of the conditions of great stability. The second value of H corresponds to the architectural proportions of a portico; it is also suited to large viaducts.

Facing of the Abutments on the Land Side.—The thickness of the abutments at the plane of the springing having been determined by formula [22], the exterior facing (the land sides) will be constructed with a talus of $\frac{1}{3}$ or 0.20 the metre of height. The thickness of the abutments at the base will, therefore, be

$$= E + 0.20 H. \quad [25]$$

This talus nearly corresponds with the retreats which many builders give to their works; this method, we think, ought to be abandoned on the ground of producing results opposed to those to obtain which it is adopted, namely, greater stability than with the talus. Each retreat is a reservoir of water furnishing a means of enabling it to penetrate the masonry.

In the case of the talus or slope we have taken the mean of the thicknesses at the springing and at the base. This mean may be taken in practice as the uniform thickness of the abutment, the value of which will be

$$E' = E + H \times 0.10. \quad [26]$$

In this case the exterior facing will be vertical. This arrangement will have the following inconvenience:—The pressure supported by the masonry on the level of the foundations will be much greater than that supported at the springing, a fact which might in certain soils be of grave consequences. Besides this, such an arrangement does not correspond in direction of resistance to the pressure of the arch.

The thickness of the abutments thus found needs no assistance of walls, which, if used, will be additional guarantees of stability. When massive walls are placed behind the abutments, if the sum of the mean thicknesses of these two walls be equal to half the width of the work between the headings, openings in the form of arches may be made in the abutments without endangering the solidity of the work. In this way a considerable saving may be effected.

It will not be prudent, however, to hollow the abutment between the walls throughout the whole of its height, for there should always be at the springing a mass of masonry of a width equal to that prescribed by the formula, to provide against the settling down of the masonry at the head and flanks of the arch in consequence of the slipping to which the latter is liable when there is not sufficient surface to resist the pressure.

Thickness of the Piers at the Springing.—Let P = the thickness of the piers at the springing, and F = the talus of the piers per metre of height. For a span of 1.00 to 8 or 10.00 we shall have

$$P = C \times 2.50, \quad [27]$$

twice and a half the thickness at the crown.

For a span above 10.00 we have

$$P = C \times 3, \quad [28]$$

three times the thickness at the crown.

Talus of the piers a metre of height in all cases

$$\frac{1}{40} \text{ or } F = 0.025. \quad [29]$$

The body of the piers will thus increase to a metre of height by $\frac{1}{40}$ or 0.05.

Besides this, it is well to give as much projection as possible to the socles in order to spread the pressure over a wider surface of natural ground. The nature of the soil, the importance of the work, the flow of the water, and the form of the foundation must guide the builder in the construction of the basis. His duty is to see that the works be firmly placed and protected from the undermining action of the water.

General Information.—According to statements made by Rondelet, in his 'Art de Bâtir,' we find:—

That thickness of the piers of a semicircular arch being = 1, the thickness of the piers for one and the same span will be, for—

Gothic arch of two segments of 60°	= 0.70	Elliptical depressed to $\frac{1}{3}$	 = 1.35
Semicircular	= 1.00	 to $\frac{1}{10}$	 = 1.40
Elliptical depressed to $\frac{1}{3}$	 = 1.18	Plat-band	 = 1.40

That representing the thrust of a semicircular arch by 1, the relative thrust of other arches will be—

Gothic of two segments of 60°	..	..	0.50	Elliptical depressed to $\frac{1}{3}$	..	..	1.93
Semicircular	..	..	1.00	..	to $\frac{1}{6}$	..	1.91
Elliptical depressed to $\frac{1}{3}$	..	..	1.40	Plat-band	..	..	1.95

Position of the Joints of Rupture.—It follows from the facts which we have gathered from various works, that the position of the joints of rupture in bridges of the semicircular and elliptical forms may be determined in a general manner by the intersection of a parallel at the level of the springing, with the curve of the intrados and the distance of which from the level of the springing is $\frac{1}{3}$, $\frac{1}{6}$, or $\frac{1}{4}$ of the rise according as the rise itself is $\frac{1}{3}$, $\frac{1}{6}$, or $\frac{1}{4}$ of the span. Calling VV' this vertical distance, we have the proportion:—

$$\frac{VV'}{F} = \frac{F}{Q}, \text{ whence } VV' = \frac{F^2}{Q}. \quad [30]$$

This formula is strictly in accordance with the position of the joint of rupture in semicircular bridges, which is always considered as being on the radius inclined to 30° with the horizontal. In segmental bridges, so long as their magnitude is less than 120°, the joint of rupture is at the springing of the arch.

Proportions of the various Parts.—*Head-bands of Arches.*—These should have a greater thickness at the springing than at the crown. This arrangement, which is more rational than one of uniformity, gives the work a certain stamp of solidity; this kind of band is called strengthened.

In arches of moderate span, the thickness of the band at the crown is made equal to the body of the arch = C .

The thickness at the level of the springing being represented for all forms of arches by B , we shall have

$$B = C + \frac{Q}{2} \times 0.025; \quad [31]$$

$$\text{or } B = C + \frac{Q}{80}.$$

For a span not exceeding 4.00 the band may be parallel; for in such a case the increase would be hardly apparent, and it seems to us useless to introduce such a condition into small works.

In arches of a wide span, 20 or 30 metres, the thickness of the head-band is often made less than that of the body of the arch. This reduction varies from 0.10 to 0.20, according to the hardness of the materials or the taste of the builder. While giving the work a bolder appearance, this reduction in no way compromises its solidity. It is besides quite in harmony with the principles which we have made known.

Tracing the Exterior Curve of the Head-band.—In semicircular arches the extrados will be determined by a segment, the centre of which will be below that of the intrados by $\frac{Q}{2} \times 0.025$, and the radius of this arc will then be equal to $R + C + \frac{Q}{80}$.

In elliptical bridges, first determine the value of B , then divide the increase of the thickness of the band, or the difference between the thicknesses at the crown and at the springing, by the length of the half of the curve of the intrados (measured simply with the compasses); this will give the increase of the band for each metre of length. Multiplying this quantity by the length, 1, of the half-arc of the summit, 2, of each of the other arcs of the ellipse, we shall have the thickness of the band at each change of curvature. The arc of the summit will be determined by three points, and will have its centre at n ; the centre of the second arc will be found upon the last radius passing through n . It is besides determined in position by its two extremities, and its centre will then be at n' ; in the same way we shall have the centre n'' , Fig. 1416.

For elliptical arches we may also trace the ellipse of the extrados, the major and minor axes of which will be determined by:—The major axis = $Q + 2B$, and half the minor axis = $F + C$.

In these kinds of arches the joints of the voussoirs should be traced according to the normals at the mean curve of the head-band, and not according to the normals at the intrados; by this means the pressure is distributed more equally on the planes of the joints. This arrangement corresponds in some degree to the inclining of the planes of the joints recommended in the learned work of Yvon-Villarcieu on 'The Construction of the Arches of Bridges considered with regard to their Stability.'

For segmental bridges the extrados will be a segment having three points, the crown and the springings: its centre will be in n , Fig. 1415.

The Voussoirs.—The key voussoir ought always to be a header; and, as far as possible, the springers should be the same. Now the key is always like the first voussoir when the half of the total number of voussoirs of one head minus one is an even number. We are thus able to fix *a priori* the number of voussoirs to be put into an arch, and the builder will be guided by this in regulating the piers and abutments.

Plinths and Cordons.—Let the total height of the structure from the top of the foundations to the bottom of the plinths = H , the height of the plinth = h , and the ledge of the plinth = s , then in all cases

$$h = 0.20 + 0.02 H. \quad [32]$$

For plinths without mouldings for small structures, $s = \frac{1}{3} h$;

$$\text{" plinths with mouldings } s = 0.70 h. \quad [33]$$

When it is required to gain width and to place the parapet beyond the masonry, it will be necessary to put a console under the plinth, the height of which console will be $0.70 h$. We have P = the thickness of the piers.

Representing the height of the cordon also by h , we shall have

$$h = \frac{P}{7}. \quad [34]$$

However, in cases in which the height of the cordon thus formed would exceed that of the plinth, it will be necessary to reduce it and to make it equal to this latter.

For details of mouldings, see Figs. 1417 to 1423.

*Details.—Piers:—*Thickness of the piers at the plane of springing:—

- 1st, up to 10 mètres span $P = 2.50 \times C$.
 2nd, under 10 mètres span $P = 3 \times C$.

Slope to a mètre in height, 0.025 , or $\frac{1}{40}$.

Plinths and Cordons:—

Total height from the top of the foundations to the under-side of the plinth = H .

Total thickness of the plinth = h .

We shall have $h = 0.20 + 0.002 \times H$.

Ledge of the plinth { Small works $0.50 \times h$.
 { Large works $0.70 \times h$.

Total height of the cordons $h' = \frac{1}{4}$ of the thickness of the pier. If this thickness exceeds that of the plinth, reduce $h' = h$.

The designs of cordon and plinth, Figs. 1417 to 1423, are specimens in which all the dimensions of ledges, plat-bands, and fillets are given, supposing the height h to be unity.

Buttresses.—The breadth of buttresses will be equal to the thickness of the plinth.

General Observation on the Construction of Arches.—We strongly recommend the placing of *bonders* here and there in arches of wide span; the *bonders* should be of cut stone of a mean depth twice that of the materials employed in the construction of the arches; iron cramps, set in cement, may be used to hold firmly together the stones composing the *bonders*. This latter arrangement has been tested by experience.

The arches of the celebrated bridge built by Perronet, over the Seine at Neuilly, one of which is shown in Fig. 1424, are 128 ft. span, and the radius of the circle, of which the coincident portions

of the outer segmental arch are parts, is 160 ft. A comparison of this bridge with a bridge on the same plan, after the designs of Roy, will be found at No. 17 in the Table, page 698.

Along the line of the Highland Railway numerous bridges and viaducts have had to be erected. Fig. 1425 is of the viaduct which spans the river Conon, in Ross-shire. From circumstances it was necessary that this bridge should cross the river on a skew of 45° to the stream, and as there were rock foundations, there was no difficulty to contend with beyond that of 4 ft. or 5 ft. of water in the channel of the river to reach the rock. The peculiarity of the skew with the river at this place could have been more easily provided for by the adoption of iron girders from pier to pier, but as it was found that iron girders would be fully as expensive and not so permanent as a stone bridge, and as there were admirable quarries in the neighbourhood, Joseph Mitchell, the engineer of the line, resolved to construct this bridge on a skew of 45° with the river, by a series of right-angled ribs or arches spanning from pier to pier. The bridge consists of five arches of 73 ft. span each, the arches being constructed of four ribs, each 3 ft. 9 in. wide; the arch stones are 4 ft. deep at the springing, and 3 ft. deep at the crown. The key-stones of the centre part of each arch were made to connect with each other, as were the stones in the haunchings of the arches, and some cramps of iron were inserted at the joints to connect the ribs. The work was

1425.

successfully accomplished, and constitutes a very perfect piece of bridge masonry. The total length of the bridge is 540 ft., and the height 45 ft. from the bed of the river. The north abutment is founded 304 ft. lower down the river than the south. The whole bridge was constructed for a single line of rails.

J. A. Roebling's System of Bridge-building: the Parabolic Truss.—Let acb and adb , Fig. 1426, represent parabolic curves of the same deflection and span. The upper curve forms an upright arch, which presses against the points a and b . If these points are connected by the chord ab , and this chord balances the pressure at a and b , the chord and the arch will be in equilibrium and at rest.

The inverted parabolic arch adb , freely suspended between a and b , will, on the other hand, produce an inside pressure upon these two points of support. If the two arches are equally and uniformly loaded, their strains at a and b will be the same, and in the directions of their respective tangents af , bf , and ae , eb . We may therefore remove the chord ab , and in its place suspend the arch adb ; then the outward pressure, exerted by the upright arch upon a and b , will be met and balanced by the inward pressure at a and b , produced by the suspended arch adb . The two arches are therefore in equilibrium, without any intermediate chord.

In a bowstring girder or arch nearly the same amount of material must be expended in the chord ab which is required in the arch itself. But the chord adds nothing to the supporting power of the arch. On the other hand, by suspending the subverted arch adb , we may dispense with the chord, and at the same time we have doubled the supporting power of the system. The great economy of the parabolic beam is therefore apparent at a glance. All that is required in practice is to provide sufficient panelling, and light bracing inside of the arches, in order to preserve their form and equilibrium under variable loads. It will be shown hereafter that a greater amount of material must be expended to obtain the same strength in other systems of girders and trusses.

To ascertain the forces of tension and compression at a and b , produced by the upright and suspended arch, draw the parallelogram $afbe$, the sides forming tangents to the curves. The pressures caused by the upright arch will then be represented by af and bf , and the tension caused by the suspended arch is measured by ae and be . Suppose the weight W to represent the whole weight of the upright arch, then this weight will act through the linear braces fa and fb upon a and b , and its relative magnitude is represented by the diagonal fe , which is the resultant of the two forces fa and fb . Let the pressure at a or b be denoted by P , then is $W : P = ef : af$; and therefore, $P = W \frac{af}{ef}$. Let x represent the deflection, or verse sine, gc or gd , y —half the chord ag or gb ; and suppose the curves to be parabolas, then gc will be equal to cf , or, $x = \frac{1}{2}gf = \frac{1}{2}gE$; and $af^2 = ag^2 + gf^2 = y^2 + 4x^2$, or, $af = \sqrt{y^2 + 4x^2}$. Substituting this value in the equation for P , and $4x$ for ef , we have $P = \frac{W}{4x} \sqrt{y^2 + 4x^2}$. The tension T , caused by the suspended cable at a and b , is equal to P , and found by the same formula.

As an example, let us suppose the span of the arch to be 500 ft., its verse sine 50 ft., and its total weight 500 tons; to find the pressure or tension at the points of support, we then have

$$P = \frac{500}{4 \times 50} \sqrt{\frac{500^2}{250^2 + 4 \times 50^2}}.$$

$$P = 500 \times \frac{269.25}{200} = 500 \times 1.34.$$

$$P = 670 \text{ tons.}$$

The figure 1.34 represents a variable coefficient, which is dependent upon x and y , but independent of the weight W . We may therefore, for convenience sake, compose a table of coefficients which will facilitate rapid calculations. The following Table gives the coefficients for versed sines of $\frac{1}{16}$ of the span to $\frac{1}{15}$ —

V. S.	$\frac{1}{16}$	$\frac{1}{15}$	$\frac{1}{14}$	$\frac{1}{13}$	$\frac{1}{12}$	$\frac{1}{11}$	$\frac{1}{10}$	$\frac{1}{9}$	$\frac{1}{8}$
Coe.	1.118	1.23	1.346	1.463	1.58	1.70	1.82	1.94	1.94

As an example, suppose a span of 1000 ft., verse sine $\frac{1}{16}$, or 125 ft., and load 1000 tons. The coefficient of pressure or tension in the Table is 1.118, therefore the pressure or tension is

$$1000 \times 1.118 = 1118 \text{ tons.}$$

As another example, suppose the same span and load with a verse sine of $\frac{1}{15}$ of the span = 66.66 ft., then the coefficient in the Table is 1.23, and therefore the pressure or tension is

$$1000 \times 1.23 = 1230 \text{ tons.}$$

It may be necessary to calculate the exact length of the arch, suspended or upright, measured by the curve. Let Z denote one-half the length of the curve, then is $Z = \sqrt{y^2 + \frac{4}{3}x^2}$. This formula applies to a parabola, and is much more simple than the formula for a true catenary. It is sufficiently correct for practice, provided x is not greater than y .

To determine the deflection x from the length of the curve and of the span, the following

equation will answer: $x = \sqrt{\frac{3}{4}(Z^2 - y^2)}$. These formulas are needed in order to calculate the rise or fall of an arch, due to its expansion or contraction from variations of temperature.

This diagram represents half a parabola, with its ordinates and abscissas. Now it is a property of the parabola that $x : x' = y^2 : y'^2$; from this we deduce $x' = \frac{x}{y^2} y'^2$; also, $x'' = \frac{x}{y^2} y''^2$; and so on. When, therefore, x and y are known, we can calculate the ordinates x', x'', x''', x'''' , for any abscissa. This will enable us to lay down the curve of the upright arch, or to calculate the length of suspenders for the suspended cable.

To ascertain the compression of the arch at its crown c , Fig. 1426, or the tension of the cable at its lowest point d , draw the lines eh and bh parallel to gb and ge in Fig. 1427; then the diagonal be represents the strain at b , while eh represents the horizontal strain at d or c , and bh represents the vertical pressure produced upon b or a , either by the arch or cable. bh being equal to cd or $2x$, of course the sum of the vertical pressures at a and b is equal to the whole weight of the arch or W .

In a similar manner can the compression or tension of the arch be ascertained at any other point of the curve by simply laying down a tangent and drawing out its parallelogram. The tension or compression is thus found to increase gradually from the centre to the points of support.

By laying down the curves accurately on a large scale, all the different strains may be measured by the scale sufficiently accurate for all practical purposes.

General Description.—The three openings of this bridge are spanned by two parallel continuous parabolic trusses, 1184 ft. in length, at a distance of 14 ft. apart in the clear; the floor beams for support of the track resting upon the lower chords. This superstructure is firmly fixed upon one of the two middle piers, while it rests upon roller-plates on all the other piers. This arrangement, therefore, admits of free contraction and expansion, caused by changes of temperature. It will be noticed that the towers which support the cables on the middle piers, form integral parts of the movable structure, and consequently will change their position in unison with the other parts of the work, when affected by contraction or expansion. The cables together with the arches form one united system, all moving together uniformly when thus influenced.

The railway track is supported at intervals of 5 ft. by rolled iron beams of 12 in. depth and 21 ft. 5 in. in length. The rails rest upon wooden stringers, 12 × 12, which are strengthened in depth by timber bridgings, 6 × 12, fitted in between the iron beams. A longitudinal iron beam of 9 in. depth underneath the bridging, suspended by bolts to the wooden stringer, adds further to the depth of bearing, which is wanted to distribute the concentrated weight of the locomotive drivers, and thus diminish their kneading action. Every second cross beam is suspended to the cables by means of suspenders, but each of the beams is also firmly riveted to the lower chords by sixteen rivets of $\frac{5}{8}$ in. diameter. This union forms the only connecting link between the arches and the cables.

There is one truss on each side of the track, and each is double throughout from end to end, leaving an open space 24 in. in width between the posts. In the centre of this space the cable is freely suspended in a vertical plane, parallel to the trusses; the suspenders run down in the same plane; so also do the wire-rope stays, which pass over the towers below the cables. Where the stays cross the suspenders, they are united with them by wire wrappings, for the purpose of preserving their straight lines, and to prevent oscillations.

The principal features, which give supporting strength as well as stiffness to the trusses, are the arches. The cables, which co-operate with the arches, are designed for strength alone, without adding much to stiffness. An additional source of strength as well as stiffness is obtained by the wire-rope stays, six on each tower; these are also very efficient in preserving the equilibrium between the spans under the action of variable loads, and also in relieving the arches at the haunches, where assistance is most needed.

At the extreme ends of the trusses four light double wire-rope stays are added to give additional strength and stiffness to those points.

At the first glance this plan may appear a complicated arrangement, defeating its own end by the want of internal harmony among its different parts. But no view could be more mistaken. In place of exhibiting a want of harmony, this system will be found in its practical working so co-operative and mutually supporting in its various parts, that nothing will be left to desire. No system is possible which, under the action of passing and variable loads, will be affected with perfect uniformity in all its parts, so that all the different members will be exposed to the same uniform proportional strain. Uniformity of strain in a plate-girder, in a lattice-girder, or in any other triangular or panelled truss, is out of the question. The arch alone, upright or suspended, comes nearer than any other system toward fulfilling this condition. When a load is placed upon any one point of the arch, the compression or tension thereby produced upon its section will be felt nearly alike throughout its whole extent, so long as its statical form is maintained. The capacity of the arch to maintain its form is strongest about the centre. Impressions upon the haunches are more apt to produce dislocations in other corresponding parts. To meet this weakness, stays are introduced next to the towers. So far as they extend, they are strong enough to support the maximum weight of that part of the structure as well as the load. Each stay in connection with the floor and tower forms a fixed triangle. This simple system of stays, as here designed, is the perfection of trussing. Nothing can be more perfect, or more simple, effective, and economical.

In the Niagara, Cincinnati, and Alleghany bridges, the conditions upon which the true action of stays depend are only partially fulfilled, because of the different material of the towers and the neutrality of the floor. And yet with these drawbacks, the stays in these works answer such an admirable purpose, that they could not be supplanted by another arrangement. But in the plan before us all parts are composed of the same material, and are allowed to expand and to contract freely, and consequently their harmonious action cannot be disturbed on that score.

Suppose the section of the arch was doubled, and made strong enough to support a maximum load and the superstructure; and suppose, further, that its ends were connected by a chord strong enough to resist the thrust; all that would then be needed would, by common consent, be spandrels of sufficient stiffness to preserve its form under the action of variable loads. No engineer would doubt the stability of this simple arch. Now, in the plan before us, we employ the same arch, but of only half the section. This deficiency of strength is made up by the suspended arch; and in place of heavy spandrels we introduce a light panel-trussing throughout its whole extent, which will be found more effective in reality than any system of spandrels can possibly be made. This panel-trussing, judging from experience on the Niagara Bridge, will be found abundantly effective to preserve the form of the arch. If there were no adjoining spans, and if there were no necessity for towers for the support of the cables, nothing more would be needed. But the towers being there, the application of stays becomes at once one of the most economical as well as most efficient means to still further secure the stability of the whole system. Only fourteen panels are left without stays in the centre opening, reducing this distance to 280 ft. In this space the arch and the panel-work have to maintain their form alone, not counting upon the assistance of the cables. With reference to stiffness alone, the plan before us may also be considered in the light of a simple bowstring-girder, with this difference in favour of the Parabolic Truss, that the haunches of the arch are greatly assisted by the stays.

The harmony of action between the arches and cables, when under the influence of variable loads, now remains to be considered. Inside of the space of the central opening, between the two longest stays, a distance of 280 ft., a want of uniformity of action is utterly impossible, because the least impression upon the arch will be equally felt by the cable throughout its whole extent, and will be checked by the upward resistance of the superstructure. As the cable becomes depressed, every other point tends to rise, but is prevented by the weight and stiffness of the truss, the arch, and the panels. Considering now that the weight of the middle span is 640 tons, the local impression made by a 40-ton locomotive will be no more than is due to the natural elasticity of the material composing the truss. The cables being the most sensitive members of the system, their action will greatly tend to spread every local impression over a large extent, and thus neutralize its effects by engaging all parts of the system to resist.

So far as the stays extend, no local depression whatever can be produced, because every attachment of stay forms a fixed point, which, in connection with the arches, cables, and panel-braces, will be found sufficiently rigid to resist the severest local action beyond that due to the natural elasticity of the materials. Roebling is positive in this statement, because his observations on the suspension-bridges he built fully justify him in making it. If any one will take the trouble to scrutinize the action of the Niagara Bridge under the passage of a single heavy locomotive and tender with sufficient care and attention, and, by means of a level placed in one of the towers, will observe the progressive depressions of that structure, which take place from the tower toward the centre, he will discover scarcely any depression inside of the reach of the stays. Beyond the stays, toward the centre, the depression increases rapidly, and becomes greatest in the centre. Similar facts will be noticed on the Cincinnati Bridge, under the action of a number of heavily-laden teams, following each other in close succession.

The cables and stays are securely fixed upon the cast-iron saddles, which are mounted upon the tops of the wrought-iron towers by means of cushions, held down by screws. The height of the towers being 62 ft. above the base, and the supporting columns of an elastic material, they will yield a little, when one span is fully taxed with a maximum load, while the adjoining spans are empty. This yield will be imperceptible to the eye, but will no doubt be susceptible of measurement. And as this movement will not result from the free working of the different members of the system, but will be entirely due to the elastic yield of the materials, it may be repeated indefinitely without impairing the integrity and safety of the structure.

Since wire possesses a much greater degree of elasticity than bar-iron, one very great advantage of the cables and stays will be, that ordinarily, when not taxed by any load, the greater part of the weight of the structure will be borne by the wire. Under the action of light loads, the cables and stays will continue to bear the greater share; but when taxed with heavy trains, then the arches will also receive their full proportion. When the structure is relieved, the cables and stays will again contract and support the largest share. And so long as this process is kept within the limits of natural elasticity, allowing for an ample margin, the structure will remain perfectly safe and intact.

Each of the two cables is represented as composed of nineteen wire-ropes. Ropes will be found in practice to be the most economical means of forming the cables, also the easiest to put up, and the quickest. Cables made of wire laid parallel may also be constructed by those who have experience in this process, and know how to make a good cable; but the same amount of wire laid parallel into cables will give less strength than the same amount of wire laid into rope, provided the lay in the latter is long, and that its manufacture has been conducted with the necessary care and proper machinery. It is impossible to obtain perfectly uniform tension in a parallel cable, but it is possible to do so in a rope. The cost of the two, per pound, will be about the same, and of course the strongest should be preferred.

In place of making the cables of wire, they can also be made of iron or steel bands, provided the bands are rolled full length, so that they can be laid into the cable without splicing. The rolling of bands, say 4 in. wide and $\frac{1}{2}$ in. thick, and 1000 ft. or more in length, is a process which

has never been attempted. But this process is perfectly practicable on a continuous mill constructed on the same principle as is Bedson's train.

The greatest depth of the superstructure in the central span is 44 ft., while its width is only 21 ft. 5 in. It is plain that this width is not enough to ensure sufficient lateral stability in heavy storms, or to prevent all horizontal oscillations under the passage of rapidly-moving trains. It must be observed that we are explaining the principle of Roebling on a bridge with a centre opening of 500 ft. and two side openings of 300 ft. each in the clear at low water. Where one or two tracks are wanted for the accommodation of common travel, in connection with railroad traffic, either the floor for common travel may be placed overhead, above the railroad floor, or on the same level. If the latter arrangement is preferred, then an increased width becomes necessary, and this will still more add to horizontal stability. To ensure lateral strength, Figs. 1428, 1429, two wire-cables in horizontal parabolic curves have been laid down, anchored to one of the piers, suspended to the lower floor and fastened at intervals to the beams, which will ensure an ample degree of safety under all circumstances. These horizontal cables, forming one system with the flooring, will expand and contract alike with the superstructure; they can consequently be screwed up tight, to ensure their efficiency.

The top chords as well as the arches are sufficiently braced among themselves, horizontally, to impart to the superstructure a degree of internal rigidity; and the same system is also carried out vertically between opposite posts, every 20 ft., so far as the arches rise above the top chords.

Supporting Power of Stays.—The plan of stays is illustrated by Fig. 1430: ab represents the tower; ah , the floor, at right angles to it; and bc , bd , bf , bg , and bh , are the six stays, their respective lengths marked in feet,

fractions omitted. It is plain that the supporting power of the different stays is measured by the ratio of the height of tower to their different lengths. Thus, if we denote the supporting power of the stay bc by P , its ultimate strength by U , we have $P : U :: 60 : 63$; and $P = U \frac{60}{63}$.

In the same way, for bd , $P : U :: 60 : 72$; and

$$P = U \frac{60}{72}.$$

The ultimate strength of each of these stays is assumed equal to 100 tons, and we therefore get their supporting power as follows:—

					Tons.
For bc	=	6000	÷	63	= 95·23
" bd	=	6000	÷	72	= 83·33
" be	=	6000	÷	85	= 70·58
" bf	=	6000	÷	100	= 60·00
" bg	=	6000	÷	117	= 51·25
" bh	=	6000	÷	134	= 44·77

Total supporting power of 6 stays, in tons 405·19

Allow $\frac{1}{3}$ of "ultimate" strength 1620·76

324·15

Each stay produces a horizontal strain upon the lower chord, which is to its supporting power or vertical action, as is the base of the triangle to its height. Thus the horizontal action of the stay bc is represented by the base-line $ac = 20$, and its vertical action by $ab = 60$, and its direct action by $bc = 63$. If, therefore, the horizontal action is denoted by x , we find its value for

					Tons.
bc	$\frac{20}{63}$	x	=	$100 \times \frac{20}{63}$	= 31·74
bd	$\frac{20}{72}$	x	=	$100 \times \frac{20}{72}$	= 55·55
be	$\frac{20}{85}$	x	=	$100 \times \frac{20}{85}$	= 70·58
bf	$\frac{20}{100}$	x	=	$100 \times \frac{20}{100}$	= 80·00
bg	$\frac{20}{117}$	x	=	$100 \times \frac{20}{117}$	= 85·47
bh	$\frac{20}{134}$	x	=	$100 \times \frac{20}{134}$	= 89·55

Aggregate ultimate horizontal action of 6 stays, in tons 412·89

Allow $\frac{1}{3}$ 82·58

The weight of the central span is, in tons 642

We will assume it at 650

The greatest possible transitory load which can be placed upon this span would be a train of locomotives, estimated at the rate of $1\frac{1}{2}$ ton a lineal foot, or for a length of 500 ft., at 750

Therefore, aggregate weight of superstructure and load .. 1400

Deduct the supporting power of 24 stays, allowing $\frac{1}{3}$ of their ultimate strength 324

Leaves for the support of the arches and the cables 1076

In order to avail ourselves fully of the economical principle of the Parabolic Truss, it is very evident that the tension produced by the cables should be exactly balanced by the compression of the arches, because the one supports the other. This exact balance of the two forces must exist at the anchor-plates, located at the ends of the superstructure, on the abutments, or on the piers, which serve as such.

These plates firmly hold the ends of the cables, and at the same time serve as supports for the ends of the arches. To further simplify this investigation at its present stage, we will assume that if the tension of the cables and the compression of the arches are equal to each other in the central span, then also the same balance will exist at the anchor-plates. This is not strictly the fact; but for the purpose of making the question plain, and to avoid intricate mathematical formulas, such as would not prove palatable to the practical engineer, and would, moreover, add nothing to the accuracy of this investigation, but, on the contrary, would tend to obscure the subject, at present, however, we assume it to be a fact.

The length of span from centre to centre of towers is 530 ft., and the deflection of the cables is 60 ft. The ratio of deflection, therefore, is $1 : 8·83$. From the table of coefficients, we find the ratio of weight and tension for $\frac{1}{8}$ = 1·23. It will be near enough to assume it here at 1·22.

The span of the lowest tier of arches is 516 ft., and its versed sine or rise 40 ft., and the ratio of deflection is 12·90 ft. The corresponding coefficient of compression in the table we find to be 1·70 ft.

Let us represent the weight to be borne by the cables by x , and the weight to be supported by the arches by y , then will be the tension of the cables = $1·22x$, the compression of the arches

1.70 *y*. And since the condition is that the tension of the cables should equal the compression of the arches, therefore is $1.22x = 1.7y$. But the aggregate weight to be borne by the arches and cables was found to be 1076 tons. Therefore, $x + y = 1076$, or $y = 1076 - x$. Substitute this value in the previous equation, and we have $1.22x = 1.7(1076 - x)$, and $x = 626.43$ tons; and also, $y = 1076 - 626.43 = 449.57$ tons.

From the foregoing we now find that the tension of the cable is $626.43 \times 1.22 = 764.24$ tons. Compression of the arches is $449.57 \times 1.70 = 764.27$ tons, both about the same.

The question may be asked here, why the weight resting upon the arches and cables is not equally divided? If this was done, then it would be necessary to observe the same ratio of span and versed sine for the cables as well as for the arches. But this would reduce the deflection of cables, and thereby diminish their supporting power; or it would increase the rise of the arch and make the structure too top-heavy and too deep in the centre. On further investigation it will be discovered that the proportions here assumed are efficient and economical. The more weight thrown upon the cables, the cheaper the structure will be. But at the same time a certain amount must be reserved for the arches, else they will be too light, and the balance between the centre span and the side spans may be endangered under the action of heavy transitory loads. Each cable is composed of nineteen smaller cables or wire-ropes. The maximum tension of each rope is, therefore, $764 \div 38 = 20.10$ tons.

Allowing six times the strength, we have the ultimate strength of each rope, $20.10 \times 6 = 120.60$ tons.

Each arch is composed of twelve channel-bars, 9 in. deep; we therefore find the maximum compression of each of the channel-bars, $764 \div 24 = 31.83$ tons.

Allowing a maximum compressive force of 4 tons to 1 sq. in. of wrought iron, we get the section of each bar, $31.83 \div 4 = 7.96$ sq. in.

In the estimate of weight this section was assumed at $7\frac{1}{4}$ sq. in. average, at the same time allowing 25 sq. in. section for the top plates in the centre. The compression at the crown being less, the estimate is sufficiently correct for the present.

For much larger spans than 500 ft., it may be found more economical, and at the same time safer, to employ a mild steel for the arches, and also to manufacture the cables out of cast-steel wire. But it would be a mistake to do so in this plan, because the weight of the structure would thereby be too much reduced for safety, and its cost would be enlarged. To ensure a proper degree of stability between the spans under the action of heavy transitory loads, the weight of the structure should not be less than 1 ton to a foot lineal, for a single-track railway, on the supposition that the maximum transitory weights do not exceed $1\frac{1}{2}$ ton the foot. In this country, where 2 tons a foot are required by law, a greater weight of structure will be needed in proportion. But for the railway traffic of America, an allowance of 3000 lbs. maximum load for single track is amply sufficient.

The cables of the side spans form portions of the same curve as those of the middle span. The only difference is, that they are cut off 62 ft. beyond the centre. An exact half-span would measure 265 ft. from centre of tower to end of truss. But the actual length of the truss is 62 ft. more, which makes 327 ft., the object being to make the side spans about 300 ft. in the clear at low-water mark. Whether the cable is anchored at that point or is continued, its tension will not vary, provided its weight or load per unit of length remains the same. In proportioning the arches of the side spans, two conditions have to be fulfilled. Their horizontal thrust at the foot of the towers must balance the horizontal pressure caused by the arches of the central span. Secondly, their horizontal pressure against the anchor-plates must balance the horizontal tension of the cables at those points. These two conditions will determine the proportions of the arches as well as the length of the spans. If, on the other hand, the length of span is fixed, we can also proportion the arches and cables so as to fulfil the above conditions. An easy and practical method for a preliminary investigation, is to lay down the curve of the table, then construct a full arch, similar to the central arch, on thick drawing-paper, cut out its curved outline and lay it down upon the plan; then try its various positions, to find out approximately what length of span and what proportions will about suit. This examination made, we can then calculate the proportions of the arch, its supporting power, and its pressure at the foot and at the anchor-plate. This process, repeated a few times, will bring us near enough to the exact quantities which are required. A practical method like this will be found much more satisfactory, and at the same time easier and more certain than the use of complicated equations.

By lowering the anchor-plate, we shorten the cable until we have reached its centre, which forms an exact half-span. By raising the anchor-plate, we lengthen out the span, and the greatest length will be obtained when the plate is at the level of the upper chord. In that case the arch would have to rise *above* the upper chord. On the other hand, we can also reduce this span to less than a true half-span by moving the anchor-plate back until we meet the upper chord. This point of intersection will then have a strong tendency to rise, which must be met by anchoring to the masonry in such a manner that contraction and expansion from changes of temperature will not be interfered with.

Strains in Arches and Cables.—The trusses of the side spans are 327 ft. long, measured from the centre of tower. The arches of the side span form part of a curve whose chord is 352 ft. in length with a versed sine of 18.8 ft. The ratio of deflection to span is therefore as 1 : 18.72, and the coefficient of compression 2.4.

The greatest weight upon the arches of the central span is 450 tons.

Or per foot lineal, $450 \div 500 = \dots\dots\dots 0.9$ „

The weight upon the side arches will be nearly the same per lineal foot, and we will compute
2 z 2

their compression by supposing their whole length weighted down at the same rate. This gives a total weight of $352 \times 0.9 = 316.8$ tons. Hence their compression at the foot of tower, $316.8 \times 2.4 = 760.32$ tons.

To illustrate :

Let $d e$, Fig. 1432, represent half the chord of the central arch, 258 ft. long, $e f$ twice the height of its rise, equal to 80 ft., then the hypotenuse $d f$ will form a tangent to the arch, and will measure 270, omitting fractions. Now, the compression of this arch is represented by $d f$, its horizontal thrust by $d e$, and its vertical pressure by $f e$. Consequently, we find the horizontal thrust of the central arches (since the compression is 449.57×1.70)

$$764 : x :: 270 : 258 x = \frac{764 \times 258}{270}, \text{ or } x = 730 \text{ tons.}$$

Also let $a b$, Fig. 1431, represent half the chord of the side arch, equal to 176 ft., and $a c$ its double rise, equal to 37.6, then $b c$ represents the tangent, and will measure 180 ft. The horizontal thrust of the arch is then found, $760 : x = 180 : 176 x = \frac{760 \times 176}{180} = 743$ tons. There is a difference of 13 tons on the part of the side arch, which is readily met by the strength of the lower chord and the stability of the foot of the tower.

Again, let Fig. 1433 represent a rectangular triangle, where $a b$ is one-half of the main span or 265 ft., $b c$ twice the versed sine of the cables or 120 ft., then $a c$ is the tangent, equal to 291, and represents the tension of the cable, while $a b$ is its horizontal force, and $b c$ its vertical pressure.

We therefore find the horizontal force or x ; $291 : 265 :: 764 : x = \frac{265 \times 764}{291} = 696$ tons.

In Fig. 1434, let a be the centre of the anchor-plate, $a d$ a horizontal line 40 ft. long, $b c$ vertical to it; then make $d c = 7.25$, and $d b = 4.0$, $a c$ will be 40.65 , and $a b = 40.20$; $a c$ represents the tangent of the arch, and $a b$ the tangent of the cable. In order to find the horizontal force of the cable and arch at a , we must first ascertain their relative tension and compression at this point.

The tension of the cable at the top of the tower is	Tons. 764
And in the centre of the curve	696
Difference	68
The decrease of tension being nearly uniform, we find the tension at the anchor-plate about	712
The compression of the arch at the tower is	760
And at the centre	743
Difference	17
The compression at the anchor-plate we find about	747

We can now ascertain the horizontal force of the cable at the point a :

$$712 : x = 40.20 : 40.00 x = \frac{712 \times 40}{40.2} = 708 \text{ tons.}$$

In the same way the horizontal thrust of the arches is found :

$$747 : x = 40.65 : 40 x = \frac{747 \times 40}{40.65} = 753 \text{ tons.}$$

The horizontal pressure of the arches is therefore 27 tons greater than the horizontal force of the cables. This excess is easily met by the resistance of the framing, composed of the upper and lower chords, and by the action of the abutment-stays. A few light tie-rods, extending from the anchor-plates to the lower chords, will also balance this excess. But if there was a necessity to establish an exact balance between the horizontal action of the arches and cables, without changing the length of span, all that would be required is to shorten the full chord of the arch, and to increase its versed sine a few feet, which change would pass them through the upper chord. This change is not desirable, but may be met by increasing the height of the trusses to the same extent. Roebling, however, prefers to leave the proportions as they are, because the ends of the side spans will be found in practice to need more stiffness than other parts of the work, and this will be obtained by an increase of stiffness in the arch.

To add still more to the stiffness of the ends, four light wire-rope stays or ties have been introduced, of sufficient strength to prevent oscillations. To meet the horizontal action of these stays an excess of strength will be found in the upper and lower chords. Another object of these stays is to resist the downward pressure of the three wire-rope stays below the floor. The object of these stays is threefold. First, they will assist in preventing oscillations from passing loads; secondly, they will resist the uplifting tendency of heavy storms and hurricanes; and, thirdly, they will

greatly assist the free and easy expansion of the structure caused by a great increase of temperature. Such assistance is desirable in case of a single-track bridge, when care must be had to provide enough safeguards to maintain lateral stiffness and to prevent the structure from getting out of line. The great tendency of the cables to assume a vertical plane will of course contribute very much to the horizontal stability of the arches; but it is still advisable to avail ourselves of such a cheap and effective auxiliary as will be provided by these under-floor stays. Their tension should be adjusted so that a maximum contraction in the winter caused by their own shrinkage and the shortening of the superstructure will not overtax their strength. But it will be observed that the tighter they are the more power they will possess to pull the structure back, when an increase of temperature occurs. On that side of the main span, where its whole length, together with one side span, expands and contracts in one, still longer stays may be applied, if it should be found desirable; and also heavy weights suspended to it to give them more deflection without an increase of tension, and thus to render them more efficient and safe in the performance of their task.

The ends of the trusses are further secured vertically, as well as laterally, by two wire-ropes, one on each side of the structure, anchored to the pier by joints, which will admit freely of the movement of the upper ends, where they are fastened to the top chords, in accordance with the contraction and expansion of the structure.

Static Condition of the Structure under the Action of variable Loads.—Suppose a maximum transitory weight of 750 tons evenly distributed over the whole length of the central span, and no loads upon the side spans, what will be the static condition?

The following Table exhibits the relative portions of weight borne by the stays, the cables, and the arches of the central span when taxed with a maximum load, including superstructure.

	Weight of Superstructure.	Transitory Load.	Total Weight.
	tons.	tons.	tons.
Borne by stays	150	174	324
„ cables	290	336	626
„ arches	210	240	450
Total	650	750	1400

We will first consider the action of the stays. This action is twofold: first they exert a force upon the top of the tower, which may be resolved in a horizontal and vertical direction, and will be fully considered hereafter. Secondly, their force produces a horizontal tension as well as compression upon the lower chords. Now, as there is a system of stays on each side of the tower, if their horizontal action is the same, the compression of the chords on the one side will be met by the compression on the other side, and there will be equilibrium. But if the side span is relieved of its transient load, while the main span remains loaded, then the equilibrium between the opposite stays will be disturbed. The tension of the stays on the side span being relieved, the top of the tower will slightly yield toward the main span, as far as will be permitted by its inherent elasticity and stiffness. This will partially restore the lost tension of the stays, and the horizontal compression of the chords will remain nearly the same. No other change can result, because the stability of the towers will be maintained by the leverage of the side span, as will appear hereafter.

Next, let us consider the condition of the central arches, under a pressure of 240 tons produced by the transitory load, without any corresponding weight upon the arches of the side spans. The compression at the foot of the arches, caused by the above weight, is $240 \times 1.7 = 408$ tons, and the horizontal thrust, Fig. 1432, $408 \times \frac{258}{270} = 390$ tons.

The ends of the arches being connected by the lower chords and framing of the floor, these parts will be exposed to this thrust most directly. Allowing 5 tons maximum tension a sq. in., a section of $\frac{390}{5} = 78$ sq. in. will be required. Now the lower chords are composed of eight channel-bars of $7\frac{1}{2}$ sq. in. section each, making 60 sq. in. Add the sections of the 9" girders, underneath the tracks, which are brought into full action by the braces at the towers, 18 sq. in. Total, 78 sq. in.

The excess of pressure of the central arches is therefore fully met. But the three spans form one continuous truss, and consequently a great resistance will also be offered by the upper chords and by the inherent stiffness of the whole structure. It is therefore plain, that so far as the arches are concerned, their stability and safety under the action of the heaviest transitory loads are sufficiently secured.

It remains now to examine the conditions brought about by the united action of the cables and stays when taxed by a maximum load in the main span, without corresponding loads in the side spans.

The weight upon the cables caused by this load is found in the above Table ..	Tons.
And the tension at the top of towers, 336×1.22	410
The horizontal force acting at the saddle is found to be, Fig. 1433, $410 \times \frac{265}{291} =$	
Add to this the horizontal force produced by 12 stays	165
Total	575

Now this combined force acts upon the top of the towers, its height serving as a lever, with a tendency to lift the adjoining side span. The moment of this force, therefore, is $538 \times 62 = 33356$.

The weight of superstructure of the middle span was assumed at 650 tons, or per foot lineal $\frac{650}{500} = 1.3$ ton. The weight of the side span per foot lineal is about 1.2 ton. The length of the side span is 327 feet. Consequently its total weight, $327 \times 1.2 = 392.4$ tons.

This weight may now be supposed as acting at the centre of the span, and the leverage of its action in maintaining the stability of the whole, is equal to half the length of the span; consequently the moment of force is $392.4 \times 163.5 = 64157$.

But the end of the side span is held down and kept from rising by the stays underneath the floor and by the two powerful wire-rope braces which secure their lateral position. These combined resistances may be estimated at least at 100 tons, and this force acts with a leverage equal to the whole length of the side span; consequently its moment is $327 \times 100 = 32700$.

Total moment, 93,857, or nearly three times as much as is needed to maintain an equilibrium.

The above investigations authorize the conclusion that this Parabolic Truss is not only amply strong in all its different parts when uniformly loaded, but that its safety and stability are also amply provided for under the variable action of maximum loads. Indeed, when comparing the rates of allowances made in this plan, with those usually observed with iron railway-bridges in this country, where cast iron is so abundantly made use of, it would almost appear there is an unnecessary strength provided for.

Roller-plates.—The whole length of parabolic superstructure is 1184 ft., and forms one single continuous truss, whose integrity and continuity must not be interfered with in any way whatever. Hence the great importance of providing for efficient means to facilitate the free contraction and expansion of the work in consequence of changes of temperature. The superstructure is permanently fastened and anchored upon one of the middle piers, and from this fixed point the side span adjoining is allowed to expand and contract. A roller-frame is therefore placed upon the abutment, or upon the pier, which serves as such. On the opposite side, the middle span together with the side span contracts and expands as one, and consequently roller-frames are placed upon the second middle pier, as well as upon the abutment.

No strife or interference between the different parts of the structure can take place while this process of contraction and expansion is going on, because all parts are made of the same kind of material—wrought iron—and therefore the arches, cables, chords, and towers will go and come in the same relative ratio. When the temperature increases, the chords, arches, and cables will increase their length, and the whole structure will be lengthened out. The panel or truss posts will increase their length: in the same ratio the arches will rise and the

cables will sink, preserving a uniform tension among the suspenders and panel-rods. At the same time the towers will raise their heads and compensate for the increased length of cables and stays. The whole truss may be considered as fastened to one metallic sheet in a vertical position, expanding or contracting in all directions.

A bar of wrought iron 150,000 ft. in length will expand or contract 1 ft. for every degree of change. Now assuming the extremes of temperature at 150° , the extreme limit of contraction and expansion of one middle and side span, which measures 857 ft. in length, will be 0.857 ft. The roller-plates on that abutment must therefore allow of this much play. Whether the temperature of the iron rises to 120° in a July sun, or falls to 30° below zero in the dead of winter, we are sure that all parts of the structure will freely accommodate themselves to these changes, and will never fail on that account to support their allotted parts.

An inspection of the cross and longitudinal section of roller-plates, Fig. 1435, will make their simple construction perfectly plain. Both the upper and lower plates are of cast iron; the rollers between are of wrought iron. The inner faces of the plates must be planed off true, so that the bearing of the rollers, which are all turned off to the same diameter, will be even and uniform. It is customary to connect the rollers by a frame; but this is an unnecessary expense and no improvement. The edges of the rollers are slightly rounded off, say $\frac{1}{8}$ in., and the plates confine the rollers between flanges 1 in. deep. These flanges are sloped $\frac{1}{4}$ in., which prevents friction between them and the rollers. At the same time the slope is too steep to admit of the mounting upon it of the edges of the rollers. To ensure parallelism between the rollers, they are placed together where the pressure is very great, and where the pressure is light, as in the case before us, they are spaced by inserting between them strips of seasoned pine-wood well soaked in linseed oil. With the weight of the structure upon the plates the rollers will keep their relative positions. It is easier and cheaper to ensure parallelism on this plan than by the employment of roller-frames. Steel rollers are sometimes used in place of iron rollers. But this is objectionable in connection with cast-iron plates. The rollers on the towers of the Niagara Bridge are made of cannon-metal, and are 5 in. in diameter. When steel is used for rollers, both plates should be faced with steel; if not, then the hard rollers will make an impression on the softer cast iron.

The rollers exhibited, Fig. 1435, are 4' 4" long and 3" in diameter. The plates are 3" thick. The lower plate is well settled on a heavy bed of rich cement-mortar. The wooden strips between the rollers are not represented on the plates which support the tower, Figs. 1436, 1437.

Towers.—The towers are 62 ft. high above the roller-plates. Each tower, Figs. 1436, 1437, is composed of two shafts, which form parts of the trusses, and are firmly connected with the chords and arches. Each of the shafts is composed of three columns, and each column again may be constructed either of four, six, or eight sections. Fig. 1438 exhibits a section of a column composed of six segments. In Figs. 1436, 1437, the columns are drawn with four segments only. The interior circle of the column is assumed at 16 in. The shafts being 59' 2" high from the roller-plate to the saddle, the sections may be rolled about 20 or 30 ft. long, so as to break joints. Every joint must be covered by a splicing-plate inside. The intermediate plates which connect the

segments, also breaking joints with them, will likewise add to the firmness of the columns. Both ends of the columns are to be planed off true, and so must be the end of every intermediate piece, so that every joint will make a tight fit. The respective columns of the opposite shafts are connected horizontally by a system of channel-bars and diagonals, which will fully ensure their lateral security. This is further increased by two lattice-beams, which connect the cast-iron saddles, as is plainly exhibited in Fig. 1437. The top roller-plate being planed off on both sides, the lower ends of the columns will have a fair level seat upon them. The shafts are thus enclosed between the foot of the arches and the lower chords, and firmly connected with them laterally by flat bars, angle-irons, and stay-bolts. When the flanges of the inner channel-bars and those of the columns meet and interfere with each other, they are cut away for a few inches. The truss-posts at the towers are also firmly connected with the shafts, and so are the upper chords, and these connections will add much to the strength of the structure. In the direction of the trusses each tower is further secured by four lattice-braces which run between the chords and arches. The stability of the towers in this direction is also increased by the stays, and in a lateral direction two powerful wire-rope guys add to their security. These guys serve as anchors, and being hinged at the lower ends, will not interfere with the free contraction and expansion of the structure. To guard against lateral vibration of the lattice-braces, their outer chords are strengthened by plates 12 in. wide and $\frac{1}{4}$ in. thick, riveted to a heavy T-bar which connects with the lattice-bars, Figs. 1560 to 1563.

It will be noticed that the towers, forming one connected whole with the trusses and arches, will move freely on the roller-plates along with the rest when affected by contraction and expansion on that pier which is provided with rollers. On the other piers the towers are stationary.

The greatest vertical pressure upon one tower (two shafts) is equal to 950 tons. Allowing 4 tons maximum compression for 1 sq. in. section of iron, we should require $\frac{950}{4} = 237\frac{1}{2}$ sq. in., or

118 $\frac{1}{2}$ sq. in. in each shaft. In place of this, we have allowed a section of 150 sq. in., which reduces the pressure upon each superficial inch to 3.16 tons at the top of the tower. As we descend, the strength increases considerably by aid of the lattice, and when the upper chords are reached the strength is nearly doubled. We are therefore sure that ample allowance is made for the supporting power of the towers.

Saddles.—The saddles on top of the towers are of cast iron, 8 ft. long by 3 ft. 6 in. wide at the bottom plate. The construction is given in Figs. 1436, 1437. The lower face is planed off, so that when the top of the columns is brought to a level, the two surfaces will have a fair and equal bearing. In order now to secure the saddle horizontally, six small segmental plates are fitted around each column, and secured to the bottom of the saddle by set screws. To do this, an exact template should be formed of the top of the shaft, before the saddle is hoisted; then the holes may be marked off for the set screws, and sunk into the saddle: the small plates can then be screwed on to its lower side before the saddle is finally put in place.

The inside section of the saddle is so shaped that the wire-ropes for supporting the cables and stays will occupy their relative positions. Four ropes are placed in the bottom row; they, together with the two outside ropes of the next tier, compose the six stays. The next three middle ropes, the second tiers, form the lowest layer of the cable.

Two forged pieces of wrought iron 4" $\times$ 6", with triangular pieces underneath, are let into the four notches of the sides of the saddle and screwed down for the purpose of securing the cables and to prevent sliding. This being done, the cables and tower now form one. When there is a greater strain on one side than on the other, the elasticity of the tower will admit of sufficient yield to equalize the difference.

Anchor-plates.—The end of each cable is secured to a cast-iron plate, which at the same time serves for the arch to butt against, and thus the two are made to balance each other. Figs. 1439 to 1441 exhibit views of both faces of the plate, and also a section in which the fastening of the ends of the wire-ropes is made clear. The dimensions of the plates are 4' 2" $\times$ 3' 8", with a thickness of metal of 8" in the centre and 3" around the sides, strengthened by ribs. A cable being composed of nineteen ropes or smaller cables (twisted or not), there are nineteen corresponding holes for their reception. These holes are conically shaped, the larger opening having twice the diameter of the smaller one. Some of the large openings are elliptically shaped, in order to gain room. That face which serves as an abutment for the channel-bars, composing the arch, is to be planed off to admit of a fair bearing. The weight of the plate is supported by its upper flange, which rests upon the ends of the upper channel-bars. A further support is provided by two cast-iron posts which fit against the face of the end truss-posts and are bolted to it. It remains now to convey a clear idea of the manner of securing the ends of the small cables within the plate. This is done by spreading apart the different wire-strands and wires which compose a rope, and inserting a number of iron points between them in such a manner that the whole span inside of the conical hole is filled out solid, Fig. 1440. By these means the end of the rope is swelled out into a conical lump 8 in. long, which cannot slip out of the plate without bursting it.

It is important that these plates should be cast of the strongest metal—good, strong, cold-blast charcoal metal—such as is used for the manufacture of good car-wheels. The points driven in between the wires may vary in length as well as in thickness. First drive in a number of long ones, 6 to 8 in. in length, about $\frac{1}{2}$ in. in diameter at the thick end and gradually reduced to a point, filed off round and dipped in linseed oil before driving, to make them go easy. Also pour

some linseed oil between the wires, to make them smooth. The oil will prevent the staving up of the wires and facilitate the process. After filling up the remaining spaces with shorter and thinner points, then cut off the ends of the wires projecting over the plate even with it, one after another, and bend their ends to a right angle over the ends of the points. This being accomplished, apply a clay mould around the whole, so as to form a raised rim, and pour in melted lead, which will fill all the remaining interstices and make the whole one compact mass. After removal of the mould apply the hammer to make the lead solid, file it smooth, and round it off a little to give it a finish. To insert the ends of the ropes without trouble, it is necessary to wrap them well with annealed wire: and as the end is forced in, the wrappings will be pushed back.

Stays.—Similar to the plan just described is the method of fastening the ends of the stays: with this difference—that each stay-rope has a cast-iron socket for itself. This socket, together with the wrought-iron stirrup which holds it, is represented by Figs. 1442 to 1445. The stirrup is made of round iron $1\frac{1}{2}$ " diameter, and varies in length to suit the inclination of the stay. Where the stirrup passes around the floor-beam, a small segmental casting, forming a seat for the stirrup, is fitted against the beam, for the purpose of giving the stirrup a fair bearing. The screws must be long enough to tighten the stays. To preserve their straight lines, they are connected with the suspenders by wire wrappings.

It will be noticed that the stays as well as suspenders, together with the cables, are all suspended in one vertical plane which passes through the centre of the 2-ft. space left open between the two rows of truss-posts. The cross-bars connecting each pair of posts are not to be put up until the stays, cables, and suspenders have been placed and fixed in their position.

At the ends of the trusses four small stays may be noticed, which are provided for the purpose of guarding against vibrations at those points, and also to add to the supporting strength. The upper and lower chords being necessary, independent of support; their strength is thereby brought into play. Accordingly as much tension is thrown upon the stay-ropes as the resistance of the chords will permit. The ropes are double, and their diameter varies from 1 to 2 in.

Cables.—There are two wire-cables, one on each side, suspended in vertical planes between the double rows of truss-posts. Each cable is composed of 19 wire-ropes of $2\frac{1}{2}$ in. diameter. The maximum tension of the two cables at the tower is 764 tons, and at the centre of the main span 696 tons. Dividing 764 by 36, we have the tension of each rope equal to $20\frac{1}{10}$ tons; and, allowing

six times the strength, we have for the ultimate strength of each rope 120·6 tons. Although the tension of the cables is less in the centre, the same section and strength are observed throughout. A chain may be tapered, but it would be false economy to attempt it in a cable. Fig. 1446 shows a section of one cable on a larger scale. The nineteen ropes are suspended in five layers, and care must be had to preserve the relative position of each layer, as well as of each individual rope, throughout its length, so that the union of the whole nineteen will in section form a hexagon. The suspenders being attached every 10 ft., a strap is laid around the cable, and screwed up tight, to preserve its form. These straps should be made by about three different patterns, to suit the inclination of the different parts of the cables. When putting them on, they are heated in a small hand-forge, and a strip of sheet iron is laid over the cable to prevent heating the wire. After closing, they are cooled by pouring on water.

To keep snow and wet out of the cables, they should be protected by a half-circular cover made of tin, secured to the straps by small wire wrappings. This is indicated in Figs. 1446 to 1449.

A uniform tension of the ropes is easily obtained by suspending them parallel to each other in level layers, and in close contact. First secure one end in the anchor-plate; then adjust the rope in the saddles with a proper deflection at the lowest point of each span. Then pass the other end through the other plate, open the seven strands, and pass the centre one through a conical tube 7 in. long, wide enough at the small end to admit the strand, and at the other end enlarged to double the diameter. The whole rope being a little longer than necessary, say 1 to 2 ft., the centre may be fastened temporarily or anchored back, preserving at the same time its central position in the hole. By slackening or tightening this centre now, the position of the rope in the cable may be adjusted. When right, drive the hollow tube into the anchor-plate some distance, and at the same time insert a number of large points, and drive them all in uniformly. When all the large pins are in, the centre may be released, and the untwisted wires may be cut off the right length. Then insert thinner points in the centre tube, and fill it, and complete the whole. To give a support to the anchor-plate, it is of course necessary to put up the truss-posts as far as they rest on the abutment, and to secure them temporarily by timber-bracing. And it will also be necessary to provide for a temporary anchorage of the anchor-plate itself before the arches are put up. This may be done by extending a few wire-ropes from the anchor-plate and posts to the next pier or abutment, and secure them; and if this masonry is not strong enough, a temporary anchorage of timber and stone must be put on shore, of sufficient strength to resist the pull of the cables. The same wire-ropes which are to be used for the abutment-stays and for the storm-cables, and which are to be delivered in long coils, may be advantageously used for this temporary anchorage with very little loss or waste.

The tension of each full cable, resulting from their weight when freely suspended, will be 63 tons; and this has to be fully met and supported. By the use of a few railroad bars laid across the posts above and below the anchor-plates, and by passing stirrups or chains around them, the anchor-ropes may be attached. On the shore they may be fastened to similar bars, placed in an excavation, the bars to be secured to a rough framework of timber and plank, and this may be kept in its place by earth, gravel, stone, and other heavy material; it may also be assisted by braces. Piles may also be driven to increase the resistance of this temporary anchorage.

In order to put up the arches and other parts of the superstructure, a temporary platform and footway will have to be suspended. As to the cables, a light foot-bridge under each will be all-sufficient, and the same anchorage which answers for the main cables will answer for the foot-bridge cables. It should be observed here, that the temporary anchorage should be made strong enough to resist a pressure of about 400 tons, because this much tension may be produced by the cables while erecting the superstructure.

While putting the ropes in the cables, they should receive another coat of durable paint. Allowance must be made for the stretch of the cables. All wire will stretch, whether made of steel or iron. A No. 8 steel wire of good quality, capable of supporting a weight of 3000 to 3400 lbs., and 5 ft. long, will stretch 1 in. before breaking. After being taxed with a full load for some time, the stretch of the cables will cease, because the material will have assumed a permanent set. After this, no more elongation will take place. The deflection of the cables in the main span, after the

wire has attained a permanent set, is to be 60 ft. An allowance of 1 to 2 ft. should be made for settlement. If the cables are well made, 1 ft. will be enough; but if poorly made, 3 ft. may not be sufficient. To be more explicit, the cables should be suspended with a deflection of, say 58 ft., if well made, and if not, 56 to 57 ft. will be safer.

In order to make the cables bear their allotted portion, the suspenders have to be screwed up repeatedly after full trains have passed over the work. The permanent set of the cables will make itself felt distinctly if attention be paid to it. On the other hand, it would be wrong to tax them too much, and thereby relieve the arches to an undue degree. A proper adjustment may at first sight appear to be impossible, or at any rate attended with great difficulty. But if the directions given here are strictly carried out, this adjustment may be readily accomplished.

The weight of the superstructure which is to be borne by the cables of the main span is 290 tons. The number of suspenders is 96, and therefore the weight borne by each is $\frac{290}{96} = 3.02$ tons.

Each suspender being attached to a stirrup which has two screws, the weights to be borne by each single screw will be $1\frac{1}{2}$ ton, or 3000 lbs. Now practise a few intelligent men in raising a weight of 3000 lbs. by such a screw, using a screw-wrench of a certain length, say 18 in. The screws should be well cut, so as to run easy and smooth. No stirrup should go into the work without having the screws well examined, well cleaned, run smooth, and oiled.

The handles of the wrenches should be just long enough to require the average strength of a man's arm. To make this operation still more certain, the wrench may be tested by a suspended weight, so that the men can compare their strength with the actual weight. Much depends upon the cut of the screws; with good uniform threads, every suspender must be brought to a fair and equal bearing.

The length of the suspenders being calculated, they are manufactured accordingly, and put in place; but the theoretical length will never exactly agree with the actual length, and the difference is made up by screwing. The above remarks on suspenders will equally apply to the stays. The ultimate strength of each stay is 100 tons, and they are calculated to bear an ultimate tension of $\frac{1}{3}$, or 20 tons, caused by the superstructure and a maximum load. Now, the proportion of weight of superstructure to that of maximum load which falls upon the stays is as 150:174, as will be seen in the Table of relative loads; consequently they may be screwed up to a tension of about 9 tons, and this is accomplished with a wrench of about $3\frac{1}{2}$ to 4 ft. long.

After the cables have obtained their permanent set, and the suspenders and stays have been adjusted, no more attention need be paid to this part of the structure. The relative supporting power of the cables, stays, and arches will remain unaltered, they will not undergo any further change. And as changes of temperature will influence the arches as well as the cables alike, no strife between the different members can arise on that account.

The curve formed by a cable when freely suspended and not loaded, will be that of a catenary, because the weight of a unit of cable is supposed to be the same throughout its length. But with a weighty horizontal platform suspended to the cables their curve is changed, and will be found to correspond more to a parabola than to a catenary. The suspenders may accordingly be calculated for a parabola, but it will be found in practice that they vary, and sometimes considerably, from both curves. The screws at the ends of the suspenders will be the means of adjustment. But another change in the curvature of the cables will take place when the stays are tightened and begin to relieve the cables at those points. They will then be lowered in the centre and raised near the towers. Allowance must be made for this in the length of the suspenders, so far as the stays extend.

Suspenders.—The maximum weight borne by the 96 suspenders of the middle span is 626 tons. Each suspender, therefore, has to support $6\frac{2}{3}$ tons. Allowing seven times the strength, we want for the wire-rope suspenders an ultimate strength of 45 tons, or $1\frac{1}{8}$ " diameter rope.

Figs. 1444, 1445, show a wire-rope suspender, both ends fastened in wrought-iron sockets, and the lower socket attached to a stirrup which passes around the floor-beam. Figs. 1447 to 1449 exhibit one of the short, solid suspenders hung to the cable-strap and to the stirrup below. The rods are $1\frac{1}{8}$ " diameter, and the stirrups $1\frac{1}{2}$ " diameter. These dimensions may appear extravagant, but when it is considered that under a heavy passing load, every single suspender is taxed more than its general proportion, this large allowance will be justified.

Chords.—The arrangement of the upper and lower chords is plainly exhibited on the plans. Figs. 1436, 1437, show it more particularly. The 9-in. channel-bars composing them extend from end to end without interruption. The lower chords are not plated underneath at any point. This is not wanted on account of strength, and their lateral stiffness is amply ensured by the floor-beams, by the plates to which the tie-rods are secured, and by the stay-bolts. Nor are the upper chords plated on top, except in the side spans from the end of the truss to the point where the cable enters. These top plates are $\frac{1}{4}$ in. thick and 50 in. wide. The cross-beams are here placed on top of these plates and riveted to it.

The splicing of the chords is done in the same manner as that of the arches. Whenever a stay-bolt is applied to the chords it is passed through a gas-tube, which is cut off on the lathe to the right length, and thus a firm and simple connection is made. In order to meet the thrust of the arches, in excess in the one span, while no load is on the other, a section of 60 sq. in. was found to be necessary for the lower chords. The horizontal action of the stays at the tower is compressional only, and does not add to the tensile strength of the arches. The horizontal action upon the chords, which results from the diagonal rods in the panels, is balanced in each panel, and requires therefore but little section.

A section of 6 sq. in. for the channel-bars of the upper chords will be an ample allowance. The same section may be observed throughout the length of chord. It is, however, necessary to make the splices of the lower chords as strong as the channel-bars themselves, so that they may

resist a full tensile strain, which may be brought upon them by the arches when the spans are unequally loaded.

Posts.—The posts are of the beam section, and 9 in. wide or deep; Figs. 1450, 1451, exhibit sections on a larger scale: the weight is 25 lbs. a foot. All the posts are 22 ft. long, except those in the centre span, which vary from 22 to 44 ft.

Each truss consists of two rows of posts planted 24 in. apart, in which open spaces the cables, stays, and suspenders are freely suspended. They are firmly connected by horizontal bars $1\frac{1}{2}$ in. square: the ends of these bars are spread out so that they will give room for 4 rivets of $\frac{3}{8}$ in. diameter, to be fastened upon the flanges of the posts. Each cross-bar is therefore held by 8 rivets.

In order to increase the lateral stiffness and stability of the trusses, the intervening space between the posts may be enlarged to 30 or 36 in.; and the connecting-bars should then be 2 in. in place of $1\frac{1}{2}$ square. The vertical stiffness of the posts in the direction of the trusses is aided by horizontal connecting-bars at the centre. These bars are only 1 in. diameter, pass through the web of the posts, and are simply screwed up by a nut at the end, as is shown, Figs. 1450, 1451.

By tightening these bars uniformly, the lateral position of the posts is secured and vibration prevented. This provision is very necessary, on account of the great length of the posts.

Arches.—The arches are formed of channel-bars, Fig. 1452. The posts being 20 ft. apart, the channel-bars are rolled of the same length so that the splices all come upon the posts. It will be noticed that the connections with the splicing-plates are made with screw-bolts, and not with rivets. This will greatly facilitate the putting up and adjustment of the arches. One of the practical difficulties in putting up such work is to make the ends meet, and to make a tight and workmanlike fit, so important in arches and chords. This difficulty is much increased by great variations of temperature, and hence the importance of using screw-bolts in place of rivets. The bars may at first be put together loosely and without any tight fit, by using small bolts temporarily, which are to be removed after the joints are brought to a close. Each pair of splicing-plates, opposite each other, is connected by six bolts of $\frac{7}{8}$ in. diameter, or three on each side of a post; on being drawn tight, they embrace them solid and firm. In order to screw these up tight, they must not be enclosed in tubes. The remaining four bolts, on the other hand, are passed through gas-tubes 9 in. long and 1 in. wide, which therefore preserve the distance between the channels and serve as stay-bolts. Two small plates $4\text{ in.} \times 7\text{ in.} \times \frac{1}{2}\text{ in.}$ thick are riveted to the post and fitted between the channels. Two of the channels are therefore firmly enclosed between these plates and the brackets. To add still further to the stiffness of the splices, the cross-channels which connect the two lines of trusses are filled in between and firmly bolted to the posts, while at the same time their flanges are riveted to the flanges of the arches. When the latter cross the posts obliquely, the cross-channels have to be heated and swedged in a block by pressure, so as to fit the oblique section. By using wedges of different shapes to correspond to the inclination of the arch, one press or one pair of blocks or dies will do for the whole. If the cost of such a press is objected to, the flanges of the cross-channels may be cut out and the stem only bolted to the post.

So far as the arches rise above the upper chords in the central span, the upper channels are connected by a top-plate of $\frac{1}{2}$ in. thick riveted to the upper flanges. Laterally, between the posts in each panel, the arches are again connected by four channels of 50 in. length each, and also by stay-bolts passing through gas-tubes.

Where the arches rise above the upper chords, the channels forming the latter are cut out and planed off to the proper level to make a good fit. Splicing-plates are then riveted over the joint, and the respective flanges are also connected by rivets. At the same time a plate of 4 ft. long by 2 ft. wide and $\frac{1}{2}$ in. thick is riveted down on top, so as to cover all the joints. The depth of each arch is 41 in., and its width 4 ft.

Considered as a straight girder freely spanning a distance of 60 ft., this combination would be stiff enough for railroad traffic. But its inherent stiffness is not calculated to serve as a supporting power, but to resist lateral deflection like a column. A round column is, of course, the best geometrical section for gaining lateral strength. But a columnar section in wrought iron for the purposes of an arch, presents many difficulties and objections. What would be gained in section would be more than lost in reduced strength of framing.

The great facilities of construction which the plan before us offers, must not be underrated. And when we consider the small section of wrought iron that is needed to make the arches effective, this plan will compare favourably with other plans heretofore attempted. The arches

of the Coblenz Bridge over the Rhine are 308 ft. wide in the clear. Each rib is 10 ft. 6 in. deep, with upper and lower flanges. The flanges of the centre rib are 3 ft. 2 in., and those of the outer ribs 2 ft. 2 in. wide. These arched ribs have been treated as flexible trusses, consequently the upper and lower flanges have been graduated like chords, with the greatest section in the centre. The upper and lower chords are connected by posts and diagonal braces. This work is considered a model work; it is well proportioned and possesses ample strength. The stiffness is in the arches alone, and no attempt has been made to increase it by spandril-bracing. Its rigidity is owing, in a great measure, to the placing of the floor *below* the crown of the arch.

The question arises, whether flanged arches with greater inherent stiffness would not be better adapted to the Parabolic Truss, than the arches here designed? So far as simple supporting power is considered, under the action of uniformly-distributed loads there would be no difference between the two plans. As regards stiffness, under the action of variable loads, however, the plan here proposed, with its great depth of trussing, will produce more rigidity, with the same amount of material expended, than would result from flanged arches. This view will apply with still greater force, when the arch descends below the lower chords. The depth of ribs in the Coblenz Bridge is 10 ft. 6 in., and the clear span 308 ft. (Prussian measure), a proportion of about 1 in 30. This depth would evidently be entirely too small for a straight girder of 308 ft. span, but it would be enough for a span of 100 ft.

In the Coblenz Bridge, the floor intersects the girders or ribs at the lower chord, and we may therefore consider the whole arch, so far as stiffness is concerned, as divided into three equal parts. The central part is stiffened by the floor, and the spandrils are stiffened by the posts which support the floor. But no further bracing has been attempted in the spandrils, on account of contraction and expansion; but this appears to be a defect, because an expenditure of very little additional material would have greatly added to the rigidity and strength of the work without materially interfering with contraction and expansion. It must be remarked, however, that the leading idea in the design of this celebrated viaduct was to interfere with the arches as little as possible, and to depend upon their own inherent stiffness, so that the ribs should be at liberty to accommodate themselves freely to variations of temperature. This same view led to the planning of the *pivot* skew-backs; but this defect has been corrected since by making the bearings of the skewbacks all solid.

When we omit the arches in our plan, considering the structure as a pure suspension-bridge, and compare its stiffness with that of the Niagara Bridge, we discover that the truss here designed possesses ample stiffness for all railroad purposes. The Niagara trusses are only 18 ft. high; those before us are 22 ft., with a span of 500 ft.; while the Niagara span is over 800. In the Niagara Bridge the truss-posts are 6 ft. apart; here they are 20 ft. The Parabolic Trusses being double, there are four diagonal rods of $1\frac{1}{2}$ in. diameter in a panel of 20 ft., while there are two rods of $1\frac{1}{2}$ in. in a panel of 5 ft. at Niagara. On the other hand again, the Parabolic Trusses are all of iron and have comparatively very strong chords, while the Niagara framing is of wood, with light chords, which are, however, very materially assisted by the floors and the central girders, which latter distribute the weight of concentrated loads.

Roebing concludes that the trusses before us (without including the feature of the arch), will be quite as stiff as are the Niagara trusses.

When compressive action takes place in chords and arches, experience has demonstrated that 4 tons of 2000 lbs. each, or 8000 lbs. a sq. in. maximum pressure, is as much as soft, puddled iron should ever be taxed. But this resistance depends so much upon lateral conditions that the above allowance of 4 tons would scarcely be safe for single arches *not* assisted by cables. But the great feature of safety in the Parabolic Truss is the cable. The arch is only an auxiliary to the cable. With ordinary loads, the cables and stays will support the greatest part of the strains; and the more they are strained the greater their tendency to maintain their vertical positions, and to assist the arches in preserving their true alignment. *Lateral flexure is the great danger to arches.* The more jointed and articulated the system is, the greater this danger. Now, these considerations must be taken into view when deciding upon the choice of material for the arches. The question of steel or iron is of course a question of comparative estimate. But if, for instance, we allow 8000 lbs. maximum compression for iron, and 12,000 lbs. for a mild steel, and the steel arch costs the same as the iron arch, both possessing the same supporting strength, then the iron arch should be preferred to the steel arch, for the following reasons:—

1. The greater section of the iron arch will ensure greater lateral stiffness than can be obtained from the diminished section of soft steel.

2. The greater weight of the iron structure adds to its stability under the action of variable loads in direct proportion to its superior weight when compared with steel. Vibrations caused by fast-moving trains will be felt more by the lighter structure than by the heavier one.

One of the best features of the Parabolic Truss, as here designed, is, that the principal members of this system are nearly uniform in their sections, and that they are not alternately exposed to such opposite strains as compression and tension in succession.

The cables and stays experience tensile strains only, while the arches are exposed to compressive action alone. This feature will add much to the lifetime of the structure.

An objection may be raised to the parabolic form of the arches, because of the variation of bevels at the joints. The difference, however, between the segment of a circle and the parabolic curve, with the proportions here observed, is so small, that the substitution of the one for the other will not have the slightest practical influence. It will therefore facilitate the work, to cut all the joints to the same bevel for a circular arch. Respecting the cables, however, the suspenders should be calculated for a parabolic curve.

Floor-beams.—The beams supporting the railroad track are 5 ft. apart and 12 in. deep, and weigh 40 lbs. a lineal foot. If manufactured of good iron, a load of 23 tons, equally distributed, will not produce a sensible deflection, and a load of 15 tons on the two rails will be within its elastic limit. The lower flange of each beam is riveted to the upper flanges of the channel-bars com-

posing the chords, sixteen rivets of $\frac{5}{8}$ in. diameter for each beam. This forms a very stiff horizontal connection of the opposite chords, and renders all further diagonal bracing unnecessary. This stiffness is further increased by the 9-in. girders, running lengthways underneath the beams, and connected with the timber stringers, the rails, and the breachings by stirrups 2 ft. 6 in. apart.

The upper joints, connecting the arches and upper chords, are channels 7 in. depth, of a light section, one on each side of a post bolted to it and riveted to the flanges of the arches and chords. Fig. 1453, which is a section on the abutment, fully explains the details. So far as the upper chords in the side spans are plated, the joints are of 7-in. beam section in place of channels, their lower flanges riveted to the plates, Figs 1454, 1455.

Diagonals in Panels.—The object of the panel-rods is to impart stiffness, and to spread any concentrated pressure over a large extent of truss. In the centre of the main span, the pressure upon any point is spread by these rods over 4 panels, or 80 ft. of length of truss. For every row of posts there is a plane of diagonals; consequently there are 4 lines, each rod $1\frac{1}{2}$ in. diameter, with screw-ends proportionally enlarged.

Fig. 1454 explains how two diagonals are joined in one, and how they are bolted to the stem of the post, between the upper chords.

It will be noticed that these rods all radiate toward central screw-rings, for the purpose of screwing them up to a proper tension, and thus to impart stiffness to the framing.

Any load upon any one point will make an impression upon 2 to 3 floor-beams, and 16 rods, of $1\frac{1}{2}$ in. diameter each, will be brought into service, and distribute the weight over a large extent of truss.

Storm-cables.—The arrangement of the storm-cables is fully explained by an inspection of Figs. 1428, 1429. Two wire-ropes of an ultimate strength of 100 tons each are suspended below the floor in such a manner as to form parabolic curves. By this plan no longitudinal strains are thrown upon the superstructure. All the strains are directed upon the floor-beams, and are regulated by screw-bolts to give the cables a proper tension. The horizontal deflection of these cables in the centre span is 41 ft., or about $\frac{1}{3}$ of the span, and therefore the coefficient of tension is 1.70. If we assume now that the force of a high wind should be so great as to produce a uniform horizontal pressure against the structure equal to 20 tons, then the strain on the cable would be $1.70 \times 20 = 34$ tons, or about $\frac{1}{3}$ of its breaking strength. This tension might be

increased even to 50 tons without at all endangering the safety of the cables. But little surface is exposed to the wind vertically as well as horizontally.

It is well known that on a structure suspended at a high elevation, the wind exerts more of an uplifting power than of a horizontal action. The uplifting force is amply met by the weight of the structure itself. Estimating the vertical area exposed to horizontal action at 3000 sq. ft. and a pressure of 30 lbs. a sq. ft. applied all over, the aggregate pressure would be 90,000 lbs., and would be met by the strength of the cables. In this calculation no allowance is made for the inherent stiffness of the horizontal framing at the upper and lower chords and the top of the arches.

As has been remarked before, an objectionable feature in the plan before us is the great height of the arches in the centre of the main span, and its tendency to lateral oscillations under the action of fast-moving trains or from the effects of heavy gusts of wind. Where, therefore, a necessity exists to preserve the whole space below the lower chords clear of all obstruction, either a double bridge must be erected at once, the two connected together, or a more effective horizontal bracing must be put up in localities which are exposed to very high winds or hurricanes. This horizontal security can be increased by heavier diagonal ties between the upper chords and arches, by doubling the storm-cables and by adding diagonal bracing. Any amount of security may thus be obtained. It will be noticed that the contractions and expansions of the storm-cables from changes of temperature are not at variance with those of the trusses, because they form one connected whole, and will always move together.

Method of Raising the Superstructure.—A most important question is the practicability, safety, and cost of erecting the superstructure of such large spans as here proposed. Short spans may be raised on temporary scaffolding, one span at a time, with facility and little risk. But the task of putting in place spans of great dimensions in a river which is subject to sudden rises, full of floating *débris*, and with an unstable bed, is formidable, and may in certain stages and at certain seasons become impracticable.

The history of the erection of the 500 ft. span of the Kuilenburg Bridge in Holland has furnished a practical demonstration of the difficulties involved in such an enterprise. Before the entire completion of the large span of that work, a heavy gale sprung up and demolished all the scaffolding, but left the trusses unaffected, their bearing parts having been previously all safely connected. Had this high wind occurred a few days sooner, the whole superstructure would have been thrown down a total wreck.

It may be of interest to notice here the method pursued by the contractor of the Coblenz Bridge (the same who put up the Kuilenburg Bridge) in raising the three arches of that work. The two halves of the arched ribs were completed on shore, then launched and floated on boats to their destination, whence they were raised to their permanent position and connected. The raising was done by a hydraulic press supported on a temporary scaffolding put up in the centre of the span. Arches of a little over 300 ft. may be managed in that way quite successfully and economically. But when the span is doubled, the drawbacks attending this process are also doubled, and it will be wise to consider other methods.

In comparing different plans of raising, the questions of relative economy and of speed of execution are of much less importance than is the question of *safety*. That method should be adopted which ensures absolute safety under all circumstances. Fortunately, the plans of superstructure here proposed, while exhibiting economy and strength, also admit of the safest mode of erection. The Parabolic Truss, as here devised and modified, is a combination of the suspension-cable and of the arch. If, therefore, we suspend the cable first, we may afterward suspend the arch to it, independent of scaffolding, flood, or ice. The whole work may be put up in this manner, without the use of any scaffolding whatever. Should the season and stage of water, however, be favourable to scaffolding, then a few light bents should be used, supported on piles and connected with the suspended platform by hemp-rope lashings, in such a manner that in the emergency of a sudden rise, the lashings may be cut in a few minutes, and the bents allowed to float off without doing any further harm. A few such light scaffold-frames put up, say every 50 or 100 ft., will much assist in preserving the proper level of the suspended platform, and therefore facilitate the joining of the various members of the structure. Those, particularly, who are without experience in suspended structures will find the assistance of bents very useful. But they are not a necessity, only a convenient auxiliary.

After the masonry of the first central pier has been completed, the erection of the wrought-iron shafts composing the tower will be commenced, and the saddles placed on top and secured. On the second centre pier where the superstructure is not to be fixed permanently, but allowed to contract and expand freely, the roller-plates and rollers have to be laid down first, before the erection of the towers can be proceeded with. The same must be done on the abutments. First lay down the roller-plates, then put up the posts, chords, and transverse beams, so far as the masonry furnishes support. Also put up the anchor-plates, and secure these to the posts. It is also necessary to secure the stability of the ends of the trusses on the abutment still further by temporary wooden and iron braces. Great security will be obtained from the lateral wire-rope braces, when put up and screwed tight.

A temporary anchorage will now have to be prepared for the purpose of meeting the strains caused by the cables. The wire-ropes provided for the storm-cables may be used for this purpose.

By making an excavation about 10 ft. deep and 25 ft. long by 25 ft. wide, and driving a few piles in front, using some of the 12-in. iron beams, railroad bars, timber, and stone, a temporary anchorage may be made, which will safely resist a strain of 500 tons.

In order to have the means of regulating the tension of the temporary anchor-cables, and to provide, to a certain extent, for contraction and expansion while engaged in raising, it will be advisable to deflect the anchor-cables a few feet, and anchor them in the centre between the anchorage and abutment to another temporary anchorage, by means of long screw-bolts and stirrups, or by block and tackle. This will afford the means of allowing the anchor-plates to

move forward towards the river just enough to close the arches and chords. Allowance must also be made for stretching the cables.

We have now proceeded far enough to take across the river two of the smaller cables or ropes which are to form parts of the large cables. An easy mode of accomplishing this will be to remove the reel which contains one coil of wire-rope upon the deck of a flat boat or barge, and to mount it upon a strong, well-secured frame, on a spindle which rests on bearings, and is allowed to revolve. Now provide one or two brakes to check and regulate the speed of the revolving reel, and employ a tug to tow the barge across the river, either above or below the line of piers.

The end of the rope should of course be first secured to one of the anchor-plates before starting. On crossing the river, the rope is simply dropped upon its bed. The other end being landed, is now temporarily secured to its anchor-plate, and preparations are made to hook up the rope at the centre piers, and to raise it to the top of the towers. Here it is rested on temporary timber-blocks, which serve as saddles, and are secured alongside of the cast-iron saddles.

After two wire-ropes have been taken across and suspended, their deflection must be adjusted, and they are then further secured to the middle towers by screw-clamps and bolts, to prevent their slipping. The object of these temporary suspension-cables being to facilitate the construction of the main cables, it is advisable to deflect them about 2 to 3 ft. *below* the main cables, so that they will run nearly parallel to them. This being done, light timber-beams or scantling, say 24 ft. long, may be thrown across the two opposite ropes, and lashed to them *from below* by hemp lines at distances of about 4 to 5 ft. apart. This process should commence at the two middle towers, and should be carried on both ways, so that the spans will be equally weighted, and their equilibrium maintained. Planks are pushed forward over the beams and secured by lashings, so that two foot-walks are formed, each about 4 ft. wide, in line of the main cables and underneath. Where these walks are very steep, the planks may be cleated, to secure a better foothold.

Two footways have now been put up, extending across the river from one abutment to the other. To facilitate the crossing of men not used to high elevations, two small wire-ropes $\frac{1}{4}$ to $\frac{3}{8}$ in. diameter may be suspended just above the position of the main cables, and connected laterally every 50 ft. by smaller cords. The men will take hold of these ropes while crossing, and use them as hand-rails.

This being accomplished, we are now enabled to go from pier to pier and to perform work independent of the river. As the stays are placed in the bottom of the saddle, they must be raised first and put in place, allowing their ends to hang down the piers. This being done, the first permanent cable-rope may now be fastened to its anchor-plate at one end, then taken across the river and run off the reel in the same manner as before. These ropes are to be dropped upon the bed of the river, either above or below the piers, always on the side of their respective towers. Whenever a rope has thus been run off, it must be raised and placed upon the saddles before another one is launched on the bed of the river. It is also necessary that each rope should be properly placed and its deflection adjusted correctly before the next one is taken up.

The section of a saddle on Fig. 1437 exhibits plainly the different layers of rope. First, there are four laid down in the bottom, forming the first row; then one is added at each end in the second row. These six ropes are the stays. Next come the three ropes which compose the first or lowest layer in the cable; this is followed by a second row of four ropes; next comes the centre layer of five ropes; next, a layer of four ropes, and then the top layer of three ropes; the whole number of 19, which are in a cable, forming the section of a regular hexagon.

It is all-important that the five different layers should preserve their stratification and their proper level throughout the whole length of cable. To facilitate this operation, strips of canvas or strong cotton sheeting, say 3 in. wide, may be wrapped around each layer, and afterward again removed. Whenever a rope is added, it should be secured at various points by ties of fine annealed wire. The best plan, however, is to introduce short strips of tin, Fig. 1456, which cross each other diagonally, the whole being kept together by temporary wire or hemp strings. After all the 19 ropes have thus been suspended, adjusted, and collected into one cable, strong temporary wire-bands, made of No. 10 annealed wire, must be put around every 10 or 15 ft.; which operation will be greatly facilitated by using iron screw-clamps made in two halves, and fitting the section of the cable.

Referring to Figs. 1436, 1437, we notice that the lattice-beams which connect the opposite saddles of each tower may be omitted for the present, and that the two ropes for the footwalks may be supported on the cross-beams next below the lattice, which will be about the right elevation for cable-making.

It was remarked that the two ropes suspended temporarily for footwalks are to be laid into the main cables *eventually*. This method is recommended for the sake of economy. But if some more wire-rope is on hand, strong enough for that purpose, then it will be better not to make temporary use of the permanent cable-ropes. It is supposed, however, that there is no spare rope on hand, and in that case two of the cable-ropes are to be suspended for footwalks, one on each side. Now, after the other 18 ropes have been raised and adjusted in each main cable, the cross-beams which support the foot-plank may be suspended to the main cables by simply throwing small manilla ropes over in such a manner that they can be easily removed. This being done with all the beams, the two wire-ropes which supported the foot-planks are now free and may be raised into the saddles, adjusted to their proper levels in the various spans, and both ends secured. After this is done, the manilla suspenders over the main cables are now lifted, one after another, and thrown over the last wire-rope, and again fastened to their respective beams. The cables are now ready for the permanent suspenders and straps. The latter are heated at one corner, so that they may be readily closed and screwed up tight. To prevent injury to the cable, a piece of sheet iron is laid around it: the strap is then closed and cooled off with water. A small hand-forge may be moved along on the suspended scaffolding for that purpose.

1456.

It will be a somewhat difficult task for those not experienced in the construction of wire-cable bridges, to get the cable straps and suspenders properly spaced.

Measurements from the towers being uncertain and the cables movable, no satisfactory adjustment can be effected in this way. But, either by calculation or actual suspension, or both, measure off the actual distances upon a small wire-cord, or upon a single wire. These distances in the suspended cable form the hypotenuses of right-angled triangles, the horizontal base of which is a *constant*, equal to the horizontal distance of the suspenders. The vertical is variable, and is equal to the difference of the lengths of the two adjoining suspenders. These triangles may all be laid off on one board, and the length of the hypotenuses transferred upon the wire-cord and marked by small wrappings made of fine wire, so that they cannot be shifted. This wire line is then suspended alongside of the centre of the cable, and whitelead marks are put upon the latter, which will correspond to the centre of the suspended ropes.

These measurements and marks being correctly made, there will be no further difficulty in spacing the suspenders correctly; their length will come out nearly correct, and the beams suspended to them will be found equally spaced.

The main cables being completed, they should be further secured in their saddles by bolting down those cushions which are to prevent their slipping. A temporary platform must next be suspended below the level of the lower chords, strong enough to support 1 ton a foot lineal. The suspenders being 10 ft. apart, timber-beams 24 ft. long, about 8 x 14, may be suspended to them by means of temporary stirrups, so made that the level may be adjusted. A plank-walk about 5 ft. wide should then be laid down under each cable. The next step is to lay down upon these plank-walks the channel-bars which are to form the lower chords. Care must be had to distribute those bars evenly and uniformly on each side of a pier, and in all the spans at the same time, so that the equilibrium of the cables is not much disturbed. This distribution being properly made, the bars may be connected by bolts temporarily, and partly spliced, but so that the posts can afterward be set up between.

In order to add to the weight of the platform, and increase its stability, the truss-posts should now be distributed uniformly, and laid down alongside of the chords, all over the work. It may also be the proper time to make use of the main-stays, and to attach their ends temporarily to the lower chords, and to the platform. When up, they will not only add to the supporting power, but also to the steadiness of the platform. The whole process of erection will be much facilitated by a narrow track, laid down in the centre of the platform between the two walks, for the support of a few small trucks, on which the bars may be transported from both abutments. With a favourable stage of water in the river, the delivery of materials may also be forwarded by boats moored at the piers and hoisting the bars up, then distributing on trucks.

The work has now so far progressed that we may proceed to put up the posts. There are several methods by which this may be accomplished. One plan is to proceed from the centre piers each way toward the main span and the side spans uniformly at the same time. As soon as one or two sets of posts are up, connect them by the upper chords, and also secure the latter by transverse beams and temporary wooden braces. Next, put in place the panel-rods, which will increase the stiffness of the framing considerably.

While this process of building out from the piers is going on, the level of the platform must be maintained at the same time, by distributing the bars for the posts and chords all along. The weights being uniformly distributed, the level will be preserved, and the steadiness of the platform will also be increased. A few small wire-ropes may likewise be applied below the platform, fastened to the masonry of the piers, to serve as storm-cables, in case of a heavy blow. Before commencing with the arches, the posts and upper chords may be put up through the balance of the spans, the panel-rods put in, the cross-connections made, and the trusses nearly completed.

Changes of temperature, causing expansion and contraction, may be accommodated by placing the lower chords on wooden rollers about 6 in. diameter.

Slight changes will not be noticed; but should great changes take place, and produce considerable contractions and expansions, it will be good policy to provide slip-joints in the chords as well as the arches at various points, and use a few temporary splicing-plates to that effect, or timbers bolted on sideways. No rigid connection should be made at any place: no riveting before the whole structure is up.

It was remarked that the whole superstructure may be put up and completed without the assistance of scaffolding. This can be done, if absolutely necessary. We therefore propose to scaffold one of the side spans, or both, leaving the central span open for navigation. This being done, we may put up the arches in the two side spans, and also put up one transverse iron beam every 20 ft., to give a good, permanent lateral connection to the lower floor. By the completion of the arches of the side spans, the resistance of the anchor-plates will have been much increased.

One half of the bents under the side spans may now be removed with safety, and put under the spring of the arches in the central opening; and as much material may also be distributed over the platform of the central span as will be necessary to balance the side spans. By this distribution we shall maintain the equilibrium of the cables. The thrust of the arches in the side spans will be fully met by the lower chords, which should be completed; so that it may be safe to remove all the bents from under the side spans and put them up in the centre opening. This being done, the closing of the arches in the centre is now to be accomplished, and the trusses may be sufficiently completed to render a further support by scaffolding unnecessary.

If, during the process of erection, a sudden flood should occur, or floating masses of ice endanger the safety of the scaffoldings, the latter should be watched day and night, and cut loose if necessary. This may cause some delay, but no further damage.

If the spring of the arches descends below the lower chords, the raising of the superstructure will be easier; and this plan should always be adopted if possible.

Statement of the Strains in the different members of a Trussed Girder Bridge of 300 ft. span in the clear.—This iron truss alone weighs 0.85 ton a ft., and is proportioned to sustain its own weight

PANELS.

[illegible]

and a moving load of 1100 lbs. The wire cables support a moving load of only 1900 lbs. a ft., Fig. 1457. Tension allowed in iron is 5 tons the sq. in. The compression allowed is 4 tons the sq. in. Panel = 18'.

In the foregoing estimate, we have taken the weight on the bridge at 1.4 ton a ft. run. The weight of the structure itself is $\frac{260.1}{306} = 0.85$ ton a ft. run. The bridge will therefore support, in addition, a moving load of $1.4 - 0.85 = 0.55$ ton, or 1100 lbs. a ft. run.

	lbs. a ft.
Moving load	1900
Top plate	490
Cable	123
Suspender	28

Total weight supported by cables .. 2541

Total weight for whole bridge = $2541 \text{ lbs.} \times 306' = 777,546 \text{ lbs.} = \dots \dots \dots 388.77$
 Tension in cable, $1.58 \times 388.77 \text{ tons} = \dots \dots \dots 614.25$
 Compression, Fig. 1458, in upper chord due to the cable = $1.5 \times 388.77 \text{ tons} = 583.16$

The cable being much smaller in this example than in the previous one, each will consist of only seven ropes: and taking the maximum tension allowed as before, at 5 tons a pound a ft., we have the strength of one rope = $\frac{614.25}{14} = 43.88$ tons; and the weight a ft. of such a rope is $\frac{43.88}{5} = 8.78$ lbs. The diameter of this rope is $2\frac{5}{16}$ in., and the diameter of one cable 7 in.

Compression.—The section required in the top plate is $\frac{583.16}{4} = 145.79$ sq. in. Weight a ft. = $145.79 \times 3.36 = 490$ lbs.

Some of this weight will be thrown upon the channel-bars, as in the previous case.

The heaviest section of channel-bar is 56 sq. in., equal to 142 lbs. a yard.

The section required for one top plate is $\frac{145.79}{2} = 72.895$. Hence we have left for the top plate $72.895 - 56 = 16.895$ sq. in.

In order to keep the channel-bars of a uniform section throughout, we will add to this top plate the varying sections of upper chord, required by the structure alone, in the calculation above. The following Table shows how this is done; the sixth line gives the number of sq. in. of section required in the top plate in each panel.

TABLE OF SECTIONAL AREA OF TOP PLATE IN EACH PANEL.

Number of Panels,	0	1	2	3	4	5	6	7	8
Total section of one top plate	72.895	72.895	72.895	72.895	72.895	72.895	72.895	72.895	72.895

Recapitulation of whole Weight.

Tie-rods, counter-rods, posts, upper and lower chords on one side	lbs.	144,927
Additional weight on one side		93,836
Extra items		21,337
Weight of top plate on one side, $72 \cdot 895$ sq. in. $\times 3 \cdot 36$ lbs. = 245 lbs.,	}	74,970
and $245 \times 306 =$		
Cable = $8 \cdot 78$ lbs. $\times 7 = 61 \cdot 5 \times 312$ ft. =		19,188
Suspenders = $14 \times 306 =$		4,284
One-half weight of whole structure		358,542 lbs.
Total weight of the entire structure		358,542 tons.

$$\text{Weight a foot} = \frac{358,542}{306} = 1.171 \text{ ton.}$$

Statement of the Strains in the different members of a Trussed Girder Bridge of 300 ft. span in the clear.—The iron truss alone weighs 0.62 ton a foot, and is proportioned to sustain only its own weight, while the moving load of 3000 lbs. a foot is supported by wire cables, Fig. 1459.

The tension allowed in iron is 5 tons to a sq. in. The compression allowed is 4 tons to the sq. in. Length of one panel = 18 in.

In the foregoing estimate we took the weight of the bridge at 0.62 ton a foot run. This agrees with the result here obtained, since $0.62 \times 306 = 189.72$ tons.

Let us now put in a pair of steel cables to support, 1st, the moving load; 2nd, the weight of the top plate required to resist the compression due to the cable; and, 3rd, the weight of the cables and of the suspenders.

Moving load	lbs.	3000
Top plate		771
Cable		193
Suspenders		36

Total weight on cables a foot run .. 4000

Total weight for whole bridge, $4000 \times 306 =$	Tons.	612
Tension in cable = 1.58×612 tons =		967
Compression in upper chord due to cable = 1.5×612 tons =		918

The ultimate strength of good steel cables is 25 tons a lb. the foot, which is equivalent to 176,000 lbs. a sq. in. solid wire-section; the maximum tension allowed is 5 tons a lb. to the foot. We have two cables, one on each side, each containing nineteen wire-ropes. Hence the strength of one rope is $\frac{967}{38} = 25.45$ tons; and the weight a foot of such a rope is $\frac{25.45}{5} = 5.09$ lbs. a foot.

The diameter of this rope is 1.7 in., and the diameter of one cable of nineteen ropes is $\frac{3}{4}$ in.

Compression.—The section required in the top plate is $\frac{918}{4} = 229.5$. Weight a foot = $229.5 \times 3.36 = 771.0$ lbs.

In place of putting all this section into a plate, it is better to divide it by increasing the section of the channel-bars in the upper chord somewhat; especially since the sections of channel-bars obtained in the calculation above were so small that they could not be executed in practice. Let us increase the sections of the four channels in one upper chord to 56 sq. in., which is equal to 142 lbs. a yard for each channel-bar, the heaviest section rolled. The section required for one top plate is $\frac{229.5}{2} = 114.75$ sq. in. Hence we have left for the top plate $114.75 - 56 = 58.75$ sq. in.

In order to keep the channel-bars of a uniform section throughout, we will also add to this top plate the varying sections of upper chord, required by the structure alone, in the calculation

One-half weight of whole structure 343,364 lbs.

Total weight of the entire structure 343.36 tons.

$$\text{Weight per foot} = \frac{343.36}{306} = 1.122 \text{ ton.}$$

For further particulars respecting this system, the reader is referred to Roebling's large work, published by D. Van Nostrand, N.Y.

Oblique Bridges are bridges in which the axis of the arch meets the supports in an oblique direction. Railways have much necessity for this kind of bridges, because the survey frequently makes it necessary to carry the track over a road or a canal, which it intersects at an angle more or less acute. From obvious economical considerations, only the leading arches and courses of the springers are constructed of hewn stone; the body of the arch is formed of materials of a weaker description, often of bricks. These considerations have led engineers to the conception of a plan appropriate to this kind of construction. Three principal systems are at present in use in the construction of *oblique bridges*: the helicoidal arrangement, which was originated in England; the orthogonal arrangement, invented in France; and that of upright arches *en retraite*, a very ancient system lately brought into use. In each of the two first systems, the arch is semicircular, and it is the mode of its subdivision into voussoirs which distinguishes it from ordinary semicircular arches.

The Helicoidal Arrangement.—This is so named from the fact that the edges of the inward arch are spirals, and the bed-joints, as well as the upright joints, are helicoidal surfaces of square-threaded screws. This arrangement is determined in the following manner:—Let EK and FJ, Fig. 1464, be the spring lines of the intrados, DH and GL those of the extrados; HL and DG the horizontal draughts of the principal planes; let E'V'F' and K'V'J' be the vertical projections of the intersections of these principal planes with the intrados; let D'C'B'G' be the projection of the intersection of the extrados on the plane DG; finally, let *abcd* and *ABCD* be the upright sections of the intrados and extrados, developed upon the plane of the spring, which is here the horizontal plane. We will suppose these upright sections to be circles, and commence by constructing at *aββ'a'* the development of the intrados: we draw the chords *aβ* and *a'β'*, dividing them into the same number of equal parts, at the points 1, 2, 3, and so on; 1', 2', 3', and so on. We join any one point of division of *a'β'* with a point of division of *aβ*, so chosen that the line of junction differs as little as possible from a perpendicular common to the two chords *aβ* and *a'β'*. We see here, for example, that to fulfil these conditions it is necessary to join the point 4' to the point 7; in the same way the point 3' to the point 6, the point 2' to the point 5, and so on; the point 5' to the point 8, and so on with the rest. We shall thus obtain a series of parallel and equidistant right lines. The number of the divisions of *aβ* or *a'β'* should be regulated in such a manner that the distance of two consecutive parallels should be equal to the thickness of the materials which are intended to be used for the body of the arch, or should only slightly exceed that thickness. If we imagine the figure *aββ'a'* to be applied upon the cylinder of the intrados, the parallels in question will become spiral parallels. These are the spirals which are taken as a guide for the edges of the inward arch. We obtain the projections of these spirals in the following manner:—If from the points of division of *aβ* and *a'β'*, which occupy the same level, we draw right lines, they will be parallel to the axis OO' of the arch, and will be nothing more or less than the generatrices of the intrados. To obtain the projections of these generating lines, we must divide the half-circumference *abcd* into as many equal parts as *aβ*; and from the points of division

draw parallels to OO' ; these are the horizontal projections of the generating lines. From the points where these projections meet the right line EF , we draw perpendiculars to the base line XY ; the points where these perpendiculars meet the semi-ellipse $E'V'F'$ will belong to the vertical projections of the corresponding generatrices; and, by drawing from these last points lines

1464.

parallel to XY , we shall have the vertical projections themselves. This being understood, if we wish to obtain, for example, the horizontal projection of the generating line $4'7'$, we mark the points $\epsilon, \phi, \theta, \zeta$, where it meets successively the leading curve $a\beta$, the generatrix $6'6'$, the generatrix $5'5'$, and the leading curve $a'\beta'$; from these points we draw lines perpendicular to OO' , ending respectively on the right line EF , the horizontal projection of the generatrix $6'6'$, on that of the generatrix $5'5'$, finally on the right line KJ ; we shall thus obtain four points, $\epsilon, \phi, \theta, \zeta$, of the required projection, and it will be easy to trace this projection. In the same manner, the horizontal projection of the other spirals will be obtained: they are marked in dark lines in the quadrilateral $EFJK$. To obtain the vertical projection of a spiral, it is necessary to mark the points where its horizontal projection meets the horizontal projections of the different generatrices of the cylinder, and from these points to draw lines perpendicular to the base line, until they meet the vertical projections of the same generatrices; we thus obtain the curves $c'h, b'l$, and so on.

Spiral surfaces with a square-threaded twist are taken for the bed-joints; that is, each of these joints is governed by a right line subject to remain parallel to the plane of the upright section of the cylinder, and to rest constantly upon the axis OO' of this cylinder, and upon the spiral which forms the edge of the inner arch corresponding to the joint under consideration. Before going further, it is necessary to determine the intersection of these spiral joints with the leading planes. The intersection of a spiral surface with a plane may be constructed by the ordinary methods of descriptive geometry. Let us suppose that the vertical line OI , Fig. 1465, is the axis of the surface; and that the directing spiral has for its horizontal projection the circumference $O A$, and for its vertical projection the sinusoid $A B' A' \dots$; and let PQ be the vertical tracing of the intersecting plane, supposed to be perpendicular to the vertical plane of projection. Draw any auxiliary horizontal plane KH ; this auxiliary plane will intersect the helicoidal surface according to a horizontal line which is projected vertically upon KH , and horizontally according to a radius ON , which will be determined by the condition that the arc ADN shall be to the entire circumference in the

1465.

ratio of AH to the space AA' . The same auxiliary plane will intersect the plane PQ , according to a line perpendicular to the vertical plane, which is projected vertically according to the point M' , and horizontally, according to a line mM , perpendicular to the base line. The point M, M' , belonging at the same time to the generatrix $I H_1 O N_2$, and to the intersection of the auxiliary and the intersecting planes, is a point of the intersection of the plane PQ with the helicoidal surface. We can obtain in the same manner as many points of this intersection as may be desired. For facility of working, it will be convenient to divide the circumference AB and the space AA' into the same number of equal parts starting from the point A , the points of division of the same level will give the radius analogous to ON , and the horizontal plane analogous to KH , which will determine one point of the desired line. Having the projections of the required intersection, we can obtain it in its true dimensions by describing the plane PQ around its vertical tracing.

To solve the same problem, we can also employ calculation. If we take for the axis of z the axis OI of the surface, for axis of x the direction of the radius OA , and for axis of y a perpendicular radius, designating by h the space AA' of the directing spiral, we shall have for equation of the helicoidal surface,

$$z = \frac{h}{2\pi} \arctan \frac{y}{x}. \quad [1]$$

If α designates the angle of PQ with the axis of x , and b the distance oc , we shall have for equation of the intersecting plane,

$$z = x \tan. \alpha + b. \quad [2]$$

Eliminating z from these two equations, we obtain the equation of the projection of the desired intersection upon the plane of xy ; that is, $\frac{h}{2\pi} \arctan \frac{y}{x} = x \tan. \alpha + b$, whence

$$y = x \tan. \frac{2\pi}{h} (x \tan. \alpha + b), \quad [3]$$

which curve we can construct by points. The intersection of the dividing plane with the vertical cylinder, which has this curve for its base, will be the intersection of the same dividing plane with the helicoid surface.

Whichever of the two methods we employ, we shall find that the curve which has for its equation the relation [3], has a form analogous to that indicated in Fig. 1466. It is composed of two branches which have a common asymptote $\alpha\alpha$, and two other asymptotes, belonging one to each, $\beta\beta, \gamma\gamma$, all three parallel to the axis of y . Other branches and other asymptotes may be obtained by paying attention to the undefined part of the helicoidal surface, which is extended outside the cylinder, whose base is the circle ADB ; but this consideration is of no value in the question with which we are occupied. If we imagine a vertical cylinder, having for its base the two-branched curve of Fig. 1466, we have seen that its intersection by the cutting plane PQ , Fig. 1465, will be at the same time the intersection of this plane with the helicoidal surface. This intersection will evidently have a form analogous to the curve in 1466.

For each helicoidal joint it would be necessary to construct an analogous curve, if it were desired to have exactly its intersection with the leading plane. But when the upright section of the arch has a great radius, as is often the case, the intersections of the joints with the leading plane have only a slight curvature, and may, without any appreciable error, be considered as right lines; we can then, in the construction of these lines, profit by a remarkable property of these curves. If from points, such as b' and c' , Fig. 1464, where the intersections of the helicoidal joints with the leading plane meet the curve of the intrados $E'E', c', b', F'$, we draw tangents to these intersections, all these tangents will come together at one point I' , situated upon the vertical line of the centre O' . Let us now consider the equation [3]; taking the differentials of the two terms,

$$\text{we obtain } y' = \tan. \frac{2\pi}{h} (x \tan. \alpha + b) + \frac{x \delta \frac{2\pi}{h} \tan. \alpha}{\cos.^2 \frac{2\pi}{h} (x \tan. \alpha + b)}.$$

Now the ordinate Y of the point, where the tangent of this curve meets the axis of y , has for its equivalent $y - y'x$; substituting for y and y' their equivalents, and reducing, we obtain

$$Y = \frac{2\pi \tan. \alpha}{h} \frac{x^2}{\cos.^2 \frac{2\pi}{h} (x \tan. \alpha + b)}.$$

But the equation of the curve gives $\tan. \frac{2\pi}{h} (x \tan. \alpha + b) = \frac{y}{x}$, whence we get

$$\cos.^2 \frac{2\pi}{h} (x \tan. \alpha + b) = \frac{x^2}{x^2 + y^2}.$$

Substituting for Y , it follows that $Y = \frac{2\pi \tan. \alpha}{h} (x^2 + y^2).$

If we consider in particular the point of the curve which is on the circumference $O A$, Fig. 1460, the radius of which we represent by r , we may write

$$Y = \frac{2\pi \tan. \alpha}{h} r^2, \quad [4]$$

which expression is independent of b ; that is to say, the distance Y would remain the same if we transposed the intersecting plane PQ in a direction parallel to itself, or, what amounts to the same, if we caused the helicoidal surface to revolve in a direction parallel to its axis. Let us observe now, that all the right lines, which on being described round the cylinder of the intrados, have become the edges of the inner arch, being parallel right lines; these edges of the inner arch are equal spirals. The surfaces of the joints which have these spirals as directing lines are then equal themselves; and they can be made to coincide by causing them to revolve sufficiently in a direction parallel to the axis of the intrados. It follows from this that in place of cutting all the surfaces of the joints by the leading plane, we should obtain the same intersections by cutting only one of them by planes parallel to the leading plane situated at convenient distances from this leading plane. The projections of the curves of intersection upon the plane of the upright section will then also be the same, that is, that to obtain them it is sufficient properly to vary b in the equation [3]. But the distance Y is independent of b ; hence, if from the points where the different curves which are projections of the intersections of the surfaces of the joints by the leading plane, meet the circumference abd , Fig. 1464, we draw tangents to those curves, they will come together at a point I , situated on the axis $O O'$ at a distance from the centre indicated by the expression of Y . But we know that the projection of the tangent of a curve is itself a tangent of the projection of this curve. If then the lines Bb , Cc , and so on, Fig. 1464, are the projections of the lines $B'b'$, $C'c'$, and so on, upon the plane of the upright section, the tangents at b , c , and so on, are the projections of the tangents at b' , c' , and so on. Now the tangents at b , c , and so on, come together at one point I , then the projecting planes of which these tangents are the tracings, and which are all parallel to the axis $O O'$, intersect in the direction of a line parallel to this axis passing through the point I . This parallel line meets the leading plane at a point of the vertical of the point O , which is projected at I' to a distance from O'' equal to $O_1 I$; finally, then, the tangents of the points b' , c' , and so on, all meet together at the point I' .

The distance $O'' I'$, or, in absolute value, Y , is easily constructed. From the centre O of the upright section we draw a line parallel to the tracing EF of the leading plane, until it meets at T with the prolongation aF of the line of the spring; and from the point T we draw TZ parallel to the right lines $4'7$, or $3'6$, and so on, which are the development of the edges of the inner arch; aZ will be the desired distance. We have already called α the angle GDA which the leading plane makes with the axis of the intrados; let us now call i the angle ATZ , equal to the angle $\alpha a'3$ which the developed spiral makes with a line parallel to the axis; there results from this, $\tan. i = \frac{2\pi r}{h}$. Now the triangle $O_1 T a$ gives $T a = O_1 a \tan. \alpha = r \tan. \alpha$, and the triangle

$T a z$ gives $aZ = T a \tan. i = r \tan. \alpha \tan. i = r \tan. \alpha \frac{2\pi r}{h}$, a quantity which is equal to Y in absolute value.

The application of this property to the purpose we are considering is easily made; join the points b' , c' , and so on, to the point I' ; the prolongations $B'b'$, $C'c'$, and so on, of the lines of junction will be the tangents at b' , c' , and so on, to the intersections of the surfaces of the joints by the leading planes, and may be taken for these intersections themselves under ordinary circumstances where these curves have only an inappreciable curvature.

To determine the upright joints, draw right lines such as $\mu\nu$, Fig. 1464, perpendicular to the right lines $\rho a'$, $\sigma\gamma$, and so on, which are the development of the edges of the inner arch. Only a few of these perpendiculars are marked on the sketch. When the figure $a\beta\beta'a'$ is applied to the cylinder of the intrados, the perpendicular in question become arcs of spirals, such as that which is projected at $m n$, normal to the edges of the inner arch. Helicoidal surfaces with a square threaded twist having these spirals for directrices are taken for the upright joints. The arch is thus divided into voussoirs by surfaces normal to the inner arch and perpendicular to one another, which is the essential condition of the arrangement of an arch. To obtain an intermediate point of the spiral projected at $m n$, we take an intermediate point upon the right line $\mu\nu$, for example, that which is found upon the generatrix $3'3'$; drawing from this point a line perpendicular to $O O'$ until we meet with the horizontal projection of the generatrix corresponding to $3'3$, we shall have the horizontal projection of the desired point. To get the vertical projections corresponding to m and n , it will be sufficient to draw from these points, perpendiculars to the base line until we meet at m' and n' with the lines $c'k$ and $b'l$, vertical projections of the generatrices, of which $r m$ and $s n$ are the horizontal projections. As to the intermediate point between m and n , we shall draw from this point a line perpendicular to $A D$, and one perpendicular to $X Y$; taking that portion of the former which is comprised between $A D$ and the circle $abcd$, we shall carry it on to the second starting from $X Y$; we shall thus have an intermediate point upon the projection $m'n'$. We may proceed in the same manner for the other upright joints. We have at $\mu\nu\sigma\rho$ the development of the panel of the inner arch corresponding to that portion of the intrados comprised between the joint $m n$ and the leading plane. The surfaces of the joints cut the extrados in the direction of spirals having respectively the same space; and this consideration affords the means of obtaining the development of the panel of the extrados which corresponds to the panel $\mu\nu\sigma\rho$ of the intrados. In fact, the two bed-joints and the upright joint which form the limits of the voussoir corresponding to $m n s r$, are cut according to two right lines starting from the points m, m' , and n, n' , which, being the generatrices of the two bed-joints, are parallel to the upright section of the intrados and meet the axis $O O'$. These horizontal projections will then be directed

according to lines perpendicular to OO' drawn from the points m and n ; and if we develop the extrados, the points where the surface is met by the said generatrices will fall at M and N situated upon the prolongation of the right lines $m\mu$ and $n\nu$. On the other hand, if AU is the development of the leading arc of the extrados, supposed to be obtained in the same manner as for the intrados, the point projected at C' will fall at R , and the point projected at B' will fall at S . The spirals of the extrados which pass through these two points having the same space as those of the intrados which pass through the points ρ and σ , will give, on development, right lines which will meet together at the same points of the line of aL , starting from which we effected the two developments; that is to say, the spiral corresponding to the point R will give the right line Ra' , which converges with ρa to the same point a' ; and the spiral corresponding to the point S will give the right line $S\sigma'$, which converges with $\sigma\sigma'$ to the same point σ' of the line aL . These right lines Ra' and $S\sigma'$ will determine the points M and N ; and we shall have at $MNSR$ the development of the panel of the extrados corresponding to the panel $\mu\nu\sigma\rho$ of the intrados.

Before proceeding to cut the voussoir, it is still necessary to effect its projection on the plane of the right section. For this, draw from the points m and n perpendiculars to AD until they meet the circumference $abcd$ at m_1 and n_1 ; then from the centre O , take the radii m_1M_1 , and n_1N_1 ; these will be the projections of the generatrices of joints which pass along the points m' , m' , and n' , n' . We have already the right lines Bb and Cc which concur at the point I , the projection of the voussoir under consideration will be comprised between the right lines Bb and M_1n_1 . To apply the draught upon stone, prepare a prism having for its base the curvilinear quadrilateral Bbm_1M , and for its height the distance of the points r and n computed parallel to OO' . After having marked upon the two bases the points $b, c, m_1, n_1, B, C, M_1, N_1$, join the corresponding points by right line, which will be the generatrices of the cylinders of the intrados and the extrados. Upon the concave cylindrical surface apply the flexible panel $\mu\nu\sigma\rho$ in such a way that the point ν falls at n_1 , upon one of the bases, the point ρ at c upon the other base, the point σ upon the generatrix starting from b , and the point μ upon the generatrix starting from m_1 . Apply upon the convex cylindrical surface the flexible panel $MNSR$, in such a way that the point N falls at N_1 , upon one of the bases, the point R at C upon the other base, the point S upon the generatrix starting from B , and the point M upon the generatrix starting from M_1 . By the help of these two panels trace spirals answering to the right lines $\mu\rho, \nu\sigma, \mu\nu, MR, NS, MN$, and the elliptical arcs corresponding to the curves $\rho\sigma$ and RS . These two last arcs will determine the plane of the heading face, and allow the face to be cut. As for the spiral joints, they will be cut by using a rule passing along points of reference marked out previously upon the right lines $\mu\rho$ and MR , upon the right lines $\mu\rho$ and NS , and upon the right lines $\mu\nu$ and MN . These points of reference are obtained easily by dividing into the same number of equal parts the right corresponding lines upon which they have to be marked. In the same way all the voussoirs belonging to the leading arcs may be cut.

Supposing the arch to be entirely constructed of ashlar work, all the longitudinal voussoirs might be cut in the same manner. They could also be obtained by a method exactly similar to that used in shaping the stones for the helix of a corkscrew staircase. But more generally the body of the arch is constructed, as has been said, of materials of small dimension, for example, of bricks. The stones which compose this construction are then identical one with another, and to place them properly, spread upon the framework, which is to bear the arch for a time, a layer of plaster forming a cylinder equal to the intrados, upon this layer trace the spirals which form the edges of the inner arch; the distance from one to another is that of the thickness of the stones which are to be used; it only remains to place these latter in the intervals between the spirals, so that the face which is to form the inner arch coincides with the layer of plaster, and they are then united by cement.

Independently of the voussoirs belonging to the head arches, the upper course of the impostas, and the triangular voussoirs marked by the letter ω in Fig. 1459, named coussinets, are constructed of stone. These coussinets must be firmly fixed in order to resist the thrust of the layers which have a tendency to slip along the bed-joints, considerably inclined towards the springers. For this reason the coussinets are shaped so as to fit in with the stones of the upper course of the impostas. These coussinets have a concave-cylindrical face on the intrados, a convex-cylindrical face on the extrados, a spiral face making part of a bed-joint, and a spiral face forming an upright joint. They are shaped like the heading voussoirs, by means of panels of development of the faces of the intrados and extrados; the figures $a1''1$ and $A1''x$, Fig. 1464, represent these two developments for the first coussinet on the left.

The defect of the helicoidal arrangement lies in the tendency of certain courses to slip outwards: thus the course projected at $b'c'k'l$, Fig. 1464, has a tendency to slip towards the back of the arch. To avoid this defect, the helicoidal arrangement may be limited to that portion of the arch comprised between the leading plane and a neighbouring upright section. If, for example, AB and CD , Fig. 1467, represent the horizontal tracing of the leading planes, and MN and OP those of two neighbouring upright sections, the helicoidal arrangement may be employed only for the portions $ABNM$ and $CDPO$ of the arch, and the portion $MNPO$ be arranged as in an ordinary cylindrical arch. The courses which have a tendency to slip outwards, at C and at B , are thus suppressed, or at least reduced to the leading voussoirs. More especially in case the arch is intended to be of great length will it be useful to adopt this arrangement.

The helicoidal arrangement has also been charged with a tendency in the courses to become twisted when the framework is taken away and before the mortar has acquired a proper consistency. To remedy this, it has been proposed to replace the upright spiral joints by plane joints parallel

to the leading planes. But, on this supposition, it would be preferable to adopt the orthogonal arrangement.

The Orthogonal Arrangement.—A line meeting normally all the curves of a series is called their orthogonal trajectory. In the arrangement under consideration the upright joints are vertical planes parallel to the leading planes; these planes cut the intrados according to curves equal to the leading arcs, ellipses for instance; the edges of the soffits are the orthogonal trajectories of these equal curves, and the arrangement ought to be called the arrangement by orthogonal trajectories.

The projections of these trajectories are constructed in the following manner. Let A C and B D, Fig. 1468, be the spring lines of the arch; we shall take the plane of the spring for the horizontal plane of projection, and the leading plane A B for the vertical plane. To make it more clear, we shall suppose that, as is most frequently the case, the leading curves are circles. Let xx, yy, zz, uu , be the tracings of planes parallel to the leading planes, and which determine the upright joints; let 0, 1', 2', 3', 4', 5', be the centres of circles according to which the intrados of these planes with the intrados are projected. It will be noticed at the outset that each of the required trajectories is projected upon the vertical plane according to a curve which is itself an orthogonal trajectory of the circles whose centres are 0, 1', 2', 3', 4', 5'. For if we consider by itself one of the required trajectories, at the point where it meets one of the circles xx, yy , and so on, its tangent is perpendicular to the tangent of this circle, which is parallel to the vertical plane. Now, when a right angle has one of its sides parallel to one of the planes of projection, we know that it is projected upon this plane at a right angle; the tangent of the trajectory in question then is projected vertically according to the normal of the projection of the circle under consideration, and as we can say the same of all the analogous circles, it results that the projection of the trajectory meets all these circles normally, and that it is in consequence their orthogonal trajectory.

This trajectory of the circles 0, 1', 2', and so on, may be determined exactly by calculation. Any one of these circles has for its equation

$$(x - a)^2 + y^2 = R^2, \quad [5]$$

R designating the radius and a the abscissa of the circle, computed on X Y, starting from any part; for example, from the point A. It is demonstrable, by the differential calculus, that to obtain the orthogonal trajectory of a series of curves, we must state the equation

$$1 + y' \frac{dy}{dx} = 0, \quad [6]$$

in which y' represents the angular coefficient of the tangent to one of the proposed curves, and must eliminate from this proportion and the general equation of these curves, the variable parameter which belongs to each curve. From the equation [5] we obtain $y' = -\frac{x-d}{y}$, consequently we

should have $1 - \frac{(x-d)}{y} \frac{dy}{dx} = 0$; eliminating d from this proportion and the equation [5], and then integrating, we obtain for the equation of the required trajectory

$$x = \log, \frac{R - \sqrt{R^2 - y^2}}{y} + \frac{\sqrt{R^2 - y^2}}{R} + \text{const.} \quad [7]$$

We see that all the orthogonal trajectories of the circles 0, 1', 2', 3', and so on, are equal curves, and that having obtained one of them, we shall get all the others by causing the first to revolve parallel to the axis X Y. If, for example, we suppose the arbitrary constant = 0, we shall find for x and y the corresponding values stated in the following Table:—

Values of $\frac{y}{R}$		Values of $\frac{x}{R}$	
1	0.4	0.000	-0.649
0.9	0.3	-0.031	-0.918
0.8	0.2	-0.092	-1.310
0.7	0.1	-0.183	-1.993
0.6	0.0	-0.298	$-\infty$
0.5		-0.460	

These values correspond with a curve of the form indicated in Fig. 1469. If the sections parallel

to the leading planes were ellipses having for semi-axes a and b , we should likewise find for the equation of the orthogonal trajectory of their projections upon the vertical plane

$$x = \frac{b^2}{a} \left[\log' \frac{b - \sqrt{b^2 - y^2}}{y} + \frac{\sqrt{b^2 - y^2}}{b} \right] + \text{const.}$$

Instead of having recourse to calculation, we may construct the curve approximately by the property which serves for its definition. For example, let M' , Fig. 1468, be the first point from which we wish to draw an orthogonal trajectory of the circles $0, 1', 2', 3'$, and so on. If from the point M' we draw a right line in the direction of the point 0 , until it meets the circle $1'$; from the point of meeting, a right line in the direction of $1'$, until it meets the circle $2'$; from the new point of meeting, a right line in the direction of $2'$, until it meets the circle $3'$; and so on; we shall obtain a broken line $M' d$, which will differ less and less from the desired curve, in proportion as the sections xx, yy, zz , and so on, are nearer one to another. But it will be a little lower in position than this curve, because its successive sides are normal only to the circle which passes round their upper extremities. If on the contrary we join M' to the point $1'$, arresting the line of junction at the circle $1'$, and from the point of meeting draw a right line in the direction of the point $2'$, until it meets the circle $2'$, and so on, we shall have a second broken line $M' B$, which will also differ very little from the desired trajectory, but which will be a little higher in position, because its sides are normal only to the curve which passes round their lower extremities. If, then, we form a broken line $M' N'$, by joining the middle points of the arcs of the circles intercepted by the two lines $M'B$ and $M'd$, the line thus traced will differ still less than the two preceding from the curve we wish to obtain.

The projection $M' N'$ of the trajectory, which is to serve as the edge of the inner arch, being obtained by one of the above methods, we can easily deduce therefrom its horizontal projection; to do this, from the points at which $M' N'$ meets the circles $0, 1', 2', 3', 4', 5'$, we let fall perpendiculars to the base line, terminated at the right lines $A B, xx, yy, zz, uu, C D$, horizontal projections of these circles; and joining by a continuous curve the points thus determined, we shall have the projection $M N$ of the trajectory upon the horizontal plane.

We take for the bed-joint corresponding with each edge of the inner arch the left surface formed by the normals to the intrados drawn from the different parts of this line. To obtain the normal to the intrados at any point of the trajectory $M N, M' N'$,—at the point P, P' , for example,—it will be observed that this normal is perpendicular to the tangent of the circle xx ; and as the latter is perpendicular to the vertical plane, the normal, for the reason already given, will be projected vertically according to a perpendicular to the tangent at P' of the circle $1'$; that is, according to the normal $P' Q'$ to this circle. Besides, the normal to the intrados being included in the plane of the upright section, it will be projected horizontally upon the horizontal tracing of this section, that is to say, perpendicularly to the axis of the arch, or according to $P Q$ perpendicular to $A C$. We proceed in the same way for all the other normals; the bed-joint is then determined by its rectilinear generatrices.

It is necessary to determine its intersection with the extrados. Let $D H E$ be the upright section of the intrados, and $F G$ that of the extrados, brought down upon the horizontal plane. To get the point of junction of the normal $P Q, P' Q'$, with the extrados, we first draw from the point P a parallel to the axis of the arch, until it meets at p with the section $E H D$; then, after having determined the horizontal tracing I of the normal, we project it at i upon $D E$; next joining $i p$, we shall have the projection of the normal upon the plane of the right section; prolonging this until it meets at q the curve of the extrados $F G$; draw from the point q a perpendicular to $D E$, which will determine the point Q ; then a perpendicular to $X Y$, which will determine the point Q' . Proceeding in the same manner for the other normals, we shall obtain the projections of the intersections of the bed-joint in relation to the surface of the extrados; and the same for the other bed-joints.

Develop, by the ordinary methods, the surface of the intrados and the surface of the extrados with the curves there traced; and we shall have the developments of the panels of the inner arch, and the corresponding panels of the extrados.

Supposing the arch entirely constructed of ashlar work, each voussoir would be shaped by a method analogous to that explained in treating of the helicoidal arrangement. The four normals which form the angles of the voussoir having been projected upon the plane of the right section, we have the projection of the voussoir upon this plane. Upon this projection is constructed an upright prism, having for height the distance of the two plane joints; for example, the distance of the right lines xx and yy . Upon the concave face of the cylinder we apply the panel of the inner arch, and upon the convex face the corresponding panel of the extrados; the two left joints will be shaped by aid of a rule extended along guiding points marked out beforehand upon each edge of the inner arch, and upon the curved edge which corresponds to the extrados. But more generally, the body of the arch being constructed of rough stones, or of bricks, a layer of plaster is prepared coinciding with the intrados; upon this layer is traced, by the aid of the development of the intrados, the orthogonal trajectories, between which it only remains to arrange the stones intended to form the arch. There will here be a little difficulty additional to that met with in the helicoidal arrangement; the trajectories, although equal one to the other, are not equidistant, and it is necessary in consequence to vary the thickness of the stone employed, according to the distance of the two curves between which it has to be placed. As to the heading voussoirs, they form a sort of arch independent of the principal arch; it results, in fact, from the defective parallelism of the edges of the inner arch that the bed-joints could not be prolonged as far as the leading planes without causing in the size of the heading voussoirs inequalities which would be displeasing to the eye; these voussoirs are then shaped independently, making the bed-joints normal to the leading planes. The shaping of these voussoirs then presents no difficulty; the

plane faces being executed, the cylindrical surfaces are afterwards shaped by means of a rule placed along guiding points chosen beforehand.

An important simplification has been proposed in the construction of the arch under consideration, which consists in replacing the left bed-joints by the cylindrical surfaces projected by the trajectories upon the leading planes, surfaces which in fact differ very little from the former, and which besides possess the advantage of furnishing only reactions situated in planes parallel to the leading planes, and in consequence not affording any component perpendicular to these planes; that is to say, not giving rise to a thrust by increasing the opening. When the arch is to be of great length, we can, as shown in Fig. 1467, arrange the portion of the arch comprised between the upright sections M N and O P as an ordinary cylindrical arch, and only employ the orthogonal arrangement for the portions A B N M and C D P O. But in place of using joints running parallel to the heads, we employ vertical planes which converge, some towards the point of junction, the right lines A B and M N, and others towards that of the right lines C D and O P. The edges of the inner arch are the orthogonal trajectories of the vertical sections of the intrados thus obtained; their tracing is necessarily more complicated. This system is that which is called the convergent orthogonal arrangement. Its advantages do not appear to make up for the difficulty of its execution and the ungraceful appearance of the arch.

Parallel Arches in Echelon.—Lastly, oblique bridges are formed of a series of upright arches, equal and parallel, but placed one behind another in echelon, as is shown in Fig. 1470, in horizontal projection. These arches are ordinary upright cylindrical arches, but of unimportant length, A B, A' B', and so on, whose centres O, O', and so on, are placed on the axis of the oblique arch. They are mutually united by other cylindrical arches M N, M' N', whose voussoirs are embayed to a greater or less extent in the thickness of the principal arches. The system is inelegant in appearance.

Oblique Bridges of Timber.—Oblique bridges are also constructed of wood, but they are all formed on the principle of the upright arches in echelon; that is, they are composed of a certain number of equal and parallel girders placed in echelon to one another, in such a manner that their homologous points are situated upon right lines parallel to the axis of the bridge, or the direction of the piers. Fig. 1471 represents the vertical projection of a semi-arch of such an arrangement, which is frequently used for the erection of a more permanent structure. Each girder is composed of a horizontal beam $a a$, supported by an upright post $p p$, by a principal rafter $j j$, and a strut $f f$. These different parts are united by hanging-braces m, m . Upon these girders are placed the joists $s s s s$, which support the roadway $b b b$ of the bridge. In the example given in Fig. 1471, the number of girders is four. The principal difficulty of this mode of construction consists in the method to be adopted to bind together the different girders, in order to form the whole into a perfectly solid system. The method most in use is that of uniting all the girders by horizontal braces $M M$, which are then parallel to the direction of the piers. But as the rafters pass through the braces in an oblique direction, it is necessary to determine by a draught the apertures to be excavated in these braces. Let A B and A' B' be, Fig. 1472 and 1473, the projections of one of these rafters, in relation to a horizontal plane passing through its lowest point O. It is necessary to first fix the transverse dimensions of the braces, by projecting the rafter upon a vertical plane perpendicular to the direction of the piers. Let C O' be this direction, and let O' X perpendicular to C O' be the near ground line. Upon the horizontal projection of the edge which starts from the point C, take any point I, which projects at K upon O X and at K' upon O' X'. Prolong the perpendiculars, and take upon the second a length K' H' equal to the distance K H, and join O' H', which will be the near vertical projection of the edge which touches the point C. The projections of the other edges will be easily obtained from this, in the manner indicated on the figure. Having thus obtained, Fig. 1474, the vertical projections of the rafters upon a vertical plane perpendicular to the direction of the braces, we can determine the upright sections M M of these braces. Mark the points 1, 2, 3, 4, and 1', 2', 3', 4', where their faces, perpendicular to the new vertical plane, meet the edges of the rafter; and project these points, Fig. 1473, upon the corresponding horizontal projections of these edges. We can thus trace the parallelograms 1 2 4 3, and 1' 2' 4' 3' according to which the rafter penetrates the lateral faces of the braces. Taking, then, in one of these faces a point o from which we suppose a horizontal parallel to the direction of the piers, let us imagine the braces to revolve round this horizontal, until the lateral faces of which we have just spoken have assumed a horizontal position, and in this position their different points to be projected upon the original horizontal plane of projection. Then, from the summits of the parallelograms 1, 2, 3, 4, and 1', 2', 3', 4', let fall perpendiculars upon the direction of the edges of the braces. Marking,

Fig. 1475, the intersections of these perpendiculars with the perpendiculars to ox which answer to the same figures, we shall obtain the upper and lower tracings of the apertures we wish to determine, such as will have to be drawn on the faces of the braces when executing these apertures. Only, it must be observed, that as a consequence of the rotatory movement imparted to the braces, it is the upper one which is placed to the right in Fig. 1475, and the lower one which is placed to the left. We may proceed in the same manner for the other apertures, but it will be noticed that they have their faces parallel, and this will much shorten the operation.

In place of uniting the rafters one to another, the hanging-braces are sometimes connected by horizontal ones. This arrangement would give rise to operations analogous to the preceding. Occasionally a direction differing from the horizontal has been given to the braces uniting the different beams.

Timber Bridge Construction.—The roadway of these temporary structures rests upon several girders, generally equidistant. The interval between two consecutive points of support is called a space.

The arrangement of the girders varies considerably; we shall only deal with the systems mostly used.

Where the interval between two consecutive points of support does not exceed 5 mètres, the girders are simply horizontal beams laid upon these supports, and it is on these beams that are placed transversely the cross-beams which sustain the roadway and the pavement. If the interval is to be from 5 to 8 mètres, supplementary beams A A, Fig. 1476, projecting 2 mètres on each side and supported by struts $f f$, are laid upon the piles. Fig. 1476 also shows the heads $m m$ of the horizontal braces uniting the stakes which form the pile, and the head M of the horizontal piece of timber forming the cap of the pile.

In the case of intervals of 8 to 12 mètres, a second row of struts $f' f'$, Fig. 1477, is added, abutting upon another supplementary beam B, placed in the middle of the interval. If these secondary struts have a length exceeding twelve times their breadth, they are supported by hanging-braces $a a$, which are themselves united from one girder to another by horizontal braces $m' m'$.

For greater intervals several stages of struts or rafters united one to another by vertical hanging-braces may be employed. When the interval is of considerable length, beams bound with iron are employed. The bridge at Wittingen, over the Linnat, forming a single span of 118^m·90, is cited as the most remarkable instance of this kind of construction: it is composed of several stages of armed beams, united by vertical hanging-braces, and supported by several systems of struts or rafters of different inclinations, the lowest of which is an armed beam.

In the several cases just indicated, the dimensions of a beam are calculated as if it were simply placed upon supports. The total weight for one interval of the roadway and pavement is calculated, and dividing by the number of beams, we have the weight uniformly diffused over the length of a beam. If the bridge is exposed to considerable and varying loads, these must be taken into consideration: such are, upon an ordinary load, the passage of a vehicle representing a weight of 6000 kilos.; or upon a railway, the passage of a locomotive weighing 60,000 kilos., which gives 30,000 kilos. for each beam, as one is ordinarily placed under each rail. Let a be the length of the span, p the weight a linear mètre, P the weight accidentally applied at the middle of the span, we must reconcile the two equations

$$R = \frac{1}{8} \frac{v}{l} (p + p') a^2 = \frac{3}{4} b h^2 (p + p') a^2 \quad [1]$$

$$\text{and} \quad R = \frac{v}{l} \left(\frac{1}{8} p a^2 + \frac{1}{4} P a \right) = \frac{6}{b h^2} \left(\frac{1}{8} p a^2 + \frac{1}{4} P a \right), \quad [2]$$

calling b the horizontal dimension of the upright section of the beam, and h its vertical dimension. We will take R equal at most to 600,000 for oak, or 800,000 for deal, say, 60 kilogrammes the square centimètre in the first case, and 80 kilogrammes in the second; find the proportion of h to b , and deduct h from these two formulæ; the greater of the two values then obtained must be adopted. We can then estimate the weight of the beam to introduce it into p , and calculate a nearer value for h .

When the same beam forms several spans, or even the total length of a bridge, it is considered as a piece of timber placed upon supports, corresponding to the piers of the abutments. We thus determine the moment of flexion corresponding to each point of support, and next the moment of flexion on any given point of the beam, the maximum of this moment, and by consequence the transverse dimensions of the beam. For the same calculations we deduce the reactions of the supports, and on the other hand the load sustained by these supports, whence we obtain the dimensions of the piles.

The dimensions of the divisions of the bridge must be calculated in the same way as for a portion of timber placed upon a certain number of supports, which are here the beams, loaded with a weight uniformly diffused, and also with a weight applied at the middle of the interval between two beams, representing the movable load caused by the passage of a vehicle. But as this calculation is a very long one, a more rapid, but less exact method is preferred. The dimensions of the portion of the bridge are calculated: 1st, as if the part of this portion comprised between two beams formed an isolated portion placed on two supports; 2nd, as if it were let into the two points of support. In the first case the maximum of the moment of flexion is given by the formula

$$\mu = \frac{1}{8} p a^2 + \frac{1}{4} P a; \text{ calling } a \text{ the distance between two beams, } p \text{ the weight uniformly spread over each portion of the bridge, and } P \text{ the movable load; in the second case we should have}$$

$$\mu = \frac{1}{12} p a^2 + \frac{1}{8} P a.$$

The mean of the values of μ given by these two formulæ is adopted. When the bridge has to support occasionally only the weight of a wagon not exceeding 4000 kilogrammes, the divisions of the bridge may be 0^m·50 distant from one another; if the accidental load will be greater, they must be placed nearer together. But it is well to observe that when only a momentary load is in question, wood can be made to support a greater tension than that which we have indicated above, and that it is allowable to increase it then to 100 or 120 kilogrammes the square centimètre.

To calculate the dimensions of the struts, suppose each beam placed upon the supports which are formed by the extremities of the piles and the struts, and determine the reactions of these points of support; for struts analogous to that which abuts on the point A, Fig. 1477, we take the resultant of the reaction lengthwise to this piece of timber. It will be necessary that this resultant, divided by a transverse section of the strut, should give a quotient equal at most to 60 or 80 kilogrammes the square centimètre, according to the kind of wood employed; for struts such as those abutting on the point B, we should distribute the reaction in the direction of the strut, and in a horizontal direction; and make use of these two resultants, to determine in the same way the transverse dimensions of the strut and the underlying beam.

For bridges of great extent, there has been employed in France for fifty years, a system in which the beams and the roadway are sustained by an arch formed of a certain number of curved rafters, bound together by iron straps, and united to the roadway by hanging-braces in a direction normal to the arch. Fig. 1478 represents one division of the bridge of Ivry-sur-Seine constructed on this plan by M. Emmerly. The arch has a chord of 22^m·50, and a versed sine of 3^m·48. The roadway rests directly on the crown of the arch, and the beams are hollowed out to accord with this arch. The weight of the roadway is also transferred to the arch by means of braces. The girders are fastened one to another, not only by horizontal braces parallel to the axis of the bridge, but also by horizontal slanting beams which assist in counteracting the effects of the wind on the whole system.

To calculate the transverse dimensions of the arch exactly, it would be necessary to consider the roadway as placed upon the hanging-braces, to determine the reactions of these supports, to

take these in a contrary sense to get the reactions of the braces upon the arch, and determine the normal component of these; we should thus have the forces which act upon the arch, independently of its weight. But we can obtain sufficiently approximative results by considering the weight of the roadway as uniformly spread over the horizontal projection of the arch. In the case we are dealing with, the formula $b h^2 = \frac{P}{R} \left(\frac{h}{\alpha} + \frac{\rho \alpha^3}{4} \right)$ is generally used, in which b is the transverse dimension of the arch in a horizontal direction, h its thickness vertically, P the total weight of the bridge, ρ the mean radius of the arch, α the length of the arc with a radius 1 similar to the arch under consideration, and R a coefficient which it is convenient to take as equal to 300,000.

Constructors employ a still more simple method, which gives results sufficiently near. It consists in regarding the proposed arch as the arc of a parabola, loaded with weights proportional to the horizontal projection of its elements. Let OM, Fig. 1479, be a portion of the arch computed from the vertex. Let us take for the axis of x the tangent to the vertex, for the axis of y the axis of the curve. Draw the tangent to M, and by a known property of the parabola this tangent will cut OX in the middle I of the abscissa ON of the point M. Let M' be a point infinitely near to the point M; draw the horizontal MH and the vertical M'H. The arch OM is in equilibrium, under the action of the weight P (borne by the arc and which passes through the middle I of ON), of the tension Q exercised at O in the direction OX, and the tension T which is exercised at M in the direction MI. These three forces are then proportional to the three sides of the triangle MIN, or of the triangle MM'H, which is similar to it. We have then

$$\frac{M'H}{MH} = \frac{P}{Q} \text{ or } \frac{dy}{dx} = \frac{px}{Q},$$

designating by P the weight a linear mètre supported by the arch. Integrating, and observing that for $x = 0$ we should have $y = 0$, we obtain for the equation of the curve $y = \frac{P}{2Q} x^2$. This equation must be completed by the co-ordinates of the spring; if the a is the semichord of the arch and f its versed sine, we should have $f = \frac{p}{2Q} a^2$, whence $Q = \frac{p a^2}{2f}$. We shall next

have $T = \sqrt{P^2 + Q^2} = \sqrt{p^2 x^2 + \frac{p^2 a^4}{4 f^2}} = p \sqrt{x^2 + \frac{a^4}{4 f^2}}$. The maximum of T answers to $x = a$, and has for its value $T = p a \sqrt{1 + \frac{a^2}{4 f^2}}$. This maximum value will serve to determine the transverse dimensions of the arc.

The arch being supposed to resist only by compression, it will be necessary that the maximum tension T divided by the area of the transverse section should give a quotient at most equal to 60 kilogrammes the square centimetre for oak, or 80 kilogrammes for deal. Calling b the horizontal dimension and h the vertical dimension, we shall have $\frac{T}{b h} = 0.6$. If we take the milli-

mètre for unity, we shall obtain b , and deduce $h = \frac{T}{0.6b}$.

For some years there have been constructed in America timber bridges on an entirely different system. They were invented to enable railways to pass across considerable streams of water, as we have before stated and illustrated. They are called trellis-bridges, because they have exactly the appearance of trellis-work. Fig. 1480 represents a portion of a bridge of this kind constructed at Richmond, U.S., on the system of Town. The girders, which are 5^m 125 in height, are formed of thick planks arranged trelliswise, applied flat without being let into each other, and joined by oak pegs. They are united by several courses of braces, horizontal as regards the length of the bridge, and by a certain number of vertical braces. Two equal guides are fastened together on each side of the bridge. These two girders leave between them an interval of 3^m 20. They are joined above and below by cross-beams, the intervals between which are filled by diagonal work. Other diagonals, placed vertically according to the transverse sections, complete the protection of this system against the wind. The exterior sides are covered with planks to secure the construction

against the effects of the weather, as is shown on the right side of the figure. This forms a long space of rectangular section.

To appreciate the resistance of such a construction, we may consider each girder as a solid placed upon two supports, loaded with a weight uniformly diffused, and with a load equal to the weight of two locomotives applied in the middle of the span. But as the openings here form about two-thirds of the total volume, it is advisable to reduce to one-third the coefficient R of the resistance, that is, to 20 kilos. a square centimetre for oak, or 27 kilos. for deal. Designating by R' the coefficient thus reduced, by p the weight of the bridge the linear mètre, by P the road applied in the middle of the span, by a the length of the span, by b the total thickness of all the traces in a horizontal direction, and by h the height of each girder, we shall have to apply the formula already used, $R' = \frac{6}{b h^2} \left(\frac{1}{8} p a^2 + \frac{1}{4} P a \right)$.

W. Presse, in his course of "Applied Mechanics," has endeavoured to estimate in a more precise manner the shock supported by each of the pieces composing these girders or beams of trellis-work. He considers first the simplest case to which the system would be reduced, as shown in Fig. 1481, to two courses of inclined rails, $A B C D \dots A' B' C' D' \dots$ jointed with inclined ties $A A', B B', C C', D D' \dots$ on the one hand, and $A' B, B' C, C' D$, on the other: and he supposes, in the first place, that the beam thus defined supports only a single weight $2P$ applied in the centre. It follows at once that the beam receives from the abutment on the pier upon which it rests a vertical reaction P applied at its extremity A . Let α be the acute angle which the inclined rails make with the vertical. There must then be equilibrium between the force P applied at A and the tensions or pressures of the ties $A B$ and $A A'$; it is then easily seen, by the parallelogram of forces, Fig. 1350, that the rail $A A'$ undergoes a pressure equal to $P \tan. \alpha$; and that the rail $A B$ undergoes a pressure equal to

$\frac{P}{\cos. \alpha}$. If we next consider the equilibrium of the point A' , we find by the same means that the forces exercised in the direction $A' B$ and in the direction of the prolongation of $A A'$ must be equal; and that the tension of $A' B$ has for its value $2 \frac{P}{\cos. \alpha} \sin. \alpha$, or $2 P \tan. \alpha$. The equilibrium of the point B shows, on projecting the forces vertically, that the pressures of $A B$ and $B B'$ are equal; and on projecting them horizontally, that the tension of $B C$ is equal to $P \tan. \alpha + 2 \frac{P}{\cos. \alpha} \sin. \alpha$, that is, to $3 P \tan. \alpha$. Adopting the same method with the point B' , we find that the pressure of $B' C$ is equal to that of $B B'$, and that the tension of $B' C'$ has for its expression $2 P \tan. \alpha + 2 \frac{P}{\cos. \alpha} \sin. \alpha$, that is, $4 P \tan. \alpha$. Continuing thus, we find that all the ties support pressures equal to $\frac{P}{\cos. \alpha}$; that the lower horizontal ties support successive tensions expressed by

$P \tan. \alpha$, $3 P \tan. \alpha$, $5 P \tan. \alpha$, $7 P \tan. \alpha$, and so on; and the upper horizontal ties, tensions expressed by $2 P \tan. \alpha$, $4 P \tan. \alpha$, $6 P \tan. \alpha$, $8 P \tan. \alpha$, and so to the middle of the span. Starting from this point, the same tensions are reproduced in inverse ratio because of the symmetry of the arrangement. If the number of the lower horizontal ties is equal, it is the middle tie which will undergo the greatest tension, and, calling $2n + 1$, the total number of these lines, the maximum tension will be expressed by $(2n + 1) P \tan. \alpha$. If the number of the lower horizontal ties is equal, the upper horizontal tie occupying the centre will undergo the greatest tension, and if $2n$ is the number of the lower ties, this maximum tension will be expressed by $2n P \tan. \alpha$.

In the second place, the case in which the trellis-work beam would be loaded with a weight $2p$ at each of the intermediate joints, B, C, D , and so on, of the lower course of braces. If n is the number of these intermediate joints, np represents the vertical reaction which is exercised at the point A . Considering, step by step, the equilibrium of the upper and lower points of junction, we arrive at the following conclusions:—

1st. The sides parallel to $A A'$ undergo pressures, having successively for their value $\frac{np}{\cos. \alpha}$, $\frac{(n-2)p}{\cos. \alpha}$, $\frac{(n-4)p}{\cos. \alpha}$, $\frac{(n-6)p}{\cos. \alpha}$, and so on.

2nd. Two inclined ties abutting at the same point, are, the one, compressed, the other extended, by the same intensity.

3rd. The pressures of the upper ties are represented by the values, $2np \tan. \alpha$, $4(n-1)p \tan. \alpha$, $6(n-2)p \tan. \alpha$, $8(n-3)p \tan. \alpha$, and so on.

4th. The tensions of the lower horizontal ties are expressed by $np \tan. \alpha$, $[n+2(n-1)]p \tan. \alpha$, $[n+4(n-2)]p \tan. \alpha$, $[n+6(n-3)]p \tan. \alpha$, and so on.

Calling i the position of a horizontal tie in each of these series, we have for the pressure of an upper tie, $2i(n-i+1)p \tan. \alpha$, and for the tension of a lower tie,

$$[n+2(i-1)(n-i+1)]p \tan. \alpha.$$

The maximum of the first expression answers to $i = \frac{n+1}{2}$, and that of the second to $i = \frac{n+2}{2}$; if these terms are not integers, the maximum will not be produced exactly, but approximately, although n may be a large number, as is ordinarily the case. We find the value of the maximum to be $\frac{1}{2} p \tan. \alpha (n+1)^2$ in the first case, and $\frac{1}{2} p \tan. \alpha [(n+1)^2 - 1]$ in the second. So that, calling N the number of times that AB is contained in the length of the span, the maximum of pressure or tension of the horizontal ties is expressed by $\frac{1}{2} p N^2 \tan. \alpha$.

There have been constructed in Bavaria timber bridges differing from the American system only in that the joints of all the pieces of woodwork are united by cast-iron sockets, and the girders enter the abutments, hollowed out for this purpose.

In America there has also been applied another system founded on the use of curved arches. Such is the bridge at Trenton over the Delaware, partially represented in Fig. 1482. The girders are five in number; in each, the principal part is an arc of a circle formed of eight planks superposed; it rests at its extremities upon the piers, and supports the roadway by means of suspending iron bars. The arch is, besides, united to the roadway by pendant ties inclined at an angle of 45° . All the woodwork is covered by a roof, and sheltered laterally by planks. The arches of two successive spans abut against each other by means of woodwork raised upon the pier and elevated to two-thirds of the height of the arches.

Lastly, there has been constructed at Liep, York county, a bridge of the same kind, but in which the roadway, in place of forming the chord of an arc, is placed at mid-height between the chord or the vertex; so that the roadway is suspended underneath the upper portion of the arch, whilst it rests upon its lower portion. This system, in which the bridge forms a girder, appears to offer more resistance.

Stone Bridges.—After the water-way has been fixed, we have to determine the dimension and the form of the arches.

There is a very simple relation between the span of a segmental arch, its height or versed sine, and the radius of the circle to which the arc belongs. If $2c$ represents the span, or the chord AB , Fig. 1483, of the arc, f the versed sine HC , and R the radius OA , the semichord AC being a mean proportional between the two segments of the diameter to which it is perpendicular, we have

$$c^2 = f(2R - f), \text{ whence } R = \frac{c^2 + f^2}{2f}. \quad [1]$$

If we wish to have the semi-arc AH in degrees, or the angle of the centre AOH , we observe that it has for its sine the proportion $\frac{AC}{AO}$ or $\frac{c}{R}$; designating the angle by α , we have then

$$\sin. \alpha = \frac{2fc}{c^2 + f^2} = \frac{2 \frac{f}{c}}{1 + \frac{f^2}{c^2}}. \quad [2]$$

It is not usual to give to the proportion $\frac{f}{c}$ a lower value than $\frac{1}{4}$, which supposes a height equal to $\frac{1}{8}$ of the span, and gives $\sin. \alpha = 28^\circ 4' 20''$, or thereabouts. However, in exceptional cases, this proportion has sometimes been reduced to $\frac{1}{5}$ or $\frac{1}{6}$.

The bridge of Solferino is an example of the form adopted in the early construction of iron bridges. The arches, Fig. 1484, have a span of 40 metres, and a height of 4^m.02. They are formed of cast-iron voussoirs, of open work in the leading arches and solid in the intermediate. The figure, 1485, represents the elevation and the transverse section of the first voussoir of an intermediate arch. It will be seen that the section represents a double T, with a central rib. The pediment, that is to say, the space comprised between the arch and the roadway, is filled up by open-work plates of a trapezoidal form. Fig. 1486 represents one of these plates.

The girders are united one to another by three systems of cross-joints, placed, some above the ribs of the intrados, others below it, and others upon the ribs which form the crown of the pediment. These latter cross-joints, at a distance of $1^m.30$, also serve to sustain arches of brick and Roman cement, upon which the roadway and the side-walks are erected. In this system of arches formed of

voussoirs, the casting is only subject to compression; the only portions exposed to extension are the cross-joints, but as they are few in number they may be executed in wrought iron. The pressures to which the voussoirs are subject can be calculated as for stone arches. But the inequalities of the load are of much greater importance here than in stone bridges. Supposing that one half of the span bears the maximum load of 400 kilos. a square mètre, whilst the other only supports its own weight, we can determine on this hypothesis the direction and intensity of the thrust on the key. Let P and P', Fig. 1487, be the weights supported by the two halves, H the point of application of the reaction N of the two halves of the arch, and BC the oblique direction of this reaction. We let fall from the springs A and A', upon this direction, the perpendiculars AC and A'C', and erect the verticals AB and A'B'. Let p and p' be the distances of the forces P and P' from the points A and A'. We shall have for the equilibrium of the first half of the arch the formula $N \times AC = Pp$, and for the equilibrium of the second half $N \times A'C' = P'p'$, whence dividing member by member, $\frac{AC}{A'C'} = \frac{Pp}{P'p'}$. But the triangle ABC and A'B'C' being similar, the first

term may be replaced by the proportion of AB to A'B', which gives $\frac{AB}{A'B'} = \frac{Pp}{P'p'}$, whence $\frac{AB}{AB + A'B'} = \frac{Pp}{Pp + P'p'}$. Now, calling H the height IH, we have $AB + A'B' = 2H$, consequently there results $AB = 2H \frac{Pp}{Pp + P'p'}$, from which we can obtain the direction of the force N, next the distance AC, and ultimately the intensity of the thrust N.

The most remarkable example of a bridge with straight iron beams is the Britannia Bridge, constructed in 1850 over the Menai Straits, by Robert Stephenson, on the Chester and Holyhead Railway. This bridge traverses an arm of the sea at 33 mètres above high water, by means of four spans, of which two are not less than 140 mètres long. This bridge has the form of a long tube, with a rectangular section of $9^m.144$ in height by $4^m.50$ in breadth. Its upper casing wall is itself formed of eight equal tubes, fastened one to another, of a square section of $0^m.533$ a side, and its flooring is formed of six similar tubes $0^m.533$ high by $0^m.711$ wide. The lateral walls are solid, and united, both above and below, by triangular brackets $1^m.22$ high by $0^m.533$ wide. Since the completion of this work, about which an immense amount of nonsense has been written, bridges with beams of iron plating have multiplied considerably. In bridges of small dimensions the beam is composed of a long plate of sheet iron, made fast at top and bottom by angle-iron; Fig. 1488 gives the section of this beam. It is strengthened from distance to distance by transverse plates having the same height as the beam, and towards the top the same width as the upper plate, while towards the bottom they are of greater width. This form is represented by the dotted lines on Fig. 1488. In the more important bridges, the beam is a tube with a rectangular section, formed of four plates of iron held together by angle-iron. Fig. 1489 is the section of a beam of this kind. The arrangement of these beams has been varied in many ways, those just described are the most generally used. On railways, beams analogous to that of Figs. 1488, 1489 are ordinarily placed above the roadway which rests on the lower ribs; these beams are three in number, and the trains pass along the spaces between them. It follows, when the bridge is of large dimensions and the beams consequently of

great height, that the prospect is completely shut out when passing over rivers, that is, at the most picturesque parts of the way. To obviate this inconvenience, the German engineers have endeavoured to replace the solid walls of the beams by walls of trellis-work; but this system, in which one of the sets of bars forming the trellis is elongated while the other is compressed, does not afford sufficient solidity.

To determine the transverse dimensions of straight beams, they are considered as prismatic bodies placed upon two supports, loaded with a weight uniformly diffused, and with a load applied at the centre. If p designates the weight a mètre uniformly diffused, P the load applied at the middle of their extent, x the length of this, R the limit of tension which must not be exceeded, h the height of the bridge, and I the moment of inertia of its upright section in relation to the horizontal drawn in this section through its middle, or, more exactly, through its centre of gravity,

we shall have to apply the empirical formula $R = \frac{1}{I} \left(\frac{1}{8} p a^2 + \frac{1}{4} P a \right)$. But it is necessary to

observe here that, as in the case of timber bridges, if the load is the weight of two locomotives crossing at the middle of the interspace, as this is an exceptional load, we may admit that the plates, in place of only having to support, as ordinarily supposed, about $\frac{1}{10}$ of the tension corresponding to its limit of elasticity, momentarily supports $\frac{1}{5}$; that is, in place of taking for R 6 kilos. a square mètre, we should take 12 kilos.

In arched metal bridges, the beams which sustain the flooring are ordinarily of cast iron, in the shape of a double T. But sometimes it is required that the resistance should be the same in all the transverse sections, at least over a certain extent, starting from the key. To this end, the distance between the internal edges of the ribs is made to vary. If, for example, h stands for the distance between the ends A and C, Fig. 1490, b the distance between the points A and B, h' the distance between the points A' and C', and b' twice the distance A'I, h' is made to vary in such a manner that the resistance caused by the weight uniformly diffused may be the same for each section within certain limits.

Let p be the weight uniformly diffused, and a the length of the interspace; each point of support will exercise a reaction equal to $\frac{1}{2} p a$; the moment of the forces which act upon this space, from the point which has for its abscissa x , computed from one of the extremities as far as the other extremity, will have for value $\mu = p(a-x) \frac{1}{2}(a-x) = -\frac{1}{2} p a(a-x)$; or $\mu = -p(a x - x^2)$.

The moment of inertia of the section in relation to the horizontal passing through its centre of gravity is besides, according to an empirical formula, $I = \frac{1}{12}(b h^3 - b' h'^3)$; finally, the ordinate of the most distant rib from the axis is $v = \frac{1}{2} h$.

Calling R the limit of tension not to be exceeded, we shall then have, taking only the absolute value of μ , $R = \frac{v \mu}{I} = \frac{b p(a x - x^2)}{b h^3 - b' h'^3}$, a formula which will give the values of h' corresponding to the values of x . But as it is not necessary that the thickness A A should be less than the thickness of the vertical nucleus, as soon as h' has attained the value that is given for this thickness, we cease adding to h' , and diminish h as far as a limit fixed beforehand. On the Auteuil railway, for instance, we have, according to M. Claudel,

$$p = 1600^k, h = 0^m \cdot 60, b = 0^m \cdot 28, b' = 0^m \cdot 26, a = 8 \text{ mètres};$$

and, taking R , for want of better knowledge, as equal to 6,000,000, we find the value of x corresponding to the key, that is for $x = \frac{1}{2} a h = 0^m \cdot 52$, which will give $0^m \cdot 08$ for the thickness of the two united ribs, or $0^m \cdot 04$ for each of them. We find that for $x = 1^m \cdot 44$ (about), the thickness of each rib is reduced to $0^m \cdot 02$, which is the thickness of the nucleus; h and h' are then diminished by an equal quantity without decreasing the thickness of the rib, until we reach $h = 0^m \cdot 40$, the limit of height fixed beforehand.

The cross-bars are also ordinarily of a double-T section. On the Auteuil railroad we have $a = 2^m$, $h = 0^m \cdot 30$, $b = 0^m \cdot 20$, $b' = 0^m \cdot 188$, whence we deduce $0^m \cdot 014$ for the thickness of the nucleus and the ribs.

Suspension Bridges.—The first consideration in suspension bridges is to determine the geometrical position of the angles of the polygon formed by the points of attachment of the suspending rods. It will be observed, first, that each couple of rods corresponding with the two sides of the roadway may be considered as bearing half the weight of each of the two interspaces comprised between the couple of rods and the preceding or following. If the rods are equidistant, they will consequently sustain equal weights. If the rods were infinite in number and infinitely close to one another, each couple would sustain an element of the roadway, and any given portion of the chain would sustain a weight proportioned to its horizontal projection. On this hypothesis it is easy to perceive that, disregarding the weight of the rods, the chain would assume the form of a parabola to the vertical axis, the equation of which is easily ascertained. Let A, Fig. 1491, be the lowest point of the chain. At this point is exercised a horizontal tension which we will represent by Q. Let us take for the axis of y , the vertical of the point A, and for the axis of x a horizontal O X drawn at the height of the roadway. Let M and M' be two points of the chain infinitely close to one another; let T be the tension of the chain at the point M, a force

which is applied in the direction of a tangent at this point. If α designates the angle of this tangent with the horizon, the horizontal and vertical components of T will be $T \cos. \alpha$ and $T \sin. \alpha$. Passing from the point M to the point M' , these components will become $T \cos. \alpha + d$, $T \sin. \alpha$, and $T \sin. \alpha + d$, $T \sin. \alpha$.

Let $2p$ be the weight a lineal mètre of the bridge, $2p dx$ will be the weight of an element of this bridge, and $p dx$ will be the weight of the portion NN' of the bridge supported by a rod jointed at the middle of the element MM' . This element being in equilibrium under the action of this weight and of the two tensions already considered, we shall have, by taking the sum of the horizontal components ($T \cos. \alpha + d$, $T \cos. \alpha$) - $T \cos. \alpha = 0$, or $d, T \cos. \alpha = 0$, whence

$$T \cos. \alpha = \text{const.} = Q;$$

and taking the sum of the vertical components,

$$(T \sin. \alpha + d, T \sin. \alpha) - T \sin. \alpha - p dx = 0, \text{ or } d, T \sin. \alpha = p dx,$$

and substituting for T its value $\frac{Q}{\cos. \alpha}$, $dQ \tan. \alpha = p dx$, or $Q dy' = p dx$, calling y' the angular coefficient of the tangent at M . Integrating and observing that the point A is the lowest point, we have $y' = 0$ for $x = 0$; we obtain $Q y' = px$, or $dy = \frac{p}{Q} x dx$. Integrating afresh and designating by y , the ordinate of the point A , we find

$$y - y_0 = \frac{p}{2Q} x^2, \quad [2]$$

the equation of a parabola which has for axis the axis of y , d being employed as the differential sign.

Without supposing the rods infinite in number, if we suppose them equidistant, as is ordinarily the case, and disregarding their weight, we may demonstrate by very slight consideration that the angles of the polygon formed by the chain are upon a parabola. Let M, M', M'' , Fig. 1492, be three consecutive points of the chain; let T and T' be the tensions of the sides MM' and $M'M''$, and P the weight supported by the rod $M'N'$. The point M' being in equilibrium under the action of these three forces, the sum of their horizontal components is equal to 0; that is to say, the horizontal projection of the tension of any given side is a constant quantity; we will designate it as above, by Q . Produce the side MM' as far as K ; the three forces T, T' , and P , will be proportional to the three sides of the triangle $M'M''K$, which are respectively parallel to them. If then we represent the tension T by the side $M'M'$, or by its equal $M'K$, the tension T' will be represented by $M'M''$, and the weight P by $M''K$. Now the weight sustained by each rod is a constant quantity, since the rods are equidistant; the length $M''K$ is then also constant. Draw the horizontals MI and $M'H$. The length $M'I$ or its equal KH being the primary difference of the ordinate MN ; that is to say, the difference between $M'N'$, and MN , and $M'H$, being the primary difference of the ordinate $M'N'$, that is the difference between $M''N''$ and $M'N'$, the length K , which is the difference between these two primary differences, is nothing else than the second difference of MN . The centre of curvature of the points of the chain has then this property, that the second difference of the ordinate is constant; it is then a curve, the equation of which is in the form $y = a + bx + cx^2$, that is, it is a parabola, whose axis is parallel to the ordinates.

Finally, still disregarding the weight of the rods, whatever may be the successive distances of the rods one from the other, the consecutive points of attachment of the chain are always upon a parabola. Let $M_0, M_1, M_2, M_3, \dots$ Fig. 1493, be the consecutive points of the chain; $x_0, y_0, x_1, y_1, x_2, y_2, \dots$ their co-ordinates in relation to two rectangular axes, the one vertical passing through the middle of the horizontal side $m M_0$, and the other horizontal; $P_0, P_1, P_2, P_3, \dots$ the weights supported by the corresponding rods; $T_1, T_2, T_3, \dots$ the tensions of the consecutive sides; Q their common horizontal projection. It is sufficient, in fact, to consider the equilibrium of any given apex and make equal to 0 the sum of the horizontal projections of the forces acting upon it, to see that all these tensions have horizontal projections equal in absolute value. Let us consider the equilibrium of the point M_0 ; the weight P_0 applied at this point has for its expression

$$P_0 = p \left(x_0 + \frac{x_1 - x_0}{2} \right) = \frac{1}{2} p (x_1 + x_0), \quad [3]$$

designating by p the weight a linear metre sustained by the chain, which is the half of the weight per linear metre of the roadway. Making equal to 0 the sum of the horizontal projections of the forces Q , T , and P , we obtain

$$Q = T_1 \cos. M_1 M_0 H = T_1 \frac{x_1 - x_0}{M_0 M_1}.$$

Making equal to 0 the sum of the vertical components of the same forces, we find

$$\frac{p}{2} (x_1 + x_0) = T_1 \sin. M_1 M_0 H = T_1 \frac{y_1 - y_0}{M_0 M_1}.$$

If we divide term by term the two proportions just established, we obtain

$$\frac{1}{2} \frac{p}{Q} (x_1 + x_0) = \frac{y_1 - y_0}{x_1 - x_0}, \text{ whence } y_1 - y_0 = \frac{p}{2Q} (x_1^2 - x_0^2). \quad [4]$$

If we consider the equilibrium of the point M_1 , we shall find in the same way

$$Q = T_2 \frac{x_2 - x_1}{M_1 M_2} \text{ and } \frac{p}{2} (x_2 + x_1) = T_2 \frac{y_2 - y_1}{M_1 M_2},$$

whence dividing term by term,

$$\frac{p}{2Q} (x_2 + x_1) = \frac{y_2 - y_1}{x_2 - x_1}, \text{ or } y_2 - y_1 = \frac{p}{2Q} (x_2^2 - x_1^2). \quad [5]$$

Applying the same method to all the other points, we shall obtain analogous relations; and if x_{n-1} , y_{n-1} , and x_n , y_n represent the co-ordinates of any two given consecutive points, we shall have

$$y_n - y_{n-1} = \frac{p}{2Q} (x_n^2 - x_{n-1}^2). \quad [6]$$

Adding term to term all the relations thus obtained, and reducing, we find

$$y_n - y_0 = \frac{p}{2Q} (x_n^2 - x_0^2),$$

so that by suppressing the index n we have for any given point of which x and y are the co-ordinates,

$$y - y_0 = \frac{p}{2Q} (x^2 - x_0^2); \quad [7]$$

this is the equation of a parabola whose axis is vertical, and which has for its vertex the point of the axis of y having for its ordinate $y_0 - \frac{p}{2Q} x_0^2$.

If the chain had no horizontal side, we should make the y axis pass through the lowest apex M_0 ; we should then have $x_0 = 0$, and applying the same method, we should find the equation of the parabola to be

$$y - y_0 = \frac{p}{2Q} x^2. \quad [8]$$

Having the equation of the curve, we can easily deduce from it the horizontal component Q of the tensions of the sides. In fact, the point at which the chain meets the vertical, elevated at the extremity of the roadway, may be considered as a point of the chain; now this point is always given. If the chain is symmetrical with relation to the lowest point, the co-ordinates of this imaginary point of attachment are the semi-span a of the bridge, and the height h of this point above the axis x ; we should then have, in the case of the formula [7],

$$h - y_0 = \frac{p}{2Q} (a^2 - x_0^2), \text{ whence } Q = \frac{1}{2} p \frac{(a^2 - x_0^2)}{h - y_0}.$$

In the case of the formula [8], we should have

$$Q = \frac{1}{2} p \frac{a^2}{h - y_0}.$$

Thus, by assuming the supposed point of attachment, and the point M_0 , we determine the ordinate of a point of the chain corresponding with a given abscissa, and consequently the point corresponding with a given rod, as well as the horizontal tension of the chain.

The actual point of attachment is always situated beyond the point which we have called the imaginary point of attachment.

It is easy to deduce from the preceding the tension of a given side of the polygon formed by the chain. Let M_{n-1} and M_n , Fig. 1494, be two given consecutive points, and T_n the tension of the side $M_{n-1} M_n$. The portion of the chain comprised between the point M_0 and the point M_{n-1} bears the weight of the roadway comprised between the axis of y and the vertical passing through the middle of M_{n-1} , M_n ; this weight has then the value

$$P_n = p \left(x_{n-1} + \frac{x_n - x_{n-1}}{2} \right) = \frac{1}{2} p (x_{n-1} + x_n).$$

This portion of the chain is in equilibrium under the action of its weight, and of the forces Q and T_n ; calling α_n the angle of the side $M_{n-1} M_n$ with the horizon, and making equal to 0 the

sum of the horizontal components and that of the vertical components of these three forces, we obtain $T_n \cos. \alpha_n = Q$, and $T_n \sin. \alpha_n = P_n$, whence, squaring, adding, and extracting the square root:

$$T_n = \sqrt{Q^2 + P_n^2}. \quad [9]$$

This tension increases with P_n ; thus the maximum of tension is placed on the last side. In order to calculate it more easily, we may suppose that the lowest point of the chain is the vertex of the parabola, which is to place it in the case of the formula [8]; and if we call b the difference $h - y_0$, or the height of the point of attachment above the lowest point, we have

$$Q = \frac{1}{2} p \frac{a^2}{b}.$$

Besides, we have then $P = pa$; calling T the maximum tension, it follows that

$$T = \sqrt{p^2 a^2 \frac{1}{4} p^2 \frac{a^4}{b^2}}, \text{ or } T = pa \sqrt{1 + \frac{a^2}{4b^2}}. \quad [10]$$

The horizontal tension and that of the different sides of the chain may also be determined geometrically when we know the inclination of the last side. To make this clear, we will take the case where there is a horizontal side. Upon a vertical of indefinite length let us take the lengths $IA, AB, BC, \dots DH$, Fig. 1495, proportional to the successive weights supported by the different rods; that is to say, to half the sum of the weights of the two adjacent divisions of the bridge. From the point I draw a horizontal, and from the extreme point H a right line, having the inclination given by the last side of the chain. These two right lines meet at a point O ; draw $OA, OB, OC, \dots OD$. The right line IH , representing the weight borne by the rods OI , will represent the horizontal tension Q , and the lines OA, OB, OC , and so on, will represent the tensions of the successive sides of the chain; OH will represent the tension of the last side, which is the maximum tension. If we first consider the portion of chain comprised between the first rod and the last, we see that it is in equilibrium under the action of the horizontal tension Q of the tension T of the last side, and of the weight P of the roadway borne by these rods. Now, these three forces being parallel to the three sides of the triangle OIH , they are proportional to these sides; and since P is represented by IH , it follows that Q is represented by OI , and T by OH .

1495.

Let us now consider the point of attachment of the last rod; it is in equilibrium under the action of the weight p , suspended to the rod, of the tension T of the last side, and the tension T' of the preceding side. Now, the two former forces being represented in magnitude and in direction by the two sides DH and OH of the triangle ODH , the third force T' must be represented in magnitude and in direction by the third side OD of this triangle. We should thus demonstrate step by step that OC, OB, OA , and so on, represent in magnitude and direction the successive tensions of the other sides. An analogous mode of reasoning would be employed in case there were no horizontal side. In both cases the force Q is the horizontal projection common to all the tensions.

It is necessary to determine the length of the chain. To obtain this, we might calculate successively each of its sides by means of the co-ordinates of its extremities. But this method is a very laborious one; and we can obtain a sufficient approximation by substituting for the polygon the circumscribed parabola, of which we have the equation. We take for this the equation [8], in which we suppress y_0 , which amounts to making the x axis pass through the lowest point; we

thus get $y = \frac{p}{2Q} x^2$, or, replacing Q by its value, $\frac{1}{2} p \frac{a^2}{b}$,

$$y = b \frac{x^2}{a^2}. \quad [11]$$

Calling s the length of the arc of the curve computed from the vertex, we have

$$ds = dx \sqrt{1 + y'^2};$$

but $y' = 2b \frac{x}{a^2}$, consequently $ds = dx \sqrt{1 + \frac{4b^2 x^2}{a^4}}$.

In the ordinary application, b is small in comparison with a ; besides, x is at the most equal to a ; the fraction under the radical is then very small; and we may, without perceptible error, add under the radical $\frac{4b^4 x^4}{a^8}$; the quantity under the radical then becomes a perfect square number, and extracting the root, we obtain $ds = dx \left(1 + \frac{2b^2 x^2}{a^4}\right)$.

Integrating, and observing that for $x = 0$ we should have $s = 0$, we find

$$S = x + \frac{2}{3} \frac{b^2 x^3}{a^4},$$

and for $x = a$,

$$s = a + \frac{2}{3} \frac{b^2}{a} = a \left(1 + \frac{2}{3} \frac{b^2}{a^2}\right), \quad [12]$$

which is the length of the parabola from the lowest point up to the point which corresponds with the extremity of the roadway.

This length of the chain is its absolute length under the action of the load which it supports; it is greater than its original length s_0 by the elongation produced by tension. Let θ be a mean between the maximum tension calculated above, and the horizontal tension Q ; the elongation of iron a linear metre being 0.00005 metre for a tension of 1 kilogramme a square millimetre of the section, calling ω the section of the chain expressed in square millimètres, $s - s_0 = s_0 \frac{\theta}{\omega} 0.00005$,

whence $s_0 = \frac{s}{1 + \frac{\theta}{\omega} 0.00005}$. The length s will vary with the temperature; the coefficient of the

expansion of iron, roughly estimated, is 0.0000122 , so that passing from 0 to the temperature t , the length s becomes $s' = s(1 + 0.0000122 t)$. From this results an increase of the versed sine, which it is necessary to know how to calculate. Now, if in the formula [12] we allow s and b to become variables and differentiate, we have $ds = \frac{4b}{3a} db$. For in considerable expansions we may admit that the final increments of s and b are plainly proportional to increments infinitely small; we then write

$$\Delta s = \frac{4b}{3a} \Delta b, \text{ whence } \Delta b = \frac{3a}{4b} \Delta s, \quad [13]$$

Δb signifies the finite difference of b .

This formula gives the increment of the versed sine Δb corresponding with an increase of length Δs of the chain. We thus find that for a bridge of 100 mètres span, in which case a is equal 50 mètres, and having a versed sine of 5 mètres, the latter is augmented by 0.00135 when the temperature is raised from 0 to 30° .

The section of the rods is easily calculated according to the weight they have to carry. Take the value of the weight of the roadway which the rod has to support, and add to it, according to the regulations laid down, a load of 200 kilos. a square metre; divide the sum by 12 kilos. in the case of iron bars, and by 18 kilos. in the case of wire rope. The quotient expresses in square millimètres the section of the rod.

The section of the chain is determined according to the maximum tension which it has to support. This tension is obtained by taking into account at first only the weight of the roadway, of its load, and of the weight of the rods. We thus obtain for the section of the chain an approximative value, whence we deduce the approximative value of the chain itself. Recommencing the calculation by introducing into the total weight that of the chain, we obtain a near value for the section, which is in general sufficiently near for all purposes. The small beams supported by the rods by means of iron straps may be considered as prisms placed upon two supports and loaded with the weight of the flooring-planks, which form two semi-interspaces, having the regulation load or weight uniformly spread over the length of the beam. The dimensions of the flooring are calculated in a similar manner. The regulation load of 200 kilos. a square metre represents the weight of three men. If the bridge is intended for the passage of vehicles, it is necessary, in the calculation of the section of the chain and that of the rods, to take into account the weight of two conveyances at least; and to consider them as crossing one another upon a given interspace. It is also necessary to consider this circumstance in the calculation for the smaller beams and the floor, independently of a weight uniformly distributed; we have then to consider a weight applied at a given point, for example in the middle, which is the most unfavourable case.

We require to calculate the lengths of the rods. If they are not equidistant, each of these lengths must be calculated by means of the equation of the parabola, and taking the sum. But the calculation is simplified when the rods are equidistant. Let us consider first the case in which there is no horizontal side. We have seen that the equation of the parabola in relation to its vertex is then $y = b \frac{x^2}{a^2}$.

Let us designate by λ the width of an interspace; the successive lengths of the rods, computed from the axis of x , that is to say, from the horizontal which starts from the lowest point, will have for their respective values $\frac{b\lambda^2}{a^2}, \frac{b4\lambda^2}{a^2}, \frac{b9\lambda^2}{a^2}, \dots, \frac{bn^2\lambda^2}{a^2}$, calling n the number of rods. The sum Σ of these rods will then be $\Sigma = \frac{b\lambda^2}{a^2} (1 + 4 + 9 + \dots + n^2)$. Now the sum of the squares of the consecutive numbers from 1 to n has for its value $\frac{n(n+1)(2n+1)}{6}$, we shall then have

$$\Sigma = \frac{b\lambda^2}{a^2} \frac{n(n+1)(2n+1)}{6}.$$

We may simplify still more this expression by observing that we have

$$a = (n+1)\lambda, \text{ whence } \frac{\lambda}{a} = \frac{1}{n+1}.$$

Substituting this value for $\frac{\lambda}{a}$, and reducing, we find

$$\Sigma = b \frac{n(2n+1)}{6(n+1)}, \text{ or } \Sigma = \frac{1}{3} bn \frac{2n+1}{2n+3}. \quad [14]$$

If there is a horizontal side, the most simple method is still to take the parabola in relation to its vertex, in which case the equation [8] is reduced further to the form $y = \frac{p}{2Q} x^2 = b \frac{x^2}{a^2}$, since the transposition of the axis of x does not change the parameter. But the abscissa of the points

of attachment of the rods are then, designating by ϵ , the half-interspace, $\epsilon, 3\epsilon, 5\epsilon, 7\epsilon, \dots (2n-1)\epsilon$, n designating the number of the rods. We have then in this case

$$\Sigma = \frac{b\epsilon^2}{a^2} [1 + 9 + 25 + 49 \dots + (2n-1)^2].$$

Now the sum of the squares of the n first unequal numbers has for its value $\frac{(2n-1)2n(2n+1)}{6}$,

$$\text{we then get } \Sigma = \frac{b\epsilon^2}{a^2} \frac{(2n-1)2n(2n+1)}{6}.$$

This expression may be simplified by observing that we have $a = \epsilon 2n + 1$, whence $\frac{\epsilon}{a} = \frac{1}{2n+1}$. Substituting and reducing, we obtain as a final result

$$\Sigma = b \frac{(2n-1)2n}{6(2n+1)} = \frac{1}{3} b n \frac{2n-1}{2n+1}. \quad [15]$$

We may remark that the values of Σ given by the formulæ [14] and [15] differ very slightly from $\frac{1}{3} b n$; so that when we only require a summary estimate, we can get the sum of the lengths of the rods by multiplying the third of the greatest by the number of these rods.

The formulæ [14] and [15] give the sum of the lengths of the rods only as far as the tangent to the vertex of the parabola circumscribed on the chain. It is necessary to add further the lengths of the portions of the rods comprised between the tangent and the roadway. If the latter is horizontal, calling δ the distance from the vertex of the curve to the roadway, we must add $n\delta$ to the sum already calculated. Sometimes the roadway has a slightly parabolic form, the convexity being turned upwards. In this case it would be necessary further to add to the sum of which we speak the sum of the ordinates of the new parabola, corresponding with the same abscissæ; they are calculated like the first sum.

We have supposed up to the present that the chain was composed of two symmetrical portions, its vertex corresponding with the middle of the roadway. This is not always the case; but, knowing the heights h and h' , Fig. 1496, of the supposed points of attachment H and H' above the tangent to the vertex, and the length $AA' = L$ of the roadway, it is easy to determine the distances a and a' from the summit of the parabola to the extremities of this roadway. For we have, first, $a + a' = L$.

Next we have, since the points H and H' are upon the parabola, $h = \frac{p}{2Q} a^2$ and $h' = \frac{p}{2Q} a'^2$,

$$\text{whence } \frac{h}{h'} = \frac{a^2}{a'^2}, \text{ or } \frac{a}{a'} = \frac{\sqrt{h}}{\sqrt{h'}}.$$

We also obtain from the two relations between a and a' the values

$$a = L \frac{\sqrt{h'}}{\sqrt{h} + \sqrt{h'}}, \text{ and } a' = L \frac{\sqrt{h}}{\sqrt{h} + \sqrt{h'}},$$

which determine the position of the point O . This point being known, we may apply to each of the branches OA and OA' the calculations and the formulæ belonging to the case in which the point O was supposed to be in the middle of the roadway.

We have also supposed that there was only one chain on each side of the bridge; generally there are several; but the projection of their vertices upon a vertical plane parallel to the direction of the bridge is upon the same parabola. The calculations are made as if all these vertices belonged to one chain. If there are four, the first bears the rods 1, 5, 9, &c.; the second, the rods 2, 6, 10, &c.; the third, the rods 3, 7, 11, &c.; the fourth, the rods 4, 8, 12, &c.

1497.

1498.

The chains or cables rest upon the piers or abutments by means of fixed or movable supports. In the first case, these supports are piers of masonry, or cast-iron pillars. The chains are not attached to these; they pass over rollers, or portions of rollers, known as revolving sectors, Fig. 1497, which themselves rest upon a plane surface. The intention of this arrangement is to distribute the pressure more equally over the different portions of any one chain, and to counteract the rupture which might result from an inequality of tension between two consecutive portions of the chain. Occasionally the chain is even made to pass over three rollers, of which one, that in the middle, is placed higher than the others, in order to diminish the angle of flexion of the chain, Fig. 1498.

The movable supports are columns or large cast-iron uprights, resting upon a fixed support by means of a horizontal rounded edge. This arrangement has the same intention as the use of friction-rollers or revolving sectors. The tension is distributed equally between the two divisions of the cable, and the resultant of the two equal tensions is directed according to the bisectrix of the angle formed by the two divisions; it leans towards one or the other side, according to the inequality of the load of the two roadways. It is plain that if, from the effect of a passing load upon one of these two roadways, the tension of the chain is augmented, the chain is drawn towards that side, and by adherence draws with it the movable pillar, making it revolve round its resting point O, Fig. 1499, until the tension diminishing on that side and increasing on the other, becomes equal to the two divisions.

The base of the pier must be so arranged that, meeting the result of the two tensions, with the weight of the pier and the revolving column, we obtain a total resultant which meets the base of the pier at a point in its interior, sufficiently removed from the nearest edge to avoid crushing the stone, and will also make with the vertical an angle inferior to the angle of the friction of the pillar on the stone, that is to say, inferior to 37° , or the *angle of friction*.

Each of the extremities of the chain, after having passed over the fixed or movable support which corresponds to the abutment, is carried into the ground, penetrating into a solid mass of masonry, united to the pier. Fig. 1500 shows this arrangement; the chain after passing over the support, takes the direction A B, generally more nearly approaching the vertical than the last side T A; at B it assumes a bent direction, so as not to require in the mass where it is moored dimensions needlessly great; with the point of inflection there usually corresponds a smaller revolving support; the chain afterwards descends in the direction B C into an inclined channel, which is terminated by a narrow opening closed by a plate of cast iron, to which the chain is fixed; below this is the mooring-hole C, into which there is access by the opening D to reach the point of attachment. The same opening usually serves for access to the two cavities on the same bank communicating one with another by a vaulted gallery. It is necessary for the equilibrium and stability of the system, that on composing the tension in the direction of A B with the weight of the mooring-block, a resultant should be obtained which meets the mass of the block at a point in its interior, at a sufficient distance from the nearest ridge, and which will make, with the vertical, an angle inferior to the *angle of friction* considered above. In accordance with this, the dimensions and consequently the weight of the block are determined.

As a rule, no great height is given to the supports, whether fixed or movable; it follows that the tension Q is rather considerable, for it varies in inverse ratio with the height; but in an economical point of view there is less inconvenience in slightly augmenting the section of the chains, than in increasing the height of the supports, which would besides have the effect of

diminishing stability. Where we are obliged to give a great height to the supports, they are united by stays A B, C D, Fig. 1501, which are attached to the top of one of the piers and fixed at the foot of the other: the figure shows this arrangement.

We have said that the actual point of attachment of the chains does not coincide with that which we have called the imaginary point of attachment, which is upon the vertical of the extremity of the roadway. In this interval, the chain having only its own weight to carry, affects the form of an arch of chainwork, which accords with the parabola circumscribed on the chain; but the two curves differ then so little one from the other, that we may without appreciable error consider the arch of chainwork as the prolongation of the parabola.

Iron Bridge Building.—The Charing Cross Bridge, erected to support the Charing Cross Railway over the Thames, occupies the site of the Hungerford Suspension Bridge.

This bridge comprises nine spans, Fig. 1502, six of 154 ft. and three of 100 ft. The superstructure over the three latter spans is fan-shaped, Fig. 1503, inasmuch as the ground available for the Charing Cross Station being somewhat restricted in length, it was necessary to begin the widening out on the bridge. It was found necessary to divide the opening between the Middlesex pier and abutment into three spans of 100 ft., instead of into two spans of 154 ft., as on the Surrey side.

The bridge is carried by cylinders, sunk into the bed of the river, and by the piers of the Hungerford Suspension Bridge, Fig. 1502, the upper portions of which have been removed, while the lower portions have been added to and modified, so as to adapt them for the railway bridge. The abutments of the Hungerford Suspension Bridge are also retained, but have been considerably lengthened and altered. The width of the river at the bridge is 1350 ft. The greatest depth of water between the two brick piers is 13 ft. below low-water spring tides, and the average depth is about 10 ft. The rise of spring tides is $1\frac{1}{2}$ ft. The level of the rails is 31 ft. above Trinity high-water mark, and the clear minimum headway is 25 ft. above the same level.

This bridge was designed by Hawkshaw, but the practical part of the work, which is by far the most considerable portion, is due to the engineering skill of Joseph Phillips.

Cylinders for the Openings 154 ft. Span.—The cylinders, excepting those at the fan end, are 14 ft. diameter below, and 10 ft. diameter above the ground, the junction between the two sizes being effected by an intermediate conical length, Fig. 1504. There are four piers (three intervening between the towers of the Hungerford Suspension Bridge and one between the tower and the abutment on the Surrey side) formed of cylinders of the above diameters, and each of the piers consists of two cylinders, 49 ft. 4 in. apart, from centre to centre. They are of cast iron, and are shown in detail in Figs. 1505 to 1507. The circumference of each cylinder of 14 ft. diameter, is divided into seven equal parts or segments, the segments being generally 9 ft. high; that of the cylinders 10 ft. diameter, is divided into five equal parts or segments, each segment being also generally 9 ft. high; whilst that of the intermediate or conical piece is similarly divided into five equal parts or segments, each 9 ft. high. The segments are fastened together inside, by bolts $1\frac{1}{4}$ in. diameter, passing through flanges cast on the top, bottom, and sides of the segments. A horizontal interior strengthening rib is cast on the middle of each segment. All the joints of the segments, both horizontal and vertical, are planed, and spaces are left inside between the flanges for the introduction of iron cement, to render the joints water-tight. The vertical joints of the segments, in each of the two lengths of different diameters respectively, are over one another. There are thus continuous vertical lines of ribs, securing a strong columnar arrangement. The

horizontal joints can also be made to fit better in this way than by breaking the vertical joints. The thickness of the metal in these cylinders is $1\frac{1}{8}$ in. throughout, excepting in the bottom length, where it is $1\frac{1}{2}$ in.

Sinking the Cylinders.—The staging for sinking the cylinders consisted of piles erected round the pier, supporting a stage or platform at the level of 4 ft. above high-water mark. When this staging was in its place, an opening of 45 ft. was left between two adjoining piers; but in order that the navigation might not be interrupted, only two openings, in the space between the two

brick piers, were allowed to be narrowed to that extent. The staging used in the two Surrey openings, which was generally similar to that employed for the other openings of the same span, is shown in Figs. 1508, 1509. The part up to the lower platform was erected for the purpose of sinking the cylinders. This was afterwards carried up, and the 45-ft. opening spanned, for the purpose of erecting the girders.

The strata through which the cylinders are sunk, Fig. 1502, consist of mud and gravel, of varying thicknesses, overlying the London clay. The cylinders were sunk by excavating the material from the inside, by means of divers, and then by weighting them as the excavation proceeded, until they had passed through all the porous material, and had entered a few feet into the solid London clay. The water was then pumped out, and the cylinder was kept dry during the rest of the operation. The sinking was then proceeded with, by excavating the material and by weighting the cylinders. The weight with which it was found necessary to load the cylinders, in order to overcome the friction of the sides, and to sink them to their final depth, averaged about 150 tons. The London clay extended to a depth far below the level at which the cylinders were founded.

The cylinders constituting the pier between the Surrey abutment and the brick pier, are sunk to a depth of 52 ft. below Trinity high-water mark. Those between the two brick piers are sunk to a depth of 62 ft. below the same level, excepting the up-stream cylinder of the middle pier, which had to be sunk 10 ft. deeper, on account of some of the material through which it passed being softer than that met with at the sites of the other cylinders.

Filling-in the Cylinders, and Weighting.—After the cylinders had been sunk, and the material had been excavated, they were filled with concrete up to where the conical part commences, and with brickwork from that level to the under-side of the granite bearing-blocks occupying the top of each cylinder. The concrete was composed of Thames gravel or ballast, that obtained from the excavation from the inside of the cylinders being used, so far as it was suitable and sufficient. This was mixed with Portland cement, in the proportion of one part of cement to seven parts of gravel. The brickwork is generally composed of the best pavioir bricks, set in Portland cement mortar, in the proportion of one part of cement to two parts and a half of sand.

Before the lengths above high water were put on, the cylinders, after they had been filled with the concrete and brickwork, were weighted with a load of about 450 tons, excepting the two cylinders in the pier nearest to the Surrey side, which were the first sunk, and weighted each with 700 tons, that being about the greatest load that could come upon any one cylinder, assuming the four lines of rails on the bridge to be loaded with locomotive engines. Upon the removal of the loads, it was found that each of the cylinders which had been weighted with 700 tons had permanently sunk 4 in., and each of the others that were loaded with 450 tons had permanently sunk, on an average, nearly 3 in. The larger loads were applied in order to test the strength of the foundations, and the subsequent smaller loads to bring the cylinders to a bearing, so as to prevent any settlement, after the completion of the bridge, from the weight of the permanent and moving loads. The load was applied by piling the permanent rails of the railway on the cylinders. After it was removed, the top lengths were put on, and were filled in with brickwork, and then the granite bearing-blocks were fixed in place. These blocks are 2 ft. 6 in. thick, and are in two equal pieces, which, when together, fill the cylinder, the joint being under and longitudinal with the girders. The granite blocks project 1 in. above the top of the cylinders, in order that the weight may be prevented from coming on the upper edge of the ironwork.

Each pair of cylinders forming a pier is connected together transversely by a wrought-iron box-girder, 4 ft. deep, strongly attached to the top of each, Figs. 1510 to 1512. This girder also serves the purpose of a cross-girder for supporting the roadway. Assuming the four lines of way on the bridge to be loaded with locomotive engines, the pressure on the base of the cylinders would amount to about 8 tons the square ft., and that on the brickwork at the top of the cone, where the cylinder is 10 ft. diameter, to about 9 tons the square ft. The former pressure, however, is on the supposition that no relief is afforded by the friction of the sides against the material through which the cylinders penetrate. If this were taken into account, as it should be, the 8 tons the square ft. would be much reduced, and it is clear that this pressure will not be approached.

Superstructure of the Openings 154 ft. Span.—The superstructure of each of the openings, 154 ft. span, consists of two main girders, underneath which are cross-girders, Fig. 1504. The main girders are, like the cylinders, 49 ft. 4 in. apart from centre to centre transversely, leaving a space between them sufficient for four lines of rails, the roadway platform being supported by the cross-girders. For the purpose of carrying the footpaths, each of which is 7 ft. wide, the cross-girders extend beyond the main girders, forming a series of cantilevers on each side of the bridge.

Main Girders Spanning the 154-ft. Openings.—These girders are of wrought iron. They are not continuous over two or more openings, but are all detached. Each has to support, inclusive of its own weight, a maximum distributed load of about 700 tons. The elevation, sections, and details of these girders are shown in Figs. 1513 to 1530. The extreme depth of the girders is 14 ft., and the depth between the centres of gravity of the top and bottom members is 12 ft. 9 in. When the girders are loaded with a maximum strain of 4 tons the sq. in. in compression, and of 5 tons the sq. in. in extension (which are the limits allowed for the wrought-iron work throughout the bridge), the sectional area in the top, at the centre of the girder, will be somewhat less than 300 sq. in., and that in the bottom, excluding the rivet-holes, will be somewhat less than 235 sq. in.; these being the respective central areas of the girders.

The sides of the girders between the bearings are divided by vertical bars into fourteen equal

parts, each division containing a double set of two diagonals crossing each other. These are placed, as nearly as practicable, at an angle of 45° with the top and bottom of the girder; and both the diagonals and the vertical bars are connected to the top and bottom webs by pins of puddled

steel. The top and bottom webs of the girders are of boiler-plate, and consist of horizontal tables 4 ft. wide at the top and 3 ft. wide at the bottom, and of four vertical ribs, the two outer rows being 24 in. deep, and the two inner 21 in. deep. The joints of the plates, in the horizontal tables

of the top and bottom webs, are covered by a continuous plate running the whole length of the girder; that in the top being of the same thickness as the plates covered, and that in the bottom $\frac{1}{8}$ in. thicker, Figs. 1525 to 1528. The joints in the vertical ribs in the top and bottom occur near the pin-holes, and are covered by 1-in. plates, 2 ft. 4 in. long, placed on both sides of the ribs, thus forming a good bearing for the pins, Figs. 1529, 1530. The vertical ribs are united to the horizontal tables by angle-iron, 6 in. by 6 in., by 1 in. thick in the centre and $\frac{3}{4}$ in. thick at the ends, covered at the joints. The rivets used throughout the top and bottom of the girders are 1 in. diameter, and their pitch is about 4 in.

The aggregate thickness of the plates in the horizontal table of the top in the centre of the girder being $3\frac{1}{2}$ in., and in the bottom $3\frac{1}{8}$ in., without the angle-iron, and $4\frac{1}{2}$ in. and $4\frac{1}{8}$ in. respectively, with the angle-iron, but excluding the angle-iron covers, it would not be easy to unite the parts composing such a thickness by rivets passing through holes punched in the metal. However perfectly the holes may be set out in the first instance, the process of punching always stretches the iron; so that, when the plates are put together, the holes do not come accurately over one another. Neither would they have been truly cylindrical throughout, as they are always, when punched, larger on one side than the other: so that where so many thicknesses had to be united, imperfect riveting would have resulted, unless rimering out to a great extent had been resorted to.

The diagonals which act as ties are of Howard's rolled suspension links, each separate tie being composed of two or three links riveted together. The diagonals acting as struts are each in one solid forging. The struts and the ties have swelled ends for the pins. The struts are united together in pairs, by zigzag bracing of wrought iron, $4\frac{1}{2}$ in. wide by $\frac{3}{4}$ in. thick, riveted to them, and by bolts passing through cast-iron distance-pipes. The ties, also in pairs, are not united together; but in the centre of the girders, where the diagonals act both as struts and ties, the pairs are united together in the two central spaces by the zigzag work. The dimensions of the struts vary from 12 in. by 3 in. at the ends, to 6 in. by $2\frac{1}{2}$ in. in the middle; and of the ties, from 12 in. by $2\frac{1}{2}$ in. at the ends, to 6 in. by 2 in. in the middle. They are 7 in. diameter at the ends of the girders, decreasing to 5 in. diameter at the centre, and are 11 ft. apart from centre to centre.

At the ends of the girders the sides over the supports are boxed, being composed of $\frac{3}{4}$ -in. plate iron, stiffened by angle and T iron. Where the girders bear upon the brick piers and upon the Surrey abutment, they rest upon roller bed-plates; but upon the cylinders sheet lead only is interposed between the girders and the granite blocks. The force of expansion and contraction will probably cause the cylinders between the brick piers to rock to and fro to a certain but inappreciable extent. The girders were put together in place on the staging, Figs. 1508, 1509. The top of the girder was put together on the top upper platform, and the bottom of the girder on the top lower platform, the two platforms being kept at the correct distances apart by diagonals, converting the whole into a framework of timber. The supports on the platforms, on which the girders were erected, were accurately adjusted to the proper camber of the girders.

The struts, with the diagonal bracing, were also put together at the works of Cochrane and Co., and the pin-holes were bored out to the full size; so that they, and also the ties, were sent up in a complete state. When the top and bottom webs were in place, the struts and the ties were erected, and the pin-holes in the girders were accurately bored out, by means of a boring apparatus worked by a small steam-engine, the gauge of the running wheels of which was so adjusted, that it might work backwards and forwards on the two outer vertical ribs of the lower part of the girder. Great care was taken to ensure accuracy in the direction and position of the holes. The pins, after being coated with grease, were forced into the holes, the diameter of the latter being such that the former could only be driven in by exerting a considerable force, a perfect fit being thereby established. The vertical bars dividing the sides into the several spaces are 6 in. wide by 1 in. thick. They have not been taken into account in calculating the strains. They fit on to the ends of the steel pins, and are in pairs, one on either side, and outside the outer vertical ribs of the top and bottom, and are connected together by bolts and distance-pipes. The only use they serve is to stiffen the girder.

The ends of the pins are covered with circular castings, screwed on; and over the ends, resting on the cylinders, ornamental castings are fixed.

The weight of each main girder spanning the 154-ft. openings is 190 tons.

One of the main girders was tested, when in place, with a distributed load of 400 tons, and the deflections were accurately taken. The load being very great, and the girder being unconnected transversely (the cross-girders not having been fixed), great care had to be observed in putting on the weight, which consisted of the rails of the railway. The manner in which it was loaded will be understood from Figs. 1531, 1532. The greatest deflection in the centre, when the

load was on, was $1\frac{1}{16}$ in., and the permanent deflection, after the load was removed, was $\frac{1}{2}$ in., Fig. 1533. If the girders had been rigidly connected transversely by the cross-girders, the deflection would doubtless have been less. This has since been proved to be the case. The whole of

the bridge, in its completed state, has been tested by a maximum load, and the greatest deflection of the main girders has not been more than $\frac{3}{8}$ of an in. in the centre.

The plate iron used throughout the bridge was also tested. These are interesting, as both the extension and the permanent set were carefully taken by an accurate *extensometer*.

1533.

It has been before stated that the girders are all detached, and not continuous over two or more openings. Hawkshaw's original intention was to connect the girders spanning the two end openings on the Surrey side, and also to connect the girders spanning the four central openings. As regards the girders spanning the two openings on the Surrey side, it was found that it was not easy to gain the full advantage from continuity, inasmuch as the girders having to support a considerable load, the thickness of the plates in the top and bottom was too great to render it practicable to reduce them to a minimum at the point of contrary flexure. Moreover, the strain on the diagonals would have been greater at the central support than at the end supports, and the uniformity in size of the struts and ties could not have been maintained, had their correct dimensions consequent upon continuity been adopted. It was also desirable not to increase the strain on the diagonals, as the end struts are already large forgings. The same remarks apply, more or less, to the girders spanning the four central openings, although in this case greater advantage would have been gained by continuity. More difficulty, however, would have been experienced in their erection, inasmuch as the Conservators of the River Thames only allowed the staging to be erected in the river for two of the central openings at one time. It is clear, also, that much more trouble would have been incurred in constructing continuous girders over several openings, than in putting together a series of detached girders. In the former case there would be a multitude of dissimilar parts, whilst in the latter all the girders would be duplicates of one

1534.

1535.

another. Better workmanship is thus ensured, and at a less cost a ton. In order to ascertain whether any saving of metal would be effected by the girders being constructed on the continuous or non-continuous system, drawings of both were prepared, and the weights were accurately calculated. The difference was inconsiderable in the case of the side openings, and was not of sufficient importance over the central openings to counterbalance the advantages to be derived from non-continuity.

Cross-girders for the Openings 154 ft. Span.—The cross-girders for the openings, 154 ft. span, are shown in Figs. 1534 to 1537. They are of wrought iron, and are suspended from the main girders. The top and the bottom of that portion of the cross-girders between the main girders consist of two plates, 18 in. wide by $\frac{5}{8}$ in. thick. The sides are of lattice-bars, united to the top and bottom by two angle-irons, 5 in. by $\frac{1}{16}$ in. thick. These cross-girders are 4 ft. deep in the middle and 2 ft. $1\frac{1}{2}$ in. deep where the cantilevers are united to them outside the main girders,

1536.

1537.

3 c

the bottom being fish-bellied, and the top having a camber of $3\frac{1}{2}$ in. in the centre. The lattice-bars are fixed at an angle of about 45° with the top and bottom. The ties are in two bars throughout, and each bar varies from 6 in. by $\frac{1}{2}$ in. at the ends to 4 in. by $\frac{1}{2}$ in. in the middle. The struts are in one bar passing between the two ties, and vary from 6 in. by 1 in. at the ends to 4 in. by 1 in. in the middle. The rivets in the cross-girders are $\frac{1}{8}$ in. diameter. The cantilevers decrease from 2 ft. $1\frac{1}{2}$ in. deep at their junction with the cross-girders to 1 ft. 2 in. deep at the extremities. The top and bottom of the cantilevers are composed of two angle-irons, $3\frac{1}{2}$ in. by 3 in. by $\frac{1}{2}$ in. thick, and the sides are of lattice-bars also placed at an angle of about 45° with the top and bottom; the ties likewise consist of two bars and the struts of one bar passing between them, each of the former being 2 in. by $\frac{3}{4}$ in. and the latter 2 in. by $\frac{3}{4}$ in.

It will be seen, therefore, that the cross-girders are generally similar in character to the main girders. They are suspended from the under-side of the main girders at the points where the pins occur. They are therefore placed 11 ft. apart, from centre to centre. The sides of the cross-girders, where they are underneath the main girders, are boxed in with plate iron. They are suspended by four angle-irons—two on either side—and outside the outer vertical ribs of the bottom of each main girder, to which, and to the boxed sides of the cross-girder these angle-irons are riveted. By this means a strong and good attachment is established. The cross-girders are connected together by wrought-iron cross-bracing attached to the centre of each, Fig. 1503. Each cross-girder, including the two cantilevers, weighs 9 tons. They were tested by erecting two cross-girders in the contractor's yard, placed transversely 6 ft. apart in the clear, the cantilevers being removed. They were then loaded with 140 tons (equivalent to 70 tons on each girder) distributed over the span. The maximum deflection in the centre, when the load was on, was 1 in.; and the permanent deflection, when the load was removed, was $\frac{1}{2}$ in. This result would doubtless have been better had the cross-girders been in place and rigidly fixed at the ends to the main girders. The whole of the cross-girders have since been tested in place with a maximum load, and the deflection has in no case been more than $\frac{3}{4}$ in. in the centre.

Fan End.—The superstructure of the three openings, 100 ft. span each, of the fan end is supported by the Middlesex brick pier and by the Middlesex abutment of the bridge, and intermediate to these by piers of cast-iron cylinders, that next to the brick pier consisting of a row of seven cylinders, and that next to the abutment of a row of nine cylinders. In these two rows, Figs. 1503, 1538, the outer cylinders are 10 ft. diameter below and 8 ft. diameter above the ground, and the inner ones are also 10 ft. diameter below but only 6 ft. diameter above the ground, the junction between the two lengths of different diameters being effected by a conical length. The circumference of the lower lengths of the cylinders, 10 ft. diameter, is divided into segments, which are generally similar, and are connected together in the same way, as the upper lengths of the cylinders already described, of the same diameter, in the piers of the openings 154 ft. span. The upper lengths of the outer cylinders 8 ft. diameter, and of the inner cylinders 6 ft. diameter, are not divided into segments, but are cast in pieces complete on the circumference, and 5 ft. long. These pieces are fastened together, by bolts $1\frac{1}{2}$ in. diameter passing through flanges cast on the top and bottom. All the joints throughout these cylinders are made water-tight by iron cement. The cylinders in these two piers have been sunk in place, precisely in the same manner as the cylinders of the openings of 154 ft. span, and to depths averaging about 40 ft. below Trinity high-water mark. When in place and when all the material had been excavated from the inside, they were filled with Portland cement concrete to the level of about 5 ft. above Trinity high-water mark. It was not considered necessary to fill in the remaining portion of these cylinders.

As some irregularities, or deviations from the perpendicular, occurred in sinking some of the cylinders in the row next the Middlesex brick pier, a horizontal casting, extending over all the cylinders of this row, was bolted to them at about the level of the ground, Fig. 1538; on this casting the upper parts of the cylinders of this pier are fixed.

On account of the great width of fan, which increases from 49 ft. 4 in. from centre to centre of the outside girders at its commencement at the Middlesex brick pier (this being the width between the parallel main girders spanning the 154-ft. openings) to 168 ft. from centre to centre of the outside girders at the abutment, the system pursued in the other openings, of supporting the roadway on cross-girders suspended from outside main girders, was clearly inadmissible. It was also undesirable to introduce intermediate main girders, projecting above the roadway. The roadway over the fan is, therefore, carried by interior plate-girders, laid at right angles to the piers and the abutment, and by the outside main girders, which are at the angle of inclination of the fan. These latter, Figs. 1539 to 1542, are of the same depth, and although lighter in all the parts, are generally of the same character, and are fixed at the same level, as the girders

of the openings 154 ft. span. The faces of the bridge have, therefore, a uniform appearance throughout.

The interior plate-girders, where they bear on the cylinders, rest on a bed-plate, Figs. 1503 to 1543, extending over all the cylinders of each row. They are connected together by cross-bracing in the centre of each span, and at points intermediate between the centre and the supports; and where they rest on the Middlesex pier and abutment are built into the brickwork. The bottom of these girders is at a lower level than the bottom of the outside main girders, inasmuch as it was impossible to obtain sufficient depth without resorting to this arrangement. As it is, the depth of these girders is only 5 ft., or $\frac{1}{20}$ of the span. If the spans in the fan had been 154 ft., the interior plate-girders instead of being $\frac{1}{20}$ would have been less than $\frac{1}{30}$ of the span. Hence the advantage of introducing the smaller spans of 100 ft. The elevations and sections of the interior plate-girders are shown in Figs. 1543, 1544. They are of the ordinary construction, and weigh about 26 tons each.

The outside main girders do not make exactly the same angle with the centre line produced of the parallel portion of the bridge. The shape of the fan is therefore not accurately that of an isosceles triangle—the distance between the centre line of the fan and the centre line produced of the parallel portion of the bridge, being 7 ft. 9 in. at the Middlesex abutment, Fig. 1503. These outside main girders, which are over the centre of the outside cylinders of the piers, are raised above the interior plate-girders by cylindrical making-up pieces of the same diameter (8 ft.) as the upper lengths of the outside cylinders, Fig. 1538. These cylindrical pieces are filled with brickwork in cement, resting on the bed-plate, the top being covered with a bed of an inch in thickness of Portland cement, raised $\frac{1}{2}$ in. above the top of the cylinder, and forming the bearing surface of the girders.

The triangular spaces between the outside main girders and the outer interior plate-girders are filled in with cross-girders, riveted to the sides of the latter and suspended underneath the former, and are terminated by cantilevers projecting beyond the face-girders, Figs. 1503, 1538. These cantilevers are similar to those outside the main girders of the 154-ft. openings, and like them are placed about 11 ft. apart from centre to centre, thus preserving the uniformity.

The girders of the fan rest directly on their supports, no rollers being interposed, excepting underneath the outside main girders, where they rest on the Middlesex brick pier and abutment; but the bearings for the interior plate-girders on the cast-iron bed-plate over the cylinders are planed. The ends of the cylinders on which the bed-plate rests are also planed.

Roadway and Footpath Platforms.—The roadway platform over the openings 154 ft. span, consists of planking 4 in. thick, spiked to longitudinal timbers, 15 in. by 15 in., placed underneath the rails, and bolted to the cross-girders. The roadway platform over the fan end consists of planking 6 in. thick, secured to the interior plate-girders and to longitudinal timbers spanning the cross-girders in the triangular spaces. By abandoning the longitudinal timbers in the fan over the shallow interior plate-girders, which the arrangement permitted, additional depth was obtained for these. The footpath platform on each side consists throughout of planking 6 in. thick, secured to the top of the cantilevers. The roadway platform is covered with tar pavement about 2 in. thick, and the footpath platforms with asphalt 1 in. thick. The longitudinals and the whole

of the planking are creosoted, and the latter is grooved and tongued with iron, and caulked with tar and oakum. The rails over the bridge are flat-bottomed, and of the ordinary section. On the outside of the footpath an ornamental railing, of cast-iron, is fixed, Figs. 1545 to 1548. A

railing of a pattern generally similar is fixed to the main girders on the inside of the footpaths, to prevent the railway being trespassed upon.

On the Charing Cross railroad there are several small iron bridges, many similar to Broadwall Bridge, Figs. 1549 to 1553. This bridge consists of six inner working girders and two face-girders

At each end of girder there is a bearing-plate. For face-girder, top flange, 9 in. wide by $\frac{1}{2}$ in. thick, not centred with web, to which it is connected by two angle-irons $3 \times 3 \times \frac{1}{2}$.

The girders in this bridge are braced by a system of diagonal bars, 3 in. $\times \frac{1}{2}$ in., connected to girders by means of short pieces of T-iron, riveted to top and bottom of webs about 6 ft. 8 in. apart.

In addition to the ordinary angle-iron cover, a strip is riveted to the opposite side of the girder.

The weight of the six working girders is $26\frac{1}{2}$ tons; of the two face-girders, $4\frac{1}{2}$ tons; and of the whole bridge, 43 tons.

Wellington Street Bridge.—This, on the same line, is the largest single-web girder bridge on the line, the length of the girders being 134 ft., and the span on skew 118 ft. The girders are 12 ft. deep at centre, and 9 ft. 8 in. at the ends.

The flanges are 2 ft. 6 in. wide, riveted with six rows of 1-in. rivets. The top flange is built up of five $\frac{1}{2}$ plates at centre, reduced to three at ends. In addition to the two angle-irons which connect this flange to web, there are two others of the same size, $5 \times 5 \times \frac{1}{2}$, riveted to each edge, Figs. 1554, 1555. The bottom flange is built up of one $\frac{1}{2}$ and four $\frac{1}{2}$ plates, reduced at ends to one

$\frac{1}{8}$ and two $\frac{3}{8}$ plates. On each side of the upper side of this flange a bar, 9 in. $\times \frac{1}{8}$, is riveted. This is shown in Figs. 1554 to 1558. Fig. 1558 shows the way the plates break joint.

The web-plates, with the exception of the end ones, are 2 ft. 2 in. wide, the end ones being 2 ft. wide, as shown in Fig. 1558, $\frac{3}{8}$ thick for a length of nine plates at either end, and $\frac{1}{4}$ for the remaining distance.

Referring to Figs. 1556 to 1558, it will be seen that a $\frac{1}{2}$ plate is riveted to the ends of the girders by means of angle-iron *gussets*, 3 in. $\times$ 3 in. $\times \frac{3}{8}$ in.; also, that at the two end web-joints $\frac{1}{2}$ *gusset*-plates are riveted, with similar angle-iron. After the bridge was erected, it was found necessary to stiffen the ends of the girders by

attaching reverse angle-iron, 3 $\times$ 3 $\times \frac{1}{2}$, to the end and *gusset* plates. The intermediate vertical joints of web are connected by two T-iron *gussets*, 6 $\times$ 3 $\times \frac{3}{8}$, and two strips, 6 $\times \frac{3}{8}$ alternately. These strips, as shown in Fig. 1551, are cranked to set over the longitudinal angle-iron.

One end of each girder was provided with a bearing-plate, 5 ft. $\times$ 4 ft. $\times \frac{3}{8}$; the other end had attached to it a cast-iron plate, 2 in. thick, to bear on eight rollers, 4 $\frac{1}{2}$ in. diameter. The roller-beds are also of cast iron, 2 in. thick, and further strengthened by having three ribs, 3 in. deep, cast on; the roller-frames are of wrought iron, 3 in. $\times$ 1 in.

A longitudinal section of this roller arrangement is shown in Fig. 1558, and a transverse section in Fig. 1557.

In Fig. 1558 the lengths of top and bottom angle covers are shown by the number of rivets in each. The first have seven and eight holes in each arm respectively, and the second nine and ten; so that, since the rivets are 4-in. pitch, the lengths are 2 ft. 8 in. and 3 ft. 4 in.

The ordinary lengths of

Angle-bars	13 ft.	Joints to flat bars	3 ft. 4 in.
Flat bars, 9 $\times \frac{1}{8}$	17 ft. 4 in.	Laminated plates	6 ft. 8 in.

The dimensions A A, Fig. 1558, are 16 in. each, so that they contain four rivets in the direction of length of girder each. Considering one plate only, since there are six rows of rivets, we have an aggregate of twenty-four 1-in. rivets, or a sectional area of 18.84 sq. in. against 14.76 sq. in., the sectional area of a bottom plate through a line of rivet-holes; or an excess in area of rivets of 4.08 sq. in.

The cross-girders are 41 ft. 6 in. long, which makes the distance, centre to centre, of main girders 39 ft. The distance, centre to centre, of the cross-girders themselves, is 4 ft. They have a central and end depth of 2 ft. and 1 ft. 4 in.; the flanges are 15 in. $\times \frac{1}{2}$, connected to a $\frac{1}{2}$ web by 4 $\times$ 4 $\times \frac{3}{8}$ angle-iron. The top flange has also riveted to it an extra plate, 19 $\times \frac{1}{2}$, for attaching roadway plate. Fig. 1555 is a section of one of the girders, showing a road-plate attached at B. The length of the girder is divided into eight panels by vertical T-irons at joints, 5 $\times$ 2 $\frac{1}{2} \times \frac{3}{8}$.

At each end of the bridge there are also shorter cross-girders; but they are the same as a 41 ft. 6 in. girder, with a piece cut off one end. The ends of the cross-girders are riveted to the mains with twenty-four rivets, 1 in. diameter.

To the ends of the cross-girder, a cast-iron cornice, C, Fig. 1554, is bolted.

The rivets through longitudinal angle-iron and webs are 1 in. diameter, and through vertical

T-irons, strips, and webs, only $\frac{3}{4}$ in. diameter. The weight of each main girder is 65 tons: of all the cross-girders, 80 tons; and of the whole bridge, 248 tons.

Bridge over the Blackfriars Road, Figs. 1559 to 1561.—One of the abutments of this bridge is at right angles to line, and the other only slightly out of square.

The main box-girders, which are 110 ft. long, have a central and end depth of 10 ft. 6 in. and 8 ft. 10 in.: both flanges are 2 ft. 6 in. wide; the top is built up of five $\frac{9}{16}$ plates at centre, reduced to four at ends; the bottom is built up of one $\frac{5}{8}$ and four $\frac{9}{16}$ plates at centre, reduced to one $\frac{5}{8}$ and three $\frac{9}{16}$ at ends. Each flange is connected to the webs by four angle-irons $6 \times 6 \times \frac{9}{16}$: eight in the whole section.

The two end web-plates at either end of each line are 2 ft. wide, and the intermediate ones are 3 ft.

The girders are braced internally at seven points by a system of lattice-bars, shown in Fig. 1559; the bars are $2 \times \frac{3}{8}$, and are riveted to T-irons, which, in this case, are substituted for the internal strips.

The cross-girders, twenty-four in number, have flanges 15 in. wide $\times \frac{1}{2}$ thick, riveted to a $\frac{1}{2}$ web by $4 \times 4 \times \frac{1}{2}$ angle-iron: they are 2 ft. deep, and each end is riveted to the main girder with twenty 1-in. rivets; the web is divided by vertical T-irons into eight panels.

The weight of both main girders is $106\frac{1}{4}$ tons; of all the cross-girders, 71 tons 12 cwt.; and of the whole bridge, 214 tons 17 cwt.

The roadway is on the second system, Fig. 1559.

The constructive arrangement of the bridge, exhibited in Figs. 1562 to 1569, introduced by Albert Fink, is a modification of the principles employed by Bollman. In this bridge a pair of diagonal tension-bars connect the foot of the principal strut, or *king post*, in each truss, with the ends of the top chord. This pair of diagonal bars support one half of the whole weight of the truss and its load. Each half-span is subdivided by a strut, and two diagonal tension-bars extend, one to the nearest end of the top chord, and the other to the top of the centre post. Each quarter-span is again subdivided into eighths, and these again, for spans greater than 100 ft., into sixteenths. In a truss of this kind, of sixteen panels, the weight at the bottom of the strut nearest to either of the piers is distributed thus:—Calling the weight one, one half is transferred directly through a tension-rod to the nearest end of the top chord, and to the pier. The other half is carried up to the top of the second strut from the pier, and is received at the bottom of that strut by a pair of tension-rods, which divide this half between them, one fourth being taken directly to the nearest pier, while the other fourth is transferred to the top of the strut at the quarter-span. This fourth is again divided at the foot of this strut, one eighth being transmitted through a tension-rod to the nearest pier, while the other eighth passes to the top of the middle strut of the span, and is received at the foot of this strut by the main tension-rods, each of which transmits one-sixteenth of the original load to each pier. Thus the weight at the foot of the first strut from the end of the truss is distributed thus:—One-half, one-fourth, one-eighth, and one-sixteenth, or, in all, fifteen-sixteenths of that weight reach the top of the nearest pier, through four converging sets of tension-rods, while the remaining sixteenth reaches the opposite pier, after being brought to the foot of the centre strut, through the intervention of three separate systems of tension-bars. With the exception of the load at the foot of the centre strut, which load is transmitted directly to the piers, the loads at the bottoms of the vertical struts are more or less subdivided before reaching the ends of the truss. In 1852, A. Fink erected a bridge of three spans, of 205 ft. each, across the Monongahela River, Figs. 1562 to 1569. The trusses for a single line are 16 ft. apart from centre to centre, and the main tension-chords are attached to the foot of the centre strut, 22 ft. 8 in. below the centre of the top chord, thus giving a depth of truss equal to 0.11 of the span. The top chords and the centre struts are of cast-iron pipes, octagonal in their external form, 12 in. diameter between their parallel surfaces, and 10 in. in internal diameter, thus giving 41 sq. in. of section. The main tension-rods in each truss are each formed of six bars, $4\frac{1}{2}$ in. by $1\frac{1}{2}$ in., giving

a section of $33\frac{1}{2}$ sq. in. The vertical struts, with the exception of the centre strut, are cast-iron octagonal pipes, 8 in. in external and 7 in. internal diameter.

Chain and Suspension Bridges.—Suppose a perfectly flexible chain or cord of uniform density and thickness to be suspended from two fixed points, A and B, Fig. 1570, and when in equilibrium to form the curve AOB; this curve is termed the *Catenary*. The equations of this curve, of so much importance in mechanics, being of a mixed exponential kind, mathematicians were obliged to resort to guessing and all sorts of dodges, to obtain results which were often very far from the truth. The results here referred to can now be obtained with the greatest ease by direct processes of the *dual calculus*, in an endless variety of ways, without the use of tables. It may be necessary to inform the reader, that here, as elsewhere, we accommodate those inexperienced in such inquiries with solutions under simple forms easily intelligible.

To find the Equations of the Catenary Curve.—Let O be the lowest point of the chain or cord AOB, Fig. 1570, OM = x ; Mr = y ; and the length of the arc Or = s . Again, let v be the length of a portion of the chain, the weight of which is equal to the tension at O. If we suppose the part Or rigid, after it has assumed the form of equilibrium, it will evidently be supported in the same manner, and the tensions at O and pqr will be the same as when it swung loosely suspended from the points A, B. O pqr is therefore kept at rest by three forces, namely, the tension at O acting in the direction of the tangent OY, the tension at the point pqr, acting in the direction of p q T, the tangent to the curve at the point pqr, and the weight of the piece of cord or chain Or, acting in a vertical direction. Because the three forces just described are respectively in the directions to the three sides of the triangle T p M, the forces being in equilibrium will be proportional to these sides.

Hence, (Weight of Or) : (Tension at O) :: TM : Mp. pqr represent a very small right-angled triangle, similar to the larger right-angled triangle T M p; in the language of the differential calculus qr is represented by dx , rp by dy , and $p q$ by ds . Whence, v being put for a piece of cord or chain, the weight of which is equal the tension at O in the direction of the tangent OY; therefore, $s : v :: dx : dy \therefore \frac{ds}{dx} = \frac{v}{s}$.

In every plane curve $(ds)^2 = (dx)^2 + (dy)^2$, and, consequently, $\frac{ds}{dx} = \left(1 + \frac{dy^2}{dx^2}\right)^{\frac{1}{2}}$.

∴ In the catenary $\frac{ds}{dx} = \frac{\sqrt{v^2 + s^2}}{s}$, or $dx = \frac{s ds}{\sqrt{v^2 + s^2}}$.

Taking the integral of this last equation, and observing that $s = 0$ when $x = 0$, we obtain

$$x + v = \sqrt{v^2 + s^2}, \text{ or } s^2 = x^2 + 2vx. \quad [1]$$

When v is determined, [1] is the equation of the catenary expressed by x and s as variables.

Again, because $\frac{dy}{dx} = \frac{v}{s} = \frac{v}{\sqrt{x^2 + 2vx}}$, which, being integrated, gives

$$\begin{aligned} \frac{y}{v} &= \log_e \frac{x + v + \sqrt{x^2 + 2vx}}{v} \\ \therefore \frac{y}{v} &= \frac{x + v}{v} + \frac{\sqrt{x^2 + 2vx}}{v}. \end{aligned} \quad [2]$$

ϵ being put for the base of the hyperbolic system of logarithms, [2] is an equation to the curve between the variable co-ordinates x and y ; v being unknown, but constant. The dual logarithm of $\epsilon = 10^8$, written $\downarrow(\epsilon) = 100000000$, $\epsilon = 2.718281828 \dots$

Transposing $\frac{x+v}{v}$, and squaring both sides of [2], we obtain

$$\begin{aligned} \frac{y^2}{v^2} - 2\epsilon^{\frac{y}{v}} \left(\frac{x+v}{v}\right) + \frac{(x+v)^2}{v^2} &= \frac{x^2 + 2vx}{v^2} \\ \therefore x + v &= \frac{v}{2} \left(\epsilon^{\frac{y}{v}} + \epsilon^{-\frac{y}{v}}\right). \end{aligned} \quad [3]$$

Further, because, [1] $s^2 = (x+v)^2 - v^2$, and $\frac{v^2}{s^2} = \frac{v^2}{x^2 + 2vx}$; $\therefore \left(\epsilon^{\frac{y}{v}} - \frac{x+v}{2}\right)^2 = \frac{s^2}{v^2}$

$$\therefore s = \frac{v}{2} \left(\epsilon^{\frac{y}{v}} - \epsilon^{-\frac{y}{v}}\right). \quad [4]$$

[4] is an equation to the *catenary* between the variables s and y ; it is to be particularly observed that v is unknown in [1], [2], [3], [4], but not variable. Suppose t to be the length of a portion of the cord or chain which is equal to the tension of Q, then $OE = x$, $EQ = y$, $OQ = s$, and $t : s :: QG : GE :: ds : dx$. $\therefore sds = tdx$. Differentiating [1], or $s^2 = x^2 + 2vx$, gives $sds = xdx + vdx$. $\therefore tdx = xdx + vdx$; dividing by dx gives $t = x + v$.

Now, suppose the tension at Q to be balanced by means of Q R, a portion of the chain passing over a pulley at Q and hanging freely; then $QR = x + v = OE + v$; consequently, $FR = YD = OC = v$, evidently a constant quantity, although unknown. Hence, if the tension be supposed to be balanced by means of portions of the chain or flexible body hanging over pulleys at the points pqr , Q, A, the lower ends will be in the same horizontal line, R, D, C.

Ques.—A heavy flexible chain, each foot in length weighing 20 lbs., is suspended at its extremities to two fixed points in the same horizontal line, 106.2 ft. asunder, the greatest depth of the curve being 15.8 ft. It is required to find the length of the curve, the tension at the lowest part, and the tensions at the points of suspension, by direct calculation, without the use of tables, or methods of approximation.

In dual arithmetic we have three corresponding numbers, namely, natural number, dual number, and dual logarithm; any one of these corresponding numbers being given, the other two may be found by a few simple additions and subtractions.

We have first to put equation [3] in form to be operated upon by dual arithmetic.

$$x + v = \left(\epsilon^{\frac{y}{v}} + \frac{1}{\epsilon^{\frac{y}{v}}} \right). \quad [3]$$

When y is put = 1, x may be represented c^2 , x and y being both given to find the value of v .

Hence [3] becomes $2c^2 \left(\frac{1}{v} \right) + 2 = \epsilon^{\frac{1}{v}} + \frac{1}{\epsilon^{\frac{1}{v}}}$

$$\therefore 2c^2 \left(\frac{1}{v} \right) = \epsilon^{\frac{1}{v}} - 2 + \frac{1}{\epsilon^{\frac{1}{v}}} = \left\{ \epsilon^{\frac{1}{2v}} - \frac{1}{\epsilon^{\frac{1}{2v}}} \right\}^2 \therefore c\sqrt{2} \left(\frac{1}{v} \right)^{\frac{1}{2}} = \epsilon^{\frac{1}{2v}} - \frac{1}{\epsilon^{\frac{1}{2v}}}; \text{ or,}$$

$$2c \left(\frac{1}{2v} \right)^{\frac{1}{2}} = \epsilon^{\frac{1}{2v}} - \frac{1}{\epsilon^{\frac{1}{2v}}}.$$

Putting $\frac{1}{2v} = z$, the last becomes

$$2c\sqrt{z} = \epsilon^z - \frac{1}{\epsilon^z}. \quad [5]$$

This question being the first of the kind solved by an independent and direct process, without employing tables or approximate methods of trial and error, it is therefore necessary that we should be particular with respect to details.

The dual logarithm of 2 is the whole number 69314718, written $\downarrow (2) = 69314718$. This logarithm is of the ascending branch, marked by a comma on the right of the logarithm below, and immediately after the arrow. The dual logarithm of the reciprocal of 2, or of $\frac{1}{2}$ is represented by the same whole number '69314718, and written, $\downarrow (\frac{1}{2}) = '69314718$; this logarithm is of the descending branch, marked by a comma to left of the logarithm above. When 69314718, is considered positive, '69314718 is considered negative, and *vice versa*.

Natural Numbers.	Dual Numbers.	Dual Logarithms.
2.00000000 .50000000	$\downarrow 7, 2, 6, 0, 7, 8, 2, 6,$ $\uparrow '6 '6 '0 '6 '8 '2 '0 '2$	69314718, '69314718

$$\downarrow (10) = 230258509, \text{ and } \downarrow \left(\frac{1}{10} \right) = '230258509;$$

the same notation and arrangement is applied to other natural numbers and their reciprocals. See the Editor's works on Dual Arithmetic.

In the question before us, $c^2 = \frac{15.8}{53.1} = .29755178907$;

$\therefore \downarrow (2c) = \downarrow (1.09096616) = \downarrow 0, 8, 7, 4, 6, 4, 5, 5, = 8706369$, and [5] becomes

$$\epsilon^z - \epsilon^z = 1.09096616 \sqrt{z} \quad \downarrow (\epsilon) = 10^8 = 100000000.$$

Then, putting u_1 , for the first dual digit of z , $\downarrow (\epsilon)$, and $'u_1$ for the first dual digit of the logarithm of $-z$, $\downarrow (\epsilon)$ the reciprocal to z , $\downarrow (\epsilon)$; $'u_1$ is nearly $= u_1$, but less than u_1 .

To place this matter in a clear light, it is only necessary to observe that

$$\text{If } x = \downarrow 1, 0, 0, 0, 0, 0, 0, \text{ then } \frac{1}{x} = \downarrow '1 1, 0, 1, 0, 0, 0, 1; (9531018),$$

$$,, x^2 = \downarrow 2, 0, 0, 0, 0, 0, 0, \quad ,, \frac{1}{x^2} = \downarrow '2 2, 0, 2, 0, 0, 0, 2; (19062036).$$

$$,, x^3 = \downarrow 3, 0, 0, 0, 0, 0, 0, \quad ,, \frac{1}{x^3} = \downarrow '3 3, 0, 3, 0, 0, 0, 3; (28593054), \text{ and so on.}$$

$$\downarrow (x) = \downarrow (1 \cdot 1) = \downarrow, 1, 0, 0, 0, 0, 0, 0, 0, = 9531018;$$

$$\downarrow \left(\frac{1}{x} \right) = \downarrow \left(\frac{1}{1 \cdot 1} \right) = \downarrow, '1, 0, 1, 0, 0, 0, 1, = '9531018; \text{ and so on.}$$

These things being premised, we have

$$1 + \downarrow [u_1 \dots] - (1 - \uparrow [u'_1 \dots]) = 2c\sqrt{z} = 2\sqrt{u_1 \times (.9531018)};$$

but since u_1 is nearly equal to u'_1 , in order to find a convenient value for u_1 the last equation may

$$\text{be put under the form, } + 2 \left(\frac{u_1}{10} \right) = 2c\sqrt{u_1 \times (.9531018)}$$

$$\therefore \frac{u_1^2}{100} = c^2 u_1 (.9531018); \text{ or } u_1 = 100 c^2 (.9531018);$$

which gives $u_1 = (.29755 \dots) (100) (.953 \dots) = 2.835 \dots$. Because 2.835 ... is less than a convenient value for u_1 , but greater than the corresponding value of u'_1 ; consequently $\downarrow 3$, is a convenient value for u_1 . By pursuing a similar process of reasoning, z as far as the fourth dual digit will be found to be equal $\downarrow 3, 0, 3, 4, u_3$; the next step gives the four succeeding digits, and at the same time develops the general plan of operating on such equations; besides, a mistake that may be made in the preceding operations will be detected.

$$\downarrow (1.33553107) = \downarrow, 3, 0, 3, 4, 0, 0, 0, 0, = 28932904,$$

Reciprocal, '28932904 = $\uparrow, '2, '7, '8, '2, '5, '1, '6, '5 = \downarrow, (.74876579)$. Putting z_1 for the dual logarithm of $\downarrow 3, 0, 3, 4, u_3$, ... divided by 10^8 , or $z_1 = .28932904 + .00001000 u_3$; now equation [5] becomes

$$\epsilon^2_1 - \frac{1}{\epsilon^2_1} = 2c\sqrt{.28932904 + .00001000 u_3} = 2c\sqrt{.28932904} \sqrt{1 + .00003803 u_3} =$$

$$(\downarrow 0, 8, 7, 4, 6, 4, 5, 5), \sqrt{.28932904} (1 + .00001902 u_3) = .58682320 (1 + .00001902 u_3)$$

$$\begin{array}{r} .58682320 \\ \hline \end{array}$$

$$\begin{array}{r} 587 \\ \hline 528 \\ \hline 1 \end{array}$$

$$\begin{array}{r} 1116 \end{array}$$

$$.00001116 \text{ for } .00001902$$

$$\therefore 2c\sqrt{.28932904 + .00001000 u_3} = .58682320 + .00001116 u_3$$

$$\epsilon^2_1 - \frac{1}{\epsilon^2_1} = 1.33553107 (1 + \downarrow [u_3]) - .74876579 (1 + \uparrow [u'_3 \dots]);$$

$$1.33553107 (1 + \downarrow [u_3 \dots]) \text{ may be put } = 1.33553107 (1 + .00001000 u_3),$$

$$\text{and } -.74876579 (1 + \downarrow [u'_3 \dots]) \text{ may be put } = -.74876579 (1 + .00001000 u_3);$$

$$\therefore \epsilon^2_1 - \frac{1}{\epsilon^2_1} = .58675628 + 2.08429686 (.00001000 u_3) \quad \begin{array}{r} 2.08429686 \\ \hline 2084 \end{array}$$

$$\therefore .58675628 + .00002084 u_3 = .58682320 + .00001116 u_3 \quad \therefore u_3 = \frac{5792}{968} = 5.983$$

$$10^8 z = \downarrow, 3, 0, 3, 4, 5, 9, 8, 3, = 28938887, \quad \therefore z = \frac{1}{2v} = .2893887$$

$$\therefore v = 1.72777897 \text{ true to the last figure, when } y = 1; \quad \therefore \text{ when } y = 53.1, v = 91.745063 \text{ ft.}$$

$$\text{From [1], } s^2 = x(x + 2v) = 15.8(15.8 + 183.490126) \quad \therefore s = 56.11395$$

$$\therefore \text{ the length of the whole curve, } QOH, \text{ Fig. 1570, is } 112.2279 \text{ ft. } x + v = 107.545 \text{ ft.}$$

$$\text{Tension at the lowest part} = 91.745 \times 20 = 1834.9 \text{ lbs.}$$

$$\text{Tensions at points of suspension} = 107.545 \times 20 = 2150.9 \text{ lbs.}$$

Ques.—The length of a heavy flexible chain AOB, Fig. 1570, is just double the horizontal line AB, joining the points of suspension A and B; required the pressure on these points and the tension at the lowest point O; the distance of O from the horizontal line AB is also required.

If A X = 1, the length of half the curve, or A Q O, = 2, and equation [4], becomes

$$2 = \frac{v}{2} \left(\frac{1}{\epsilon^v} - \frac{1}{\epsilon^v} \right); \text{ and putting } z = \frac{1}{v} \epsilon^v - \frac{1}{\epsilon^v} = 4z.$$

When $z = 2$ the dual logarithm of ϵ^v is nearly = the dual log. of 8; $4z = 8$ also. It may be remarked here that, in operating with the dual calculus, we may take dual digits much greater or much less than any particular one pointed out, and yet obtain, without tentative artifices, a result as near the truth as we please. Since this method gives the same result as near the truth as we please, by several direct processes, it presents a series of direct operations, and not a succession of approximate trials.

$$\downarrow, (7.38905604) = 200000000, \text{ and } \downarrow, (.13533528) = '200000000; \text{ consequently we may assume } 7.38905604 (1 + \downarrow [u_1 \dots]) - .13533528 (1 + \downarrow [u'_1 \dots]) = 4(2.200000000 + .09531018 u_1); \text{ (A)}$$

$$200000000, \text{ is increased by } 9531018, \text{ for every unit in } u_1; \text{ and } 2.000000000 \text{ by } .09531018.$$

To find a convenient value for u_1 , (A) may become

$$7.25372076 + 7.52439132 \frac{u_1}{10} = 8.00000000 + .38124072 u_1$$

$$\therefore .37119841 u_1 = .74627924 \quad \therefore u_1 = + 2 \text{ or } \downarrow 2,$$

In practice, one-tenth of the figures here employed would not be required to find that $\downarrow 2$, is a convenient value for u_1 . This may be too great, but that is of no consequence, as the next digit may be negative to compensate for the excess in taking

$$u_1 = \downarrow 2, 200000000, + 19062036, = \downarrow, (8 \cdot 94075744) \text{ and } '219062036 = \downarrow, (.11184734).$$

To find a convenient value of u_2 , the equation now takes the form,

$$8 \cdot 96075744 (1 + \downarrow [u_2 \cdot]) - .11184734 (1 + \uparrow [u_2 \cdot]) = 4 (2 \cdot 19062136 + .00995033 u_2);$$

$$\text{therefore we may put } 8 \cdot 82891010 + 9 \cdot 05260478 \frac{u_2}{100} = 8 \cdot 76248144 + .03980132 u_2$$

$$\therefore u_2 = -1 \cdot \text{ or } \downarrow 0, '1.$$

For every unit in u_2 , we employ 995033, and .00995033; but for every unit in $'u_2$ we employ '1005034 and - .01005034.

$$\begin{array}{r} 219062036, \\ '1005034 \end{array}$$

$$218057002, = \downarrow, (8 \cdot 85134984); \quad '218057002 = \downarrow, (.112977175)$$

$$\therefore 8 \cdot 85134984 (1 \downarrow [u_3]) - .11297718 (1 + \uparrow [u_3 \cdot]) = 4 (2 \cdot 18057002 + .0009950 u_3)$$

$$\text{This gives } u_3 = -3 \text{ or } \downarrow '0 '0 '3$$

This process being continued gives $z = 2 \downarrow 2, '1 '3 '3 '5, 0, 5, 2$, the log of ϵ^z is 217731902, for $\downarrow, 2, '1 '3 '3 '5, 0, 5, 2$, Putting B for the base 1'00000001, then $B^{217731902} = \epsilon^{2 \cdot 17731902}$.

The reciprocal of $2 \cdot 17731902 = .45928042 = v$, the length of chain which is = tension at O.

But as $x^2 + 2vx = s^2$; $x = 1 \cdot 592779 = X O$.

$x + v = 2 \cdot 052059$ = the length of the chain that amounts to the tension at A and B.

Ques.—Given the length of a heavy flexible chain R Q O H N = 1130 ft. (2 a), Fig. 1570; this chain hangs freely over two pulleys Q, H in the same horizontal line Q H, = 226 ft. (2 b); required the position in which it will rest, the length of Q R, and the length of chain that is equal to the tension at O. Let Q E : O Q R :: 1 : n or b : a :: 1 : n. It is evident that when the chain is in a state of rest, what in the foregoing questions was the pressure on the points of suspension Q, H, will be equal to the weight of either H N or of Q R = $x + v$, the parts hanging vertically. Putting s = the length of Q O, when Q E = 1 = y; O Q R = n; and Q F = E O = x, then $x + v + s = n$; $v = F R = O C$.

$$\left. \begin{array}{l} \text{From [3].} \quad x + v = \frac{v}{2} \left(\epsilon^{\frac{1}{v}} + \frac{1}{\epsilon^{\frac{1}{v}}} \right) \\ \text{From [4].} \quad s = \frac{v}{2} \left(\epsilon^{\frac{1}{v}} - \frac{1}{\epsilon^{\frac{1}{v}}} \right) \end{array} \right\}, \text{ since } y = 1.$$

Whence, from adding these equations together we obtain $x + v + s = n = v \epsilon^{\frac{1}{v}}$

$$\therefore \downarrow, n = \downarrow, v + \downarrow, \left(\epsilon^{\frac{1}{v}} \right) = \downarrow, v + \frac{1}{v} \downarrow, \epsilon \quad \therefore v \downarrow, n = v \downarrow, v + \downarrow, \epsilon \quad \therefore v \downarrow, n - \downarrow, \epsilon = v \downarrow, v$$

$$\text{or } \frac{n^v}{\epsilon} = v^v \text{ or } \frac{1}{\epsilon} = \left(\frac{v}{n} \right)^v$$

Taking the $\frac{1}{n}$ root of both sides of the last equation we obtain an equation easily solved by the dual method. $\left(\frac{1}{\epsilon} \right)^{\frac{1}{n}} = \left(\frac{v}{n} \right)^{\frac{v}{n}} = z^z$, putting z for $\frac{v}{n}$

Hence we have the final equation $z^z = \left(\frac{1}{\epsilon} \right)^{\frac{1}{n}}$, or $z \downarrow, z = \downarrow, \left(\frac{1}{\epsilon} \right)^{\frac{1}{n}} = \frac{1}{n} \downarrow, \left(\frac{1}{\epsilon} \right)$.

Before the introduction of dual arithmetic, independent and direct solutions of equations of the above forms could not be effected.

$$\downarrow, \left(\frac{1}{\epsilon} \right) = '100000000; \text{ and } \frac{1}{n} = \frac{1}{5} = \frac{b}{a}; \quad \therefore z \downarrow, z = '20000000.$$

$$\therefore z = \frac{1}{12} \downarrow, '0 '6 2, 5, 6, 8, 3, 3, = .078658307; \quad \therefore v = .393291535, \text{ see Byrne's 'Essential Ele-}$$

ments of Practical Mechanics,' p. 124. The value of $z, = \frac{v}{n}$, not attainable by any previously known method, may be almost instantly obtained under a variety of forms by the dual calculus to any required degree of accuracy. In the present case,

$$z = \frac{1}{12} \downarrow, '0 '6 2, 5, 6, 8, 3, 3, 1, 7; \quad z = \frac{1}{20} \downarrow, 4, 7, 2, 1, 9, 8, 2, 2, = .078658307, \text{ and so on.}$$

Under the last form all the dual digits are positive.

$$\downarrow, \left(\frac{v}{n} \right) = '254264202 \quad \therefore \downarrow, \left(\frac{n}{v} \right) = 254264202,$$

$$\therefore \frac{n}{v} = 12 \cdot 7132147; \text{ and hence } \frac{1}{v} = 2 \cdot 54264294.$$

But we have before shown that

$$n = v \epsilon^{\frac{1}{v}} \quad \therefore \downarrow, \left(\frac{n}{v} \right) = \downarrow, \left(\epsilon^{\frac{1}{v}} \right) = 254264202, \text{ and } \downarrow, \left(\frac{1}{\epsilon^{\frac{1}{v}}} \right) = 254264202;$$

$$\text{Whence } s = \frac{v}{2} \left(\epsilon^{\frac{1}{v}} - \frac{1}{\epsilon^{\frac{1}{v}}} \right) \text{ becomes known.}$$

$$s = \frac{v}{2} (12.7132147 - .078658307) = (.393291535 \times 6.3172782) = 2.48448448;$$

Because, $x + v + s = n = 5$. $\therefore x = 2.12222398$.

In these calculations, $Q E = y$ is put = 1; but in the question, $Q E = 113$ ft.

$\therefore x = 239.8113097$ ft. = $E O = Q F$; $s = 280.74675$ ft. = arc $Q O$; and $v = 44.441966$ ft. = $F R = O C$ = the length of chain that is equal to the tension at O . $v + x = 284.253254$ ft. = $Q R$ = the length corresponding to the tension at Q or H .

Ques.—In the Chelsea Suspension Bridge, Thomas Page, engineer, the central span between the piers is 348 ft. with a deflection $O X$, Fig. 1571, of 29 ft.; supposing the entire weight of the

chain $A O B$, when the weight of the platform, roadway, and full load is transferred to it, to be 1.5 ton for each foot of its length, required the strains at the highest points A and B , and the tension at the lowest point O , as well as the length of the catenary curve passing through the points A, O, B .

$$\frac{348}{2} = 174; \frac{29}{174} = \frac{1}{6} = c^2 \quad \therefore 2c = .81649658.$$

Whence equation [5] becomes

$$.81649658 \sqrt{z} = \epsilon^z - \frac{1}{\epsilon^z} = 2c \sqrt{z}; \quad [a]$$

z being put for $\frac{1}{2v}$; v representing the length of the chain, whose weight is equal to the tension at the lowest point O .

We propose to find the value of v under the form $\downarrow u_1 u_2 u_3 \dots$. To find a convenient value for u_1 , assume $z = \downarrow u_1$, then [a] gives

$(1 + \downarrow [u_1, \dots]) - (1 + \uparrow [u_1, \dots]) = 2c \sqrt{z} = 2c \sqrt{u_1} \times .09531018$
 9531010 , being the dual of a logarithm of $\downarrow 1$, or of each unit in u_1 . Since we arrive at the exact value of z , whether we assume u_1 too great or too small,

$$(1 + [u_1]) - (1 - [u_1]) = + 2 \frac{u_1}{10} \text{ may be put } = 2c \sqrt{u_1} \times .09531018$$

$$\therefore \frac{u_1^2}{100} = c^2 (u_1 \times .09531018) = \frac{1}{6} (u_1 \times .09531018).$$

$$\therefore u_1 = \frac{9.531018}{6} = 1.59.$$

∴ The reciprocal of u_1 , or u_1 , may be put = $\downarrow 1'5'9 \dots$ or $u_1 = \downarrow 1,7$,
 $\downarrow (1'17934889) = \downarrow 1,7,0,0,0,0,0,0 = 16496249$.

Reciprocal = $16496249 = \downarrow 1'5'9'3'4'5'7'7 = \downarrow (.84792554)$.

It is easily found that o , is the most convenient value for u_3 , hence we may put in $[a]$
 $z = \downarrow 1,7,0, u_4$,

$$\therefore \epsilon^2 - \frac{1}{\epsilon^2} = 2c \sqrt{.16496249 + .00010000 u_4}$$

$$= 2c \sqrt{.16496249 (1 + .00030310 u_4)} = .33162478 (1 + .00030310 u_4);$$

$\epsilon^2 - \frac{1}{\epsilon^2}$ may also be put under the form

$$1.17934889 (1 + \downarrow [u_1 \dots]) - .84792554 (1 + \uparrow [u_4 \dots]) = (1.17934889) (1 + .00010000 u_4)$$

$$- (.84792554) (1 - .00010000 u_4) = .33142335 + .00020373 u_4$$

$$\therefore .33142335 + .00020373 u_4 = .33162478 (1 + .00030310 u_4) = .33162478 + .00010052 u_4$$

$$\therefore u_4 = \frac{.00020143}{.00010052} = \frac{20143}{19052} = 1.952$$

∴ z may be again put = $\downarrow 1,7,0,1,9, u_6$, when a greater degree of accuracy is required.

$$\downarrow (1.17957297) = \downarrow 1,7,0,1,9,0,0,0,0 = 16515249,$$

$$\text{Reciprocal, } 16515249 = \downarrow 1'5'9'5'3'6'2'1 = \downarrow (.84776406)$$

$$1.17957297$$

$$1.17957297$$

$$.84776406$$

$$.84776406$$

$$.33180891$$

$$2.02733 \overline{703}$$

$$.00000 \overline{203 u_6}$$

$$2c \sqrt{.16515249 + .00000100 u_6} = 2c \sqrt{.16515249 (1 + .00000303 u_6)}$$

$$= .33181570 (1 + .00000303 u_6)$$

$$\therefore .33180891 + .00000203 u_6 = .33181570 + .00000101 u_6$$

$$\therefore u_6 = \frac{.00000679}{.00000102} = \frac{679}{102} = 6.66 \quad \therefore \downarrow z = \downarrow 1,7,0,1,9,6,6,6 = 16515915,$$

$$\text{or } \epsilon = \frac{1}{.16515915} - \frac{1}{\epsilon^{.16515915}} = (.81649658) \sqrt{.16515915}.$$

To find the value of z in such equations as $[a]$, to any required degree of accuracy, and by such direct, independent, and simple means, is, without doubt, a great mathematical achievement.

$$z = \frac{1}{2v} \quad \therefore v = 3.02738298 = \text{three times the length of } O C.$$

$x + v = 3.19404964$; and the length of the catenary curve passing through the points

A, O, = $\sqrt{x^2 + 2vx}$, [1];

∴ the length of the curve A O = 1.01828555. But when A X = 174 ft., then $v = 526.7646$ ft.;
 $x + v = 555.7646$ ft.; and the length of the catenary curve passing through the points A, O, B,
 $= 354.36337$ ft. $(526.7646) \times (1.5) = 790.1468$ tons, the tension at the lowest point O in the
direction of the tangent O F, and represented by the lengths of the three lines O C, Fig. 1572.
 $(555.7646 \times (1.5) = 833.6469$ tons, the tension at the highest point A, but in the direction of
the tangent A T; this tension is represented by the lengths of the three lines F R, and the line
A F. The sectional area at the centre of the bridge = 214 sq. in. and the sectional area at
A and B = 230 sq. in.; hence a weight of only 5 tons to the sq. in. gives a power at O of
1070 tons, and at A and B a power to sustain a tension of 1150 tons with ease.

COMPARATIVE MERITS OF DIFFERENT SYSTEMS OF IRON BRIDGE BUILDING ACCURATELY EXAMINED.

Taken from Jules Gaudard's excellent work, 'Étude Comparative de Divers Systèmes de Ponts en Fer.'

General Symbols.

M = Moment of rupture, or moment of resistance which is equal to it;

F = Stress or transverse strain;

R = Resistance the square mètre (6000000 for tension or compression, 4000000 for shearing strain) (see No. 18);

p = Permanent continuous load, the lineal mètre of girder;

p' = Moving load, the lineal mètre of girder;

q = Proportion $\frac{p'}{p + p'}$ of the moving to the whole load;

P = Sometimes a weight applied to a certain point of a girder, sometimes the weight of the girder itself in its length of bearing;

l = Bearing of the girder;

L = Length of the girder;

$\frac{P}{l}$ = Mean weight of girder, the lineal mètre (see No. 37);

$\frac{P L}{l}$ = Weight of the girder;

d = Void between the abutments;

$\frac{P L}{l d}$ = Weight the lineal mètre of girder spanning the void;

δ = Interval between two successive points to which the load is applied, in girders loaded in a discontinuous manner;

$$N = \frac{l}{\delta};$$

$$m = \frac{l}{2\delta} \text{ or } \frac{l-\delta}{2\delta}, \text{ according as } \delta \text{ enters an even or an odd number of times into } l;$$

n = Number indicating the order of a section of flange or a lattice-bar, the numbering beginning at the middle of the bearing;

α = Angle of inclination of the struts;

β = Angle of inclination of the ties;

h = Height of the girder;

t = Weight the lineal mètre of a prism capable of supporting a strain of 1 kilogramme, or proportion of the weight of a cubic mètre to the resistance per square mètre. For iron

$$t = \frac{7800k}{6000000} = 0.0013;$$

U = Coefficient applied to the flanges, the actual weight of which is always greater than the theoretical weight (see Nos. 63 and following);

V = Mean coefficient of stiffness applied to compressed bars (see Nos. 68 and following);

Ω = Supplementary term taking into account the weight of various accessories independent of h .

The dimensions of an iron plate are denoted by the symbol a/b , the letters a and b being replaced by numbers indicating respectively the breadth and the thickness of the section.

For an angle-iron, we write $a/b/c$ or $\frac{a/b}{c}$, a and b being the breadth of the arms, and c the mean thickness; for a simple T , $\frac{a/b}{c/d}$, a being the total breadth of the double arm and c its thickness, b the length of the single arm (including the thickness c), and d its thickness.

For a double T rolled, $\frac{a/b}{c/d}$, a being the total height, c the thickness of the web, b the breadth of the flanges, and d their thickness; and, generally, for a double T , consisting of plate and angle iron, we indicate successively the dimensions of the web, one of the four angle-irons, and one of the flanges.

When angle-iron with arms of unequal length is used, the lesser arm is applied to the plate and bears the bolts, and the greater forms the projecting mouldings or flanges.

1. *Moments of Rupture and Transverse Strain for Girders resting freely upon Two Supports.*—Let us consider, Figs. 1573, 1574, a portion ABCD of a girder included between any section CD and a support B, and subjected to various loads or vertical forces, as P. The reaction of the abutment is a force R also vertical. The reactions exerted at CD may be reduced to a force F and a couple. The other forces being vertical, F must be vertical also: it is in equilibrio with the vertical transverse strain in the section considered, the value of which is $F = R - \Sigma P$, the sign Σ indicating a sum. The condition of equilibrium relative to the moments of the forces requires that the moment of the couple, or *moment of resistance* of the section CD, should be equal to the moment of the other forces with respect to this same section. This latter moment, called *moment of rupture*, has the value

$$M = R x - \Sigma P (x - x_1). \text{ Its differential } \frac{dM}{dx} = R - \Sigma P = \text{transverse strain.}$$

The vertical rib, or web of the girder, is besides subjected to a sliding strain upon its longitudinal fibres or horizontal transverse strain. Indeed, if we conceive the fragment COO'C', limited by two sections infinitely near CO, C'O', and by a horizontal fibre OO', this fragment is subjected, upon CO, to a certain pressure T, and upon C'O' to $T + dT$; the resultant dT ought to be held in equilibrio by a force of adhesion $R_1 e dx$ upon OO' (e = thickness of the web, R_1 = resistance to shearing strain).

The maximum of this action occurs when OO' is situate upon the neutral axis; for then T is resisted by the force of all the compressed fibres situate above this axis. As the flange has a section usually greater than the rib, and, besides this, contains the fibres which are most acted upon, the point of application of the resultant T will be very near the flange, and its value will be approximatively equal to the moment of rupture M divided by the height h of the girder. Consequently we shall have $dT = \frac{dM}{h} = R_1 e dx$, whence $e = \frac{dM}{dx} \cdot \frac{1}{R_1 h} = \frac{F}{R_1 h}$, which may be explained by saying that the vertical section eh of the rib should be capable of resisting a shearing force equal to the transverse strain, a condition which enables us to calculate the thickness e .

2. *Moment of Rupture and Transverse Strain due to a Load uniformly distributed.*—If the load p per lineal mètre extends throughout the whole length of bearing l , the figure of the moments of rupture will be the parabola $M = \frac{1}{2} p x (l - x)$, the abscissæ being reckoned from the abutment.

This parabola has its axis vertical, and the value of its parameter is $\frac{2}{p}$; the maximum moment in the middle of the bearing is $\frac{p l^2}{8}$. The transverse strain is represented by the right line having

for equation $F = p \left(\frac{l}{2} - x \right)$; it is = 0 in the middle of the bearing. Considering the beginning of the co-ordinates in the middle of the girder, we should have $M = \frac{p}{2} \left(\frac{l^2}{4} - x'^2 \right)$ and $F = -p x'$.

3. Let us now consider a load p' per lineal mètre, uniformly distributed as p , but extending only over a portion of the bearing included between the fixed abscissæ $x = a$, and $x = a + b$, reckoned from the left abutment. Then, in the first interval, of length a , the moment of rupture due to p' will be represented by a right line $M = \frac{p' b}{2 l} (2 l - 2 a - b) x$; in the second interval, of length b , by an arc of a parabola tangential to the preceding right line, and expressed by $M = \frac{p' b}{2 l} (2 l - 2 a - b) x - \frac{1}{2} p' (x - a)^2$; and in the third interval, of length $l - a - b$, by a new tangent to the parabola, namely, $M = \frac{p' b (2 a + b)}{2 l} (l - x)$. The figure of the transverse strains is a broken line, the extreme portions of which are horizontal.

For the maximum of the moment of rupture p' must extend over the whole bearing; but for the maximum of strain at the point, the abscissa of which is x , p' must lie only between this point and the most distant support. If it lies between the point in question and the right abutment, the force is positive, if we consider as positive those forces which act upwards; it is expressed by $F = \frac{p'}{2 l} (l - x)^2$, and is consequently represented by an arc of a parabola, the ordinate of which

upon the left support is $A C = \frac{p' l}{2}$, Fig. 1575, the ordinate in the middle $O E = \frac{p' l}{8}$, and the

ordinate at $B = 0$; this latter point is the summit of the parabola. When, on the contrary, the load is placed upon the length included between A and the point the abscissa of which is x , we have as the figure of the straining forces, then negative, another parabola $A F D$, having its summit in A , and the maximum ordinate of which, absolutely expressed, is $- B D = - \frac{p' l}{2}$. Thus the load p' , by changing its position, produces at each point of the bearing transverse strains sometimes positive, sometimes negative.

4. In brief, if we have at the same time a dead weight p and a moving weight p' , the maximum moment of rupture will be $M = \frac{1}{2} (p + p') x (l - x)$, and the transverse strain in the left half bay $F = \frac{1}{2} (p + p') (l - 2 x) + \frac{p' x^2}{2 l} = \frac{1}{2} (p + p') \left(l - 2 x + \frac{x^2}{l} q \right)$, q denoting the proportion of the moving weight p' to the total weight $p + p'$.

The value of the area comprised between the figure of the moments of rupture and the axis of the x 's is $\frac{1}{12} (p + p') l^3$, and the area of the maximum straining forces, absolutely expressed, is $\frac{1}{4} (p + p') l^2 \left(1 + \frac{1}{6} q \right)$ for the whole bearing. Dividing these areas by l , we shall have the mean ordinates of the moments of rupture and of the maximum straining forces. Sometimes the effects do not depend exclusively upon F or M , but upon a function of the form $B F - A M$. Now if we consider only p' , this function will be greatest when p' extends between the point considered and the farthest abutment; it will then attain the value $\frac{p' (l - x)^2}{2 l} (B - A x)$.

5. *Effect of Loads uniformly distributed at certain intervals.*—When a girder supports discontinuous weights $P, P' P'', \dots$ applied to points having as their abscissæ $a, a + b, a + b + c$, and so on, and such that $P = \frac{1}{2} p (a + b)$, $P' = \frac{1}{2} p (b + c)$, and so on, the figure of the moments of rupture is a polygon inscribed in the parabola which would correspond with a load p per lineal mètre, uniformly distributed over all the parts of the girder.

Supposing each of the extreme intervals equal to a , all the intermediate intervals to δ , and $l = 2 a + N \delta$, the permanent weights applied to the points of division will be equal to $p \delta$, except at the extreme points, where they will be $\frac{1}{2} p (a + \delta)$. The load p' will furnish analogous weights, but they can be only on a certain number of consecutive points of division. The transverse strain for a given load is constant in each interval, but varies from one to the other. In order that it may reach its maximum in the interval preceding the point having as its abscissa $a + \kappa \delta$, the load must be applied to this point and to all those which follow it, as far as the right abutment, the point in question being supposed on the left of the middle of the girder. We shall thus obtain for this maximum,

$$F = \frac{\delta}{2} (p + p') (N - 2 \kappa + 1) \left[1 + \frac{\kappa (\kappa - 1) \delta^2 + a (2 \kappa \delta - \delta + a)}{\delta (N \delta + 2 a) (N - 2 \kappa + 1)} q \right];$$

but this formula does not apply when $\kappa = 0$, that is for the extreme interval; in that case we have $F = \frac{1}{2} (p + p') (N \delta + a)$.

6. Usually all the intervals are equal to each other. Making, therefore, $a = 0$, and $l = N \delta$, we shall have $F = \frac{\delta}{2} (p + p') (N - 2\kappa + 1) \left[1 + \frac{\kappa(\kappa - 1)}{N(N - 2\kappa + 1)} q \right]$ in the interval included between the abscissas $(\kappa - 1)\delta$ and $\kappa\delta$. This formula holds good for the first interval.

To find the sum of the values of the transverse strain in all the intervals when N is an even number, take the sum of the preceding expression in which κ assumes the successive values $1, 2, \frac{N}{2}$, and double the result for the whole bearing. We thus obtain

$$\Sigma F = (p + p') \frac{Nl}{4} \left(1 + \frac{N^2 - 4}{6N^2} q \right),$$

and multiplying by δ we shall have the area of the polygon of the maximum straining forces absolutely considered. When N is an odd number, find the sum on the supposition that κ varies from 1 to $\frac{N-1}{2}$, double the result, and add the force of the middle interval which will

correspond with $\kappa = \frac{N+1}{2}$. We thus obtain $\Sigma F = (p + p') l \frac{N^2 - 1}{4N} \left(1 + \frac{1}{6} q \right)$.

The area of the polygon of the moments of rupture may be found by taking from the area of the circumscribed parabola N small segments, the chords of which have each δ as a horizontal projection, and the surfaces of which have the constant value $\frac{1}{12} (p + p') \delta^3$. We thus obtain for

the area sought $(p + p') l^3 \frac{N^2 - 1}{12N^2}$, a formula which applies whether N be an even or an odd number. We should have $\frac{1}{12} (p + p') (l^3 - N\delta^3 - 2a^3)$ in the more general case in which $l = 2a + N\delta$.

7. When we have to consider an expression of the form $BF - AM$, where M denotes the moment of rupture with respect to the point the abscissa of which is $\kappa\delta$, and F the force in the interval preceding this point, we shall raise it to its maximum by applying the load to the point the abscissa of which is $\kappa\delta$ and to the following points of division as far as the right abutment, $\kappa\delta$ being supposed less than $\frac{l}{2}$. We obtain in this way the maxima value

$$\frac{p'\delta}{2N} (N - \kappa) (N - \kappa + 1) (B - A\kappa\delta),$$

the term due to the permanent load not included. If, on the contrary, F were the force beyond the point the abscissa of which is $\kappa\delta$, to obtain the maximum we should have to suppress the weight at this point, and the formula would then be $\frac{p'\delta}{2N} (N - \kappa) (N - \kappa - 1) (B - A\kappa\delta)$.

If the expression considered were of the form $BF - AM - A'M'$, M being the moment at the point the abscissa of which is $\kappa\delta$, M' that at the preceding point the abscissa of which is $(\kappa - 1)\delta$, and F the force between these two points, this expression would be

$$\frac{p'\delta}{2N} (N - \kappa) (N - \kappa + 1) [B - A\kappa\delta - A'(\kappa - 1)\delta].$$

8. *Moments of Rupture produced by the Passage of a Wheel.*—A weight P applied to the point the abscissa of which is a , reckoning from the abutment, would produce moments of rupture represented by two right lines beginning at the supports and meeting at the loaded point where the ordinate reaches the value $\frac{Pa(l-a)}{l}$. But if this weight P be a wheel rolling from one end of the bearing to the other, the maximum moment at any given point will be produced when the wheel is passing over this point, and the maximum moments will be the parabola having the equation $M = \frac{Px(l-x)}{l}$ and the parameter $\frac{l}{P}$.

If the girder support besides a uniform load P per lineal mètre, it will be sufficient to substitute for P in the preceding equation $P + \frac{pl}{2}$.

But the parabola representing the moments due to P is only an imaginary one, since at any given instant there exists only one of its points, the one determined by the ordinate on the right of the load; and the moments of rupture at this instant are the broken line of which we have already spoken. The force F is also not derived from the parabola, but the inclination of one or the other of the right lines composing the broken line, according as we wish to find the force on one side or the other of the section considered.

9. *Moments of Rupture produced by Two Wheels.*—The two wheels occupying a determinate position, the moments of rupture are a broken line composed of three right lines. But to have at a given point the maximum moment we must bring one of the wheels of the vehicle upon it, the other wheel so placing itself that their common distance d remains constant. If the left wheel P be placed upon the point the abscissa of which is x , the moment of rupture will be $M = \frac{x}{l} [Q(l-x) - P'd]$, Q representing the quantity $P + P' + \frac{pl}{2}$, on the hypothesis that the girder supports besides a permanent load p a lineal mètre.

If P' be brought upon the section in question, the wheel P removing to the left, we shall have

$$M' = \frac{x}{l} [Q(l-x) + P d] - P d.$$

The first equation will give a greater value than the second so long as x is $< \frac{Pl}{P+P'}$; beyond this limit we must take the second equation.

These two equations represent two parabolas $A C E$, $B F E$, Fig. 1576, of the same parameter $\frac{l}{Q}$, and having their axes vertical. But if the left wheel P be heavier than the right wheel P' , the parabola $A C E$ produced by bringing the wheel P on the point the abscissa of which is x , will descend lower than the other. Now, when the vehicle returns in the opposite direction, we shall reproduce symmetrically the two parabolas, and then it will be the curve $A C E$ and its symmetrical which will furnish the greatest ordinates, so that we shall have to lay aside the second equation.

We must observe again that the equation of the parabolas supposes both wheels always acting, even when one of them has passed beyond the support, in which case it will rest no longer upon the bearing, but upon the support. As the girder is supposed to terminate at the support when one of the wheels has passed beyond it, the curve is no longer applicable; we must in that case consider the parabola $A C F B$ due to a single wheel towards the middle of the bearing. It is applicable only when the common distance d of the wheels exceeds half the bearing; and supposing this condition fulfilled we obtain the various values numbered on the figure.

If with a certain section the girder offers an insufficient moment of resistance μ in the parts subject to the greatest strain, it will be necessary to strengthen the flanges throughout a length $\frac{1}{Q} (P' d + \sqrt{(Q l - P' d)^2 - 4 Q l \mu})$, on the condition that this value be greater than $2 d - l$.

In the contrary case, the theoretical length of the strengthening will be $\sqrt{\frac{P l^2 - 4 l \mu}{P}}$.

10. When the two wheels of the vehicle are equal to each other the maximum moment occurs at the abscissa $\frac{2 P (2 l - d) + p l^2}{2 (4 P + p l)}$ and its value is $\frac{[2 P (2 l - d) + p l^2]^2}{8 l (4 P + p l)}$.

11. *Moments of Rupture due to Three Wheels.*—Let P, P', P'' represent the weights of the three wheels moving from left to right, and d, d' their common distances.

There are three geometrical figures of the moments of rupture to be considered during the passage of the vehicle, and each of these figures is composed of three parabolical arcs, the equations changing when one or two of the wheels pass beyond the bearing.

1. *Figure of the Moments obtained by bringing P'' upon the Variable Section considered.*

Making $P + P' + \frac{p l}{2} = Q, P' + P'' + \frac{p l}{2} = Q'$, and $P + P' + P'' + \frac{p l}{2} = Q''$.

From $x = 0$ to $x = d'$, P'' acts alone and gives $M = \frac{x}{l} (l - x) \left(P'' + \frac{p l}{2} \right)$;

From $x = d'$ to $x = d + d'$ we have $M = \frac{x}{l} \{ Q' (l - x) + P' d' \} - P' d'$;

From $x = d + d'$ to $x = l$, $M = \frac{l - x}{l} \{ Q'' x - (P + P') d' - P d \}$.

2. *Figure of the Moments obtained by bringing P' upon the Section.*

From $x = 0$ to $x = d$, we have $M = \frac{x}{l} \{ Q' (l - x) - P'' d' \}$;

From $x = d$ to $x = l - d'$, $M = \frac{x}{l} \{ Q'' (l - x) + P d - P'' d' \} - P d$;

From $x = l - d'$ to $x = l$, $M = \frac{x}{l} \{ Q (l - x) + P d \} - P d$.

3. *Figure of the Moments obtained by bringing P upon the Section.*

From $x = 0$ to $x = l - d - d'$, $M = \frac{x}{l} \{ Q'' (l - x) - (P' + P'') d - P'' d' \}$;

From $x = l - d - d'$ to $x = l - d$, $M = \frac{x}{l} \{ Q (l - x) - P' d \}$;

From $x = l - d$ to $x = l$, $M = \frac{x}{l} (l - x) \left(P + \frac{p l}{2} \right)$.

The parameter of each parabola is the reciprocal quantity of the mean load per lineal mètre, reckoning only the half of the uniformly distributed load p .

Having constructed these three geometrical figures, we have to consider each of them only in that portion in which it gives ordinates greater than the others; and as the vehicle may be brought back in the other direction, we can reproduce symmetrically the maxima curves, which will always eliminate, if not already eliminated, the cases of a single wheel expressed by the first and last of the nine equations given above.

12. The following particular case deserves notice. If the vehicle be turned so that

$$P > P'' + P' \frac{d-d'}{d+d'},$$

it will be sufficient to consider the first half of the girder. Again, if $l-d-d'$ exceeds each of the quantities d, d' , and $\frac{P(d+d)}{P+P''}$, we must consider only the seventh and fifth of the nine equations,

the seventh between the abscissæ 0 and $\frac{Pl}{P+P'+P''}$, and the fifth between the latter abscissa and the middle of the girder. A girder, the simple section of which has a moment of resistance μ inferior to the maximum moment of rupture, should be strengthened throughout a length expressed by $\frac{P''(d+d') + P'd}{Q''} + \frac{1}{Q''} \sqrt{\{Q''l - P''(d+d') - P'd\}^2 - 4Q'l\mu}$, on the condition that this length exceed $\frac{P'+P''-P}{P+P'+P''}l$. In the contrary case the theoretical length of the strengthened part should be $\frac{Pd - P''d'}{Q''} + \frac{1}{Q''} \sqrt{(Q''l + Pd - P''d')^2 - 4Q''l(\mu + Pd)}$. The value of the maximum moment is $\frac{1}{4} \left\{ Q''l - 2Pd - 2P''d' + \frac{(Pd - P''d')^2}{Q''l} \right\}$.

For example, if $l = 6$ mètres, $P = P' = P'' = 6000$ kilogrammes, $p = 0$, $d = 1.40$ mètre, $d' = 1.90$ mètre, the maximum moment will be 17120, equal to that which would be given by a uniformly distributed load of 3800 kilogrammes the lineal mètre.

13. *Moments of Resistance of Solid Girders.—Girders with Equal Flanges.*—For girders of inconsiderable height, the moment of resistance is calculated by the exact formula

$$\frac{R}{6h} (bh^3 - b'h'^3 - b''h''^3 - b'''h'''^3), \text{ Fig. 1577.}$$

Tables I. and II. give the moments ready calculated of various sections. Part of these results has been taken from more extensive Tables published by M. Foy in the 'Annales de la Construction' of M. Opperman, 1863. As usual, the value of R has been taken as 6000000; but if it be required to give to R another value, it will be easy to modify these results by a simple proportion.

When a section according to the Table would be too weak or too strong for the girder proposed, we can modify the thickness of the flanges or of the vertical rib, remembering always that every millimètre added to or taken from the latter increases or diminishes the moment of a quantity = $1000h^2$; and that every millimètre in each of the two flanges causes an alteration of $6000bh$.

14. When the girder is not a very low one, the moment of resistance may be rapidly calculated by an approximative formula. With the dimensions denoted in Fig. 1577, the moment of resistance of the horizontal flanges, abstracting the rib and angle-irons, is exactly $Rb \frac{h^3 - h'^3}{6h} = M$;

but if we take $M' = Rb'h' \cdot \frac{h-h'}{2} = Rsh'$, s being the section of one of the horizontal flanges, we

shall have $\frac{M'}{M} = \frac{3h'h'(h-h')}{h^3 - h'^3}$.

For example, if h' is at least 0.8 of h , and this is always the case when the girder is of inconsiderable height, the proportion $\frac{M'}{M}$ will be equal to 0.983, which is very near unity.

As h' differs little from h , we may consider the moment of resistance of the vertical rib of thickness e as equal to $Rc \frac{h'^2}{6}$ or $\frac{1}{6} Rsh'$, s being the section eh' . Thus the vertical rib gives a moment of resistance equal to only $\frac{1}{3}$ of that which the same quantity of material would possess if equally distributed between the two horizontal flanges.

For the angle-irons, if we limit ourselves to $\frac{80/80}{10}$ and $\frac{100/100}{12}$, we can make use of Table III., which gives the moments of resistance ready calculated of four angle-irons (two at the top and two at the bottom), supposing that R reaches the value 6000000 in the fibres situated at the extremities of the height h' . If we get beyond these limits, we can reduce the values of the Table.

Thus for angle-irons of $\frac{100/100}{15}$ we must add $\frac{1}{4}$ of the value given by the Table for angle-irons of $\frac{100/100}{12}$. When the height is inconsiderable, instead of considering the angle-irons apart, we may include them in the section s of the flange.

Let us take, by way of example, a girder 0·80 mètre in height, consisting of a vertical rib of 700/12 millimètres, four angle-irons of $\frac{80/80}{10}$, and two flanges of 300/50. We shall have

$$k' = 0\cdot70, s + \frac{1}{6}s' = 0\cdot0164, \text{ and consequently}$$

The moment of resistance of the rib and flanges = 6000000 $\times$ 0·0164 $\times$ 0·70 = 68880

The moment of resistance of the angle-irons, according to Table III. .. 11014

Total 79894

The exact calculation gives 78158. Supposing the moment of rupture to be equal to 79894, the girder would have to bear a strain of 6·13 kilogrammes instead of 6, a difference which is of no importance.

15. *Moments of Resistance of Unequal Sections with respect to the so-called Neutral Axis.*—The strain which iron is usually reckoned to bear is 6 kilogrammes the square millimètre, both in those parts which are subject to compression and in those which are subject to tension, the compressed parts requiring only a proper form to prevent twisting. But if it be required to employ a higher coefficient for the flange subject to tension than for the one subject to compression, we must increase the strength of the latter, that is, we must adopt an unequal section with respect to the neutral axis.

These unequal sections may be unavoidable in certain cases; for example, in girders of the form given in Fig. 1588. In such a case, it is often possible to assimilate the section to an equal one having the two flanges equal to the weakest of the given section. But if the exact calculation be required, we must proceed as follows:—

First find, by the theorem of moments, Fig. 1578, the sides of a height δ and δ' which fix the position of the centre of gravity G of the section, which coincides with the neutral axis when the girder is only subject to forces normal to its length. Then, between the coefficients R and R_1 , which express respectively the maximum resistance of the two flanges, we shall have the proportion

$$\frac{R}{R_1} = \frac{\delta}{\delta'}.$$

The moment of resistance may be expressed either in terms of R or of R_1 which are connected by the preceding proportion; in terms of R, for example, Fig. 1579, its value will be

$$\frac{R}{3\delta} (b\delta^3 + b_1\delta_1^3 - b'\delta'^3 - b_1'\delta_1'^3).$$

In the particular case of a simple T, Fig. 1579, we shall have $\delta = \frac{1}{2} \cdot \frac{b h^2 - b' h'^2 + b' h^2}{b h' - b' h' + b' h}$.

Moment of inertia $I = \frac{1}{3} \{ b \delta^3 - (b - b') (\delta - h')^3 + b' (h - \delta)^3 \}$. Moment of resistance = $\frac{R_1 I}{h - \delta}$, R_1 referring to the fibre which is farthest from the neutral axis.

16. *Solid Girders of small dimensions.*—Coefficient R.—Riveting.—Theoretically the thickness of the vertical rib should vary with the strain to which it is to be subject; but in small girders this thickness is fixed, and offers an excess of resistance, for the conditions of rigidity prohibit the reduction of the thickness of the iron plates below certain limits. We may, therefore, consider the thickness e of the rib as given.

If we first suppose the section constant, and represented in detail by Figs. 1580 to 1585, the value of the moment of resistance will be

$$M = \frac{R}{6h} \left\{ b h^3 - (b - e) (h - 2e)^3 \right\} = R e (b - e) \left(h - 2e + \frac{4e^2}{3h} \right) + \frac{R e h^2}{6}.$$

We may neglect, relatively to h , the term $\frac{4e^2}{3h}$, and take

$$M = R \left\{ e (b - e) (h - 2e) + \frac{e h^2}{6} \right\}; \quad [1]$$

$$\text{whence } b = \frac{M}{R e (h - 2e)} + e - \frac{e h^2}{6 e (h - 2e)}.$$

The area of the section, or the volume of the lineal mètre of girder, is expressed by

$$2 b e + (h - 2e) (e + \psi);$$

ψ representing the volume of the joint-plates and mouldings of the rib the square mètre, that is, the additional thickness which must be given to the rib to equal the weight of these mouldings and joint-plates.

Substituting this value for b , the expression becomes $\frac{6M + 2Reh^2 - 6Ree h}{3R(h - 2e)} + \psi(h - 2e)$,

and it is reduced to a minimum by the following value of h :

$$h = 2e + 2\sqrt{\frac{3M - 2Ree^2}{2R(2e + 3\psi)}}. \quad [2]$$

This formula gives the height to be adopted in order to have the lightest possible girder, offering a given moment of resistance, the quantities e , ψ and ϵ being also given.

Eliminating M between [1] and [2], and supposing $e = \epsilon$, we obtain

$$h = \frac{6e(b + \psi)}{e + \psi}, \quad [3]$$

a formula which establishes between h and b the most advantageous relation, e being always given, and, in the interests of economy, requiring to be chosen as small as the necessary rigidity will allow. In girders of rolled iron $\psi = 0$, and, consequently, $h = 6b$; thus, for this kind of girder, if we choose the area S of the section, the best form will be obtained by adopting for e the smallest possible value, and then taking $h = \frac{3S}{4e}$ and $b = \frac{S}{8e}$.

Formula [2] assumes the following form in the case of a girder supporting a uniformly distributed load p per lineal metre of bearing l .

$$h = 2e + \frac{1}{2} \sqrt{\frac{3pl^2 - 16Re\epsilon^2}{R(2e + 3\psi)}}. \quad [4]$$

17. Let us now consider the case of girders having flanges of varying thickness. As the increase of thickness is obtained by placing one plate upon another, the variation takes place by redans or gradations, from the middle to the extremities of the bearing. If μ denote the moment of resistance of one of the sections, the additional material to be added in the middle will, theoretically, be equal in length to $\sqrt{l^2 - \frac{8\mu}{p}}$, supposing the girder loaded with p , the lineal mètre.

This length should, in practice, be slightly increased, in order that the added plate may form sufficient consistency with the flange by means of its extreme rivets, at those points in which the strengthening becomes necessary.

Let us suppose that Figs. 1580 to 1585 represent the section at the ends of the girder, ϵ being the least thickness it is thought proper to adopt for the flanges; then, admitting approximatively that from the extremities this thickness increases as the ordinate of a parabolical segment, so as to reach its greatest value z in the middle of the bearing, the thickness z will be determined by the following equation, in which the moment of resistance is expressed in the approximative manner explained in 14.

$$R h \left(bz + \frac{\epsilon h}{6} \right) = \frac{p l^2}{8}, \text{ whence } bz = \frac{p l^2}{8 R h} - \frac{\epsilon h}{6}. \quad [5]$$

Let κ be a coefficient 1.10 taking into account the joint-plates of the flanges. The volume of the lineal mètre of girder will then be $l h (\epsilon + \psi) + 2 \kappa l b \left\{ \epsilon + \frac{2}{3} (z - \epsilon) \right\}$; or, by substituting the value of bz , $l h \left\{ \psi + \epsilon \left(1 - \frac{2}{9} \kappa \right) \right\} + \frac{2}{3} \kappa l b \epsilon + \frac{\kappa p l^3}{6 R h}$.

This expression becomes a minimum if we take

$$h = l \sqrt{\frac{\kappa p}{6 R \left\{ \psi + \epsilon \left(1 - \frac{2}{9} \kappa \right) \right\}}}, \quad [6]$$

which shows that the height of girders should vary as $l \sqrt{p}$.

The height being determined, the middle section of the flanges is calculated by equation [5]. The breadth b must be sufficient to ensure the rigidity of the girder, and to prevent the thickness z from exceeding a certain limit, such as 0.06 or 0.07 mètre.

Examples.—Let $l = 20$ mètres, $p = 6000$ kilogrammes, $\epsilon = 0.010$ mètre, $\psi = 0.008$, $R = 6000000$, and $\kappa = 1.10$. We find $h = 2.17$ mètres, and $p z = 0.0194$. If, for example, we make $z = 0.050$, we shall have $b = 0.39$ mètre. Supposing $\epsilon = 0.010$, the girder will weigh about 11 tons, or 22231 lbs.

The above formulæ apply only to cases in which we are free to realize the most advantageous forms. It frequently happens that the height allowed is limited, in which cases we must adapt the height of the girder to the circumstances imposed upon us. The thickness of the vertical rib varies in girders of great importance.

18. *Coefficient R.*—The practical resistance of iron both to tension and to compression is usually taken as 6 kilogrammes to the square millimètre, and this coefficient is regarded as applicable to the solid section, that is, without any deduction for rivet-holes. In the parts subject to compression, these holes do not weaken the piece in the slightest degree, if they are exactly filled by the shank of the rivets; but this condition is not always fulfilled. In the parts subject to tension the hold which the heads of the rivets have taken upon the plate in consequence of the shrinking of the metal, partly compensates the loss of strength occasioned by the hole; but we must always reckon upon a loss in virtue of which R will exceed 6 kilogrammes.

When certain points, such as the situation of joint-plates, for example, require a greater degree of perforation than the other parts, it will always be advisable to slightly increase the section in these points.

In the case of bars fixed to gussets by several rows of rivets, the loss may in most cases be rendered trifling by a proper arrangement of the holes: for example, one rivet only may be put in the transverse section A B, Fig. 1586, two in C D, three in the following row, and so on; for it is enough if, in any section, the net resistance retained equals the strain upon the bar diminished by the resistance of the rivets which precede the row under consideration. Or, instead of this, we may vary only the diameter of the rivets which should increase towards the end of the piece. Or, again, the two methods may be combined. In lattice-girders, in which every bar is of inconsiderable section, a single hole, even when it is of small size, may be an important fraction of the section, in which case it will be advisable to increase the section, at least in the bars subject to tension; in those subject to compression it is often necessary to enlarge the dimensions for the sake of rigidity, and this excess of section, needed in the middle to prevent deflection, is serviceable at the extremities in compensating the loss occasioned by the rivets.

Thus in certain cases it is necessary to take into account the weakening of the material by rivet-holes, but, generally, we may consider that the coefficient $R = 6000000$ is sufficiently low to permit us to neglect it.

19. *Rivets and Bolts.*—The resistance of these to shearing force might be considered equal to their resistance to tension or compression, when it is effected under favourable circumstances. But as the joints often require a greater number of rivets, they will not resist in an equal degree. For

this reason it is usual to reckon their resistance at 4 kilogrammes the square millimetre. In accordance with this, a rivet of 0^m·022 in diameter, offering a single section, should support 1½ ton, or 3031 lbs.; and one of 0^m·25, 2 tons, or 4042 lbs. The distance of the holes apart may be about 0^m·08.

When a small surface only of a bar rests upon its gusset, it is often necessary to double the sections of the rivets to enable them to resist the shearing strain; this is effected by placing a joint-plate on the opposite side of the gusset, extending an equal distance along the bar. The space between the bar and the joint-plate is then filled up, so that the gusset is fixed into a kind of fork, which can be torn away only by shearing the rivets through two sections. In certain cases, it will be easier and less expensive to enlarge the gusset and retain only a single section of bolt. By doubling the gussets and joint-plates, the rivets will offer a quadruple section. The thickness of the gussets should be so calculated that there may be no risk of their giving way along the perimeter enveloping the rivets of the bar.

We may observe, with respect to the joint-plates of the flanges, that it will be prudent to place considerably apart the holes of those transverse rows which are nearest to the joint and to the ends of the joint-plate, and, on the contrary, to place them closer together in the intermediate rows. This condition may be disregarded with respect to the rows nearest the joint, if we increase the thickness of the joint-plate. But even then it is as well to increase the length, and to place the rivets farther apart.

The vertical rib of a malleable iron girder has a tendency to slide between the two angle-irons which fix it to each of the horizontal flanges. We saw in I that this horizontal shearing strain requires a thickness of rib e given by the equation $\frac{dM}{h} = R, e dx$. Taking account of the rivets, we shall have $\frac{dM}{h} = n Q dx$, n being the number of rivets the lineal mètre, and Q the strain borne

by one of them upon a double section. Whence we deduce $n = \frac{1}{Qh} \cdot \frac{dM}{dx} = \frac{F}{Qh}$.

Supposing $p\kappa$ the lineal mètre of girder, the maximum of strain F will be $\frac{pl}{2}$, and by using rivets of 0^m·025 we shall have $Q = 4000$ kilogrammes; consequently $n = \frac{pl}{8000h}$, that is, at the extremities of the girder, the rivets fixing the rib to the angle-irons of the flanges should be placed apart the distance of $\frac{1}{n} = \frac{8000h}{pl}$. With a diameter of 0^m·022 the distance should be $\frac{6000h}{pl}$.

The same considerations apply to the rivets which hold together the plates of the flanges, or which fix them to the horizontal arm of the angle-irons, but in these cases the distance may be increased on account of the relatively less sliding strain.

The foregoing condition will, in general, allow us to place the rivetings wide apart throughout the greater part of the length of the flanges; but in the flange subject to compression the rivetings serve another purpose, which must be borne in mind; namely, that of preventing the exfoliation of the plates, which would inevitably occur if they were insufficiently fixed together. This condition requires that the plates should not be left free throughout a length exceeding 0^m·15; but when there are several rows of rivets, the distance may in certain cases be doubled, provided we take care to alternate the holes.

The holes should be placed closer together in a line with the joint, in order to avoid uselessly increasing the length of the joint-plates.

When the number of plates of which the flange is composed is great, the joints are near together; and in this case the rivetings should extend, at small intervals, throughout the whole of the length.

20. *Flooring of Bridges.*—*Parts beside the chief Girders.*—When the rails do not rest directly upon the principal girders, these are made to support cross-girders, upon which again are placed, longitudinally, other and lesser girders, and it is upon these latter that the rails are laid.

We may consider these minor supports as simply resting upon the cross-girders, and we may take as their bearing the distance of these latter from each other. If the rolling load consists of the wheels of a locomotive, the weight of which is 7 tons, and their distance apart 1^m·40, one of the wheels in the middle of the girder will give the maximum moment, when the bearing is less than 2^m·40. Above this it will be necessary to consider two wheels. The dead weight, which is of small importance relatively to the rolling load, may be reckoned at the rate of 500 kilogrammes the lineal mètre. With these hypotheses, we can adopt, according to the various lengths of bearing and the height to be given to the girder, the double T sections of Table IV., in which l denotes the bearing, M the maximum moment of rupture, and h the height of the girder. As we have done in the Table of the moments of resistance, so in this we describe a section by indicating, first the dimensions of the vertical rib, then those of one of the four angle-irons, and last, when there is occasion for it, those of one of the flanges; for these latter, we give also the length, which in secondary girders of more than 3 mètres may be considerably less than the bearing, for these horizontal plates must be regarded as simple additions made for strength. When the length is omitted, it is understood to be equal to that of the angle-irons. The letter P denotes the mean weight of the girder a lineal mètre, having taken into account the reduction in the length of the strengthening portions, and the cutting away of the angle-irons at the ends of the girder, where the vertical rib alone is retained to be fixed to vertical flanges in the cross-girder. These vertical flanges are not reckoned here, because we consider them as forming a part of the cross-girder.

In sections consisting only of a rib and angle-iron, the latter should offer a broad surface to the balks of timber carrying the rails; it will sometimes be advisable to substitute unequal-armed angle-iron for equal-armed, care being had to preserve nearly the same weight: the resistance will be increased by the change, but if this condition is already amply satisfied, we need alter only the top angle-irons. In a bridge hereafter described, we have secondary girders reaching a length of bearing equal to 6 mètres. The mean weight of each of these is about 110 kilogrammes the lineal metre.

21. When the height allowed is very limited, hollow girders in the form of caissons are sometimes used. This form is less economical than that of the double T, but it is favourable to the reduction of the thickness of the flooring without diminishing the necessary thickness of the timbers. Figs. 1591, 1594, 1595, give an example of this arrangement. Other sections suitable for bearings of $1^m \cdot 50$ to $2^m \cdot 50$ are found in Figs. 1587 to 1590. It is useless to consider longer bearings than these, for when the height is very limited the cross-girders should not be placed far apart.

1598.

When the thickness will allow us to give a height of, at least, $0^m\cdot350$ to the cross-girders, we may adopt the double T form for the longitudinal girders.

22. *Cross-girders for Bridges of Three Girders.*—Figs. 1591 to 1598 represent various kinds. When the height allowed is very limited, the distance of the cross-girders apart should be reduced to about $1^m\cdot50$. It will be useless to go lower than this, for we should still have to consider the cross-girder as loaded, in a line with each rail, with one wheel of the locomotive. In these cases, the principal girders should be placed as near together as possible, in order to diminish the bearing of the cross-girders. Taking their distance apart equal to $4^m\cdot20$, as in Figs. 1591, 1594, 1595, the length of the cross-girder will be 4 metres, its actual bearing being, in consequence of the projecting of the gussets, $3^m\cdot60$. Under these circumstances, the height of the cross-girder may be reduced to $0^m\cdot220$, as in the figure; its weight is about 730 kilogrammes, including its two gussets; the cross-girders, therefore, will weigh 975 kilogrammes the lineal metre of flooring under two lines of rails.

For a height of $0^m\cdot250$, we may take a rib of $210/10$ millimètres, angle-irons of $110/70/11$, and flanges of $270/20$ composed of two plates, one extending over a length of $3^m\cdot50$, and the other over $2^m\cdot70$ only. The weight of the cross-girders will be reduced to 830 kilos.

It will be brought down to 715 kilos., if we can take a section of $0^m\cdot300$ in height, composed of a rib of $260/12$, angle-irons of $70/70/10$, and flanges of $220/20$, the first plate of which should extend $3^m\cdot50$ and the other $2^m\cdot70$.

Again, this same weight will be reduced to 640 kilos. for cross-girders of $0^m\cdot350$, the rib being $330/10$, the angle-irons $80/80/10$, and the flanges $250/10$ throughout a length of 3 metres.

23. But generally we shall follow the example given in Figs. 1592, and 1596 to 1598, in which the chief girders are placed at a distance of $4^m\cdot50$ apart. In this case the space between the two lines of rails, known as the "six-feet way," is increased to 3 metres at each end of the bridge, in

order to keep clear of the middle girder. The length of the cross-girders is $4^m \cdot 30$, and they may be regarded as simply resting upon two supports, the actual bearing being about $4^m \cdot 10$. The rolling load acts in two distinct points, in a line with each rail, and we may suppose the dead weight to act in the same manner. The moment of rupture will be equal to $1 \cdot 30 P$, the letter P denoting the maximum total weight acting in a line with each rail. This weight increases with the distance between the cross-girders; and if we consider the case of locomotives carrying 10 tons per axle, with a distance of $1^m \cdot 10$ between the axles, or carrying 12 tons, with a distance of $1^m \cdot 40$ and $1^m \cdot 90$, we may allow the following values of P :—

Distance apart of cross-girders	Mètres. 1·50	Mètres. 2·00	Mètres. 2·50	Mètres. 3·00	Mètres. 3·50	Mètres. 4·00	Mètres. 4·50	Mètres. 5·00
Portion of P due to the dead weight	Kilos. 1700	Kilos. 2000	Kilos. 2100	Kilos. 2300	Kilos. 2500	Kilos. 2800	Kilos. 3100	Kilos. 3500
Portion of P due to the rolling load	7600	9500	10600	11400	12300	13000	13600	14000
Total value of P	9300	11500	12700	13700	14800	15800	16700	17500

We are thus able to form a Table (see Table V.) in which M denotes the maximum moment of rupture. The weights include the vertical flanges by means of which the lesser girders are fixed to the cross-girders, and the triangular gussets by means of which the latter are fixed to the principal girders. On the other hand we have deducted the portions of angle-iron or horizontal plates, which are removed towards the ends of the cross-girders.

24. *Cross-girders for Two-girder Bridges.*—Exemplars of these are given in Figs. 1599 to 1604. The total length of the cross-girder is supposed equal to 8 mètres, and we may admit $7^m \cdot 80$ as the actual bearing. The

maximum moment of rupture, between the inner rails, will be $4 \cdot 30 P$, when the two lines are simultaneously loaded, whilst it will be only $2 \cdot 70 P$ in the case of one line being loaded. We may reckon the mean $3 \cdot 50 P$ as equal to the moment of resistance $R = 6000000$. By this means we shall obtain cross-girders supporting generally a strain of 4·5 kilos. the square millimètre, omitting the exceptional case of both lines being loaded simultaneously, when the strain may rise to 7·5 kilos. In a line with the exterior rails, the mean moment will be $2 \cdot 40 P$.

Table VI. gives a certain number of sections for various distances. The weights include all accessories.

25. *Vertical Trussing.*—When the girders of a bridge are very high and their flanges comparatively narrow, they are liable to incline or sag from one side to the other, especially if they are loaded on the upper part. If the direction of the sagging is different at the two ends of the girder, a strain of torsion is produced, which changes the plane of the vertical rib into an oblique surface. The principal object of vertical trussing is to counteract these effects of sagging. The strain borne by these pieces is caused by the motion of the trains, which produces lateral oscillations, or by the deflections which occur in the flange subject to compression. But it is often needful to strengthen the oblique pieces of the transverse section, because they may serve as supports to the cross-girders, of which arrangement Figs. 1605 to 1611 and Figs. 1580 to 1585 are examples.

The object of vertical trussing cannot be to equalize the deflections of the several girders in cases when these girders may be unequally loaded, for in such cases the deflections must of necessity differ: it could be prevented in part only by means of very strong pieces, and there would then result a strain of torsion. Yet, when the girders are high and rigid, the deflections are so inconsiderable that the vertical trussing does offer some resistance, because, by its elasticity, it adapts itself sufficiently to the different curves which the girders assume under the rolling load. Between two girders equally loaded, such as two girders supporting directly the

the bridge, which may be the case in a certain degree when the principal girders are straight. The section of the iron is usually flat, because, of the two diagonals forming a Saint Andrew cross, there is always one which resists tension, whilst the cross-girders serve as compression-bars; besides, the compressed diagonal does not remain quite inactive when it is fixed in several points throughout its length, as is usually the case. When, on the contrary, the bars are left free throughout a considerable length, it is preferable to make them of T-iron, to avoid yielding.

In bridges of small span—of less than 25 mètres, for example—the breadth of the flooring is a large fraction of the length, and the trussing may be omitted, because the rigidity of the flooring itself offers a sufficient resistance to transverse oscillations.

For a bridge loaded on the upper part, Figs. 1612, 1613, and Figs. 1580 to 1585, the horizontal trussing may weigh, according to the span, from 50 to 90 kilogrammes the lineal metre of flooring under two lines of rails (bars of 160/12 to 200/16 millimètres), including the gussets.

For a three-girder bridge, loaded on the lower part, we may reckon from 80 to 150 kilogrammes; for a two-girder bridge, loaded on the lower side, from 50 to 100 kilogrammes. Tubular bridges absorb the lineal metre, from 130 (two-girder bridges) to 180 kilogrammes (three-girder bridges) and above, for their double trussing or cross-bracing, which, added to their great breadth, gives them a transverse rigidity greater than bridges of an equal span loaded on the upper part, and having corbels, could possess.

In ordinary road bridges the horizontal cross-bracing may be considerably inferior

in strength to that required for railway bridges. Flat bars of 100/12 are in general amply sufficient.

27. In cases when the height allowed is unlimited, the lines of rails may rest upon the upper part of the girders. When the span is inconsiderable we shall have, generally, four principal girders, supporting directly the rails, as in Figs. 1612 to 1614; for in such cases the other pieces serve only

to tie the girders, and may be of small dimensions. But when the span is great, the saving in the secondary pieces should be sacrificed in favour of the more important saving which may be effected by reducing the number of the principal girders. One girder costs less than two that are only half loaded, and, besides, this one girder will be subject to the full strain only in the exceptional case of two trains crossing the bridge simultaneously. Figs. 1580 to 1585, and Figs. 1606, 1615, 1616, 1617, give examples of bridges of two girders of various heights, and, consequently, applicable to bridges of small and great span. Between two-girder and four-girder

bridges are those of three girders, Figs. 1605 and 1618 to 1620, which require strong cross-girders, but less important than those of two-girder bridges.

When the height allowed is limited, the load is placed upon the lower part of the girders; in such cases the girders form the sides or parapets of the bridge when they are not very high, and when their height is great, advantage is taken of the circumstance to tie them on the upper part; this latter arrangement constitutes the tubular system. Figs. 1591 to 1598 are examples of three-girder bridges constructed according to the first method, and Figs. 1621 to 1624 are examples respectively of three-girder and two-girder tubular bridges. In the various kinds of bridges loaded on the lower part, we distinguish again those in which the height of the cross-girders is limited, and those in which this height is great, for this is of considerable importance when we regard the weight of the minor and cross girders. For example, in Figs. 1591, 1594, 1595, in which the cross-girders have a height of 0·220 metre, this weight reaches 1350 kilogrammes the lineal metre of flooring under two lines of rails; whilst in Fig. 1593, with a height of 0·850 metre, it is reduced to 630 kilogrammes. A limited thickness obliges us to increase the number of cross-girders, and induces us to give the preference to three-girder rather than to two-girder bridges.

Regarded from the point of view of tying the principal girders, the distance between the cross-girders will be determined by the transverse rigidity of the former. Girders with narrow flanges may need to be tied every 2 metres, or 2·50 metres; whilst in large bridges, provided the cross-girders be strong and firmly fixed, they may be placed 4 metres apart and even more.

28. The weight of the various parts beside the principal girders may be taken generally as follows:—

Weight of the parts beside the chief Girders and the horizontal Trussing, the lineal metre of flooring under two lines of rails.

1. Loaded on the upper side.	Four-girder bridges.	Distance between cross-girders, 2 metres: 320 to 450 kilogrammes, according as the height of the girders varies from 1·50 to 4·00 metres;
		Distance between cross-girders, 3 metres: 260 to 350 kilogrammes, according as the height of the girders varies from 1·50 to 4·00 metres;
		Three-girder bridges: 460 to 800 kilogrammes, according as the height varies from 2 to 5 metres;
2. Loaded on the lower side.	Three-girder bridges.	Two-girder bridges: 540 to 920 kilogrammes, according as the height varies from 3 to 8 metres;
		Three-girder bridges: 960 to 630 kilogrammes, according as the height of the cross-girders varies from 0·35 to 0·85 metre;
		Three-girder bridges: 1050 to 730 kilogrammes, according as the height of the cross-girders varies from 0·60 to 1·00 metre;
		Three-girder tubular bridges: 1050 to 730 kilogrammes with cross-girders of 0·35 to 0·80 metre;
		Two-girder tubular bridges; 900.

We omit those exceptional cases of bridges loaded on the lower part, in which the height allowed is so limited as to render necessary very expensive arrangements.

1621.

Three-girder Tubular Bridge. Scale, 0·01.

1622.

Top cross-bracing.

Bottom cross-bracing.

29. The planking of railway bridges is composed of planks 0·06 or 0·07 mètre thick. The longitudinal timbers supporting the rails are 0·13 or 0·15 thick by 0·25 or 0·30 broad. As the calculation of the timbers can be always easily made, it is useless for us to consider it here. Generally we shall have from $(0·60)^3$ to $(0·70)^3$ mètre, the lineal mètre of flooring under two lines of rails.

30. For ordinary road bridges we prefer wood in the construction of the flooring to corrugated iron, because with wood we may place the beams farther apart, which is a more economical arrangement. It is true that the wood will require to be sooner renewed, but that is a labour which is readily executed, even without interrupting the traffic. In Figs. 1607 to 1625, the planking is 0·07 mètre thick, and is covered with a boarding 0·03 mètre thick which serves the double purpose of protecting the planking, and of increasing its power of resisting by preventing a single plank from yielding beneath the weight of the wheel of a vehicle. The planking rests upon joists 0·250 mètre deep by 0·125 mètre broad, placed at distances of 0·375 mètre apart.

When corrugated iron is employed, it may be 0·003 metre thick for a distance of 1·40 metre between the cross-girders, the ridges being 0·080 metre in height and having a mean breadth of 0·160 metre; but this iron does not resist well unless it is covered with a sufficiently thick layer of earth to prevent the wheels from concentrating their action upon a single ridge.

There yet remains for very important works the heavy but indestructible system of brick arches, springing from iron beams. But our purpose is only to study the most economical arrangements.

1625.

*Road Bridge.*Roadway, 4^m; footway, 1^m. Small span.

Scale, 0·02.

31. The planking of the above-mentioned figures, cubes a square metre, or has as its reduced thickness 0.183 metre. With this planking, the proper distance between the cross-girders is 1.80 metre. We may consider the cross-girders as subject to a maximum weight of 1000 kilogrammes

the lineal metre (the layer of earth varying from 0.15 to 0.25 metre), and to an accidental load of two wheels, each exerting a pressure of 3 tons, placed 1.50 metre apart, and in the most unfavourable position, which gives the moment of rupture expressed by the formula in 10. When the bearing of the cross-girder exceeds 4 metres, we must consider the case of two heavy vehicles passing in opposite directions. The wheels may vary in respective position, but as the ballast serves to distribute the pressure, we shall admit that the total weight of 12 tons for the four wheels, simultaneously situate upon the cross-girder, is distributed uniformly throughout its length. Table VII. gives for these conditions, some sections ready calculated. The weights include gussets similar to those in the figures already referred to, and suppose that the distance between the girders exceeds by 0.40 metre their bearing.

Cross-girders of more than 8 metres will generally be divided in their length by one or more of the principal intermediate girders.

32. The figures referred to in 30 represent bridges of three different breadths:—

6 metres, composed of 4 metres of roadway and two footways of 1.00 metre each.					
10	"	7	"	"	1.50
14	"	10	"	"	2.00

And for each of these breadths we may distinguish the cases of,—1, small span, which requires only a moderate thickness between the level of the road and the under-side of the girders; 2, wide span with unlimited height; and 3, wide span with limited height. This gives occasion

for nine different transverse sections, or rather for twelve, for Figs. 1626 to 1630 are double, and represent either girders loaded on the lower side or tubular bridges. Cross-girders supporting the road are always placed 1·80 metre apart; but cross-girders used only as tie-beams, struts, and braces, are placed only at double intervals. In Figs. 1607 to 1611 there is, therefore, one out of every two cross-girders untrussed; but the want of this is compensated by an additional plate in the flanges. In Figs. 1608, and 1626 to 1630, the cross-girders, which are very long, are held in the middle of their length by longitudinal bars in double T-iron of 20 kilogrammes to the lineal metre. In bridges of a rather wide span we add a horizontal cross-bracing of flat bars of 100/12 millimètres, and which, when fixed to the

cross-girders, serves to prevent their lateral deflection. Tubular bridges require the cross-bracing both on the upper and the lower side.

The following Table gives the weight of iron the lineal metre of flooring, not including the principal girders, for each of the transverse sections referred to above:—

			Kilogrammes.
Flooring, 6 metres broad.	Small span		340
	Wide span, with unlimited height (girders 3·50 metres high)		460
	Wide span, with limited height (girders loaded on the lower side)		430
Flooring, 10 metres broad.	Wide span, (tubular bridge)		535
	Small span		430
	Wide span, with unlimited height (girders 4·50 metres high)		810
Flooring, 14 metres broad.	Wide span, with limited height (girders loaded on the lower side)		835
	Wide span, (tubular bridge)		985
	Small span		745
Flooring, 14 metres broad.	Wide span, with unlimited height (girders 5 metres high)		970
	Wide span, with limited height (girders loaded on the lower side)		1260
	Wide span, (tubular bridge)		1500

Those kinds which are applicable to wide spans admit, in the case of unlimited height, of truss-bars, the length of which increases with the height of the girders: it is for this reason that we have indicated the particular height for which the calculation has been made.

The weight includes the cross-bracing adopted in the cases of wide span; it includes also the parapets of 30 kilogrammes the lineal metre, except in those cases in which the girders themselves form parapets.

33. *Loads applicable to the principal Girders.*—Proportion between the Span, the Bearing, and the total Length.—Bearing-rollers.—A girder of a considerable bearing is always calculated on the hypothesis that the loads are uniformly distributed, namely:—

1. A permanent load of p kilogrammes the lineal metre, throughout the whole length.
2. An accidental load of p' kilogrammes the lineal metre, throughout a certain length of the bearing.

Loads p and p' applicable to Railway Bridges.—Sometimes the dead weight p is purposely increased by means of a thick layer of earth or ballast, for the purpose of deadening the vibrations caused by the rolling load p' ; this, besides, allows us to make the lines of rails independent of the flooring, by placing them upon sleepers not fixed to the metal part of the bridge. But this is an exceptional arrangement; usually the dead weight of the indispensable parts is reduced, for the reason that the iron is capable of resisting the vibrations which are produced by the passage of the trains, when the girders are calculated for a strain of 6 kilogrammes the square millimètre. An increase of the permanent load may no doubt be favourable to the power of resistance in the material, but if it be adopted, it will only be logical to take for R a greater value than 6000000, for it is acknowledged that this coefficient offers perfect security in cases in which the vibrations are exerted in the usual manner. At any rate, we shall suppose only a thin layer of ballast to protect the planking from the burning coals dropped by the engine.

By adding the weight of the rails, of the timber, and the various pieces of the flooring, we may take as the average the lineal mètre of each of the chief girders, not including its own weight, the following permanent loads:—

Bridges loaded on the upper part.	of 4 girders: $p_1 = 500$ to 600 kilogrammes.
	of 3 " 800 " "
	of 2 " 1200 " "
Bridges loaded on the upper part.	of 3 girders { outside girders: 800 " 700 kilogrammes, according as the thickness is great or otherwise. middle girder: 1700 to 1400 kilogrammes, according as the thickness is great or otherwise.
	of 2 girders: 1400 kilogrammes.

To obtain p , we must add to p_1 , given above, the weight p_2 of the girder itself a lineal mètre, a weight which it is of small consequence to know exactly, and which may be corrected, if it be deemed necessary, by a second calculation. When we wish to obtain only the net value, we may get rid of the weight p_2 , by remarking that in general the weight of the girder a lineal mètre is, at least in the greater part, proportional to $(p + p')l$. Supposing, then, $p_2 = D(p_1 + p_2 + p')l$, we obtain $p_2 = \frac{D(p_1 + p')l}{p_1 - lD}$; or by making $D(p_1 + p')l = p_2$, $p_2 = \frac{(p_1 + p')p_2}{p_1 + p' - p_2}$; we can, there-

fore, deduce the weight p_2 , found from the weight p_3 , which is obtained by neglecting in the dead weight the weight of the girder itself. The result will not be strictly true, because the proportion q of the rolling load to the total load is increased by the reduction of the latter; but the error is small, q having but a slight influence except upon a few lattice-bars.

34. Let us now consider the moving load p' .

An engine with its tender may be placed upon a bridge of 10 mètres, and if the weight amounts to 60 tons, we shall have 6000 kilogrammes the lineal mètre for one line of rails, admitting, as we may for this length of span, that the load produces nearly the same effect as it would do if uniformly distributed.

Beyond a span of 60 mètres, we always suppose, in calculations, a load of 4000 kilogrammes.

Between 10 and 60 mètres, this assumed load should vary as follows:—

Spans	= 10, 20, 30, 40, 50, 60 mètres, and above.
Load P' (for a single line)	= 6000, 5000, 4600, 4300, 4100, 4000 kilogrammes.

A girder may have to support two rails, one rail, or a fraction of a rail, according to the system of flooring. The following Table gives the necessary information regarding this matter, omitting altogether rails which are not loaded.

		Number of Rails supported by 1 Girder.

Loads p and p' applicable to Road Bridges.—The following Table gives the loads applicable to the girders of various kinds of bridges. The dead weights p are calculated on the hypothesis that there is a layer of earth, or ballast, 0·20 mètre deep, and the moving loads p' on the hypothesis that the roadway is loaded at the rate of 400 kilogrammes, and the footways at the rate of 200 kilogrammes, the square mètre.

36. *Bearing-rollers.*—Cast-iron plates are interposed between the girders and the masonry, where the former rest upon the abutments. For spans of more than 20 mètres, friction-rollers, or, as they are usually called, bearing-rollers, are placed between these plates and the girders to provide for the movement caused by the expansion of the metal. We may calculate in the following manner the maximum load which these rollers are liable to bear.

The girder is fixed in the direction of CD, Fig. 1631, to a plate, the thickness of which = ϵ , resting upon rollers having a diameter of $2r$, which, in their turn, rest upon a lower plate, cemented into the masonry. The diametrical plane AB undergoes no distortion, it only sinks in consequence of the depression at the bottom; if we admit that the face CD also remains plane after compression, the planes CD and AB will have approached each other by the quantity λ , on account of the pressure Q exerted by the girder, and supposed collected upon 1 lineal metre of roller. The lower face of the plate offers a depression into which the roller penetrates, and which is itself flattened.

The value of the ratio $\frac{GH}{HI}$ of the compression of the roller to that of the plate, for an elementary prism FM, is $\frac{GH}{HI} = \frac{GM}{FI} = \frac{\sqrt{r^2 - x^2}}{\epsilon}$. To find HI, for example, we deduce from this proportion $\frac{GH + HI}{HI} = 1 + \frac{\sqrt{r^2 - x^2}}{\epsilon}$; or $GH + HI$, or $GI = \lambda - r + \sqrt{r^2 - x^2}$, and, consequently, denoting the modulus of elasticity by E, the portion of the load which the elementary prism FM supports will be $dQ = E \cdot \frac{HI}{\epsilon} = E \cdot \frac{\lambda - r + \sqrt{r^2 - x^2}}{\epsilon + \sqrt{r^2 - x^2}} dx$.

To determine λ , we remark that the metal must not be subjected to a strain greater than R the unity of section, so that λ cannot exceed the value $\frac{R}{E} (\epsilon + r)$, which value will be substituted in

$$\text{the integral } Q = 2E \int_0^{\sqrt{\lambda(2r-\lambda)}} \frac{\lambda - r + \sqrt{r^2 - x^2}}{\epsilon + \sqrt{r^2 - x^2}} dx.$$

Now the value of the integral of the form $\int \frac{A + \sqrt{r^2 - x^2}}{B + \sqrt{r^2 - x^2}} dx$ is

$$\int \frac{A + \sqrt{r^2 - x^2}}{B + \sqrt{r^2 - x^2}} = C + x + 2(B - A) \tan^{-1} \frac{\sqrt{r^2 - x^2}}{x - r} + Z,$$

C being the arbitrary constant, and the term Z being equal to

$$\frac{B(A - B)}{\sqrt{r^2 - B^2}} \log_e \frac{\frac{B\sqrt{r^2 - x^2}}{x - r} - r - \sqrt{r^2 - B^2}}{\frac{B\sqrt{r^2 - x^2}}{x - r} - r + \sqrt{r^2 - B^2}}, \text{ in the case in which } r > B;$$

to $\frac{2(r - A)(x - r)}{r - x + \sqrt{r^2 - x^2}}$, in the case in which $r = B$; and to

$$\frac{2B(A - B)}{\sqrt{B^2 - r^2}} \tan^{-1} \frac{\frac{B\sqrt{r^2 - x^2}}{x - r} - r}{\sqrt{B^2 - r^2}}, \text{ when } r < B.$$

Usually, we have $E = 0.100$ mètre, and the diameter $2r$ of the rollers $= 0.150$ mètre. It will, therefore, be the last expression of Z that we shall have occasion to apply, and by calculating the definite integral which gives the value of Q , we obtain

$$Q = 2E \left\{ \sqrt{\lambda(2r-\lambda)} - 2(\epsilon+r-\lambda) \left[\tan^{-1} \frac{r-\lambda}{r-\sqrt{\lambda(2r-\lambda)}} \right. \right. \\ \left. \left. - \frac{\pi}{4} - \frac{\epsilon}{\sqrt{\epsilon^2-r^2}} \left(\tan^{-1} \frac{r+\frac{\epsilon(r-\lambda)}{r-\sqrt{\lambda(2r-\lambda)}}}{\sqrt{\epsilon^2-r^2}} - \tan^{-1} \frac{\epsilon+r}{\sqrt{\epsilon^2-r^2}} \right) \right] \right\}.$$

For $R = 6,000,000$ and $E = 8,000,000,000$, a value applicable to thick cast-iron plates, the formula gives $Q = 36370$ kilogrammes the lineal mètre of roller, say 24 kilogrammes the square centimètre of diametrical section: this value we shall adopt as a maximum.

But when there are several rollers it is difficult to load them all equally. In order that no roller may exceed its limit of elasticity, it is essential that the bed-plates be fixed with care; the keys or bolts which hold them should, as far as possible, be tightened in an equal degree while the trial load is upon the bridge. When the distance of the load has modified the deflection of the girder, the pressure will be unequally distributed between the rollers; but this is no longer of consequence, because the rollers are greatly eased of the total weight. But in practice, a certain latitude must be allowed; and we should consider that the pressure has always a tendency to concentrate itself towards the facing of the abutment. If we admit that the centre of pressure, under a full load, may move forwards along 0.60 of the bearing upon the abutment, reckoning from the end, the mean pressure will be $\frac{5}{8}$ of the maximum 24 kilogrammes, say 15 kilogrammes the square centimètre of diametrical section of the rollers. If this pressure be referred to the total surface of the plates, it will be necessary to deduct the play of the rollers, and we must then reckon upon about 13 kilogrammes.

The evil of imperfect bed-plates cannot be remedied by increasing indefinitely the number of the rollers; for, under a full load, the extreme rollers support hardly anything. And, even if a roller should be subjected to a strain a little too great, the consequence will, in general, be of small importance.

In bridges of several spans, or bays, upon very high piers, the rollers should turn freely in order that the expansion of the iron may not cause a great horizontal strain upon the masonry. The bed-plates should be as equal as possible in all respects, both when the bridge has no load upon it and when it is fully loaded; and there is but one case in which the resultant of the pressures will, in any considerable degree, be diverted from the middle of the face of the support, namely, when the load is applied to one only of the contiguous bays. This case allows us to reckon upon the maximum pressure of 24 kilogrammes, or near it, for the full load, say 20 kilogrammes after having made the deduction for the play between the rollers.

37. *Relation between the Span, the Bearing, and the total Length.*—From what precedes, reckoning upon 13 kilogrammes the square centimètre, the bearing c , Fig. 1632, of a girder upon the abutment

may be calculated by the formula $c = \frac{(p+p')L}{260000\beta}$, L being the total length of the girder (single bay), and β the breadth of the plates or the bearing length of the rollers, which usually exceeds by 0.14 mètre the breadth of the flange of the girder, in the case of moderate span. For very large bridges, it will be preferable to increase β , and perhaps also the diameter of the rollers, in order that they may offer more elasticity to lessen the effect of the inclination produced by the deflected girder.

In general, supposing that the dimension b of the figure is 0.60 of c , the total length L of the girder should be made $= 1.045l$.

As to the ratio of the real bearing l to the span d , it depends upon the dimension a , which should, in the first place, be at least equal to 0.40 c , and, in the second place, sufficient to keep the resultant of the pressures at a suitable distance from the facing of the abutment, and to prevent a crushing of the masonry. This condition depends itself upon the dimensions and talus of the abutment; but we shall generally do right by making $a = 0.025d$.

Thus, to recapitulate, in calculations for bridges, we shall adopt $l = 1.050d$ and

$$L = 1.045l = 1.0973d.$$

We shall usually consider the mean weight of the lineal mètre of girder in reference to the total length L . If we obtain the total weight P by a direct measurement including the ends of the girder, $\frac{P}{L}$ will be the mean weight; we shall take, on the contrary, $\frac{P'}{l}$, if the weight P' results from a theoretical formula which supposes the length of the girder to be l , subject to the corrections necessary to take into account, according to the case, the ends of the girder. To obtain the weight in reference to the span, we must multiply the weight found for the mètre of total length, by 1.0973 or 1.10.

38. In *Skew bridges*, the normal span being d , and the angle of the skew being α , the skew span will be $\frac{d}{\sin \alpha}$, the real bearing $1.05 \frac{d}{\sin \alpha}$, and the total length of the girders $1.0973 \frac{d}{\sin \alpha}$. This

1632.
 L , Length of the girder. l , Real bearing.
 P , Apparent bearing. d , Span.

case presents no difficulty; the cross-girders are normal to the chief girders; some of them at the extremities are short, and rest upon an oblique piece which holds together the ends of the girders along the abutment. The first complete cross-girder forms with this oblique piece and the principal girder an unyielding triangle, which allows us to have recourse to a less expensive system of counter-bracing than would be required for a straight bridge of the same span. Beyond this difference, in the matter of calculating the weight and the resistance, a skew bridge and a straight bridge of the same span are alike.

The bridge, Figs. 1633, 1634, erected near Calcutta, was constructed according to the system of bridge-building introduced and practised by A. Sedley. The span, Fig. 1633, is 75 ft., and the structure was calculated to support a moving load of 120 lbs. to the sq. ft. of roadway. The total weight, including rods, girders, and Mallet's buckled-plates, is 30 tons. The iron was proved to 20 tons to the sq. in. of cross-sectional area; the tension or suspension bars are of the best Bowling iron. The cantilevers have merely the effect of increasing the range of the piers, and if the suspension-rods support the lattice-girder without destroying its perfect contact across and on each of the two brackets, the system is reduced to a lattice-girder resting on supports.

Hydraulic Swing Bridge over the River Ouse.—The information that we give respecting this bridge is taken from 'Proceedings of I. M. E.,' August, 1869.

This bridge was designed by Harrison, the engineer of the North-Eastern Railway. Near the bridge there was no supply of hydraulic power, and the total power required was too great to be supplied by hand labour. It was further necessary, on account of the position of the swing bridge, either to convey the power to the centre pier by a pipe under the bed of the river, or to produce it upon the pier by placing a steam-engine within the pier itself; and the latter plan was the one adopted.

The construction of the Ouse Bridge is shown in Figs. 1635 to 1646. Figs. 1635, 1636, show an elevation and plan of the swinging portion. Fig. 1637 is a vertical transverse section at the centre pier, showing the engine-room and accumulator, which are situated within the centre pier; and Fig. 1639 is a plan of the centre pier at the level of the engine-room, showing the arrangement of the driving-gear with the steam-engines and hydraulic engines. Fig. 1640 is an enlarged section of one half of the engine-room, and Fig. 1641 a sectional plan of the accumulator. Figs. 1647, 1648, are a plan and elevation of the hydraulic engines for turning the bridge; and Figs. 1643 to 1646 show the gear at the two extremities of the bridge for working the adjusting-supports and the locking-bolts.

The total length of the bridge, fixed and movable, is 830 ft. The fixed portions consist of five spans of 116 ft. each from centre to centre of piers. The bridge being for a double line of railway, each span is composed of three wrought-iron plate-girders, the centre girder having a larger section to adapt it for its greater load; these girders have single webs, and are 9 ft. deep in the centre. The total width of the bridge from outside to outside is 31 ft. Each of the piers for the fixed spans consists of three cast-iron cylinders of 7 ft. diameter and about 90 ft. length. The depth from the under-side of the bridge to the bed of the channel in the deepest part is about 61 ft. The headway beneath the bridge is 14 ft. 6 in. from high-water datum, and 30 ft. 6 in. from low water.

The swinging portion of the bridge, Figs. 1635, 1636, consists of three main wrought-iron girders, 250 ft. long, and 16 ft. 6 in. deep at the centre, diminishing to 4 ft. deep at the ends. The centre girder is of larger sectional area than the side girders, and instead of being a single web is a box-girder 2 ft. 6 in. in width, Fig. 1640, with web-plates $\frac{7}{16}$ to $\frac{5}{16}$ in. in thickness, and the top and bottom booms contain together about 132 sq. in. section. The roadway is carried upon transverse wrought-iron girders resting upon the bottom flanges of the main girders, Figs. 1640 and 1644. In the centre of the bridge the main girders are stayed by three transverse wrought-iron frames securely fixing them together; and over the top of these frames a floor is laid, from which the bridgeman controls the movements of the bridge.

An annular box-girder A A, 32 ft. mean diameter, is situated below the centre of the bridge and forms the cap of the centre pier, Figs. 1637 and 1640; this girder is 3 ft. 2 in. in depth and 3 ft. in width, and rests upon the top of six cast-iron columns, each 7 ft. diameter, which are arranged in a circle and form the centre pier of the bridge. Each of these columns has a total length of 90 ft., being sunk about 29 ft. deep in the bed of the river. A centre column B B, 7 ft. diameter, is securely braced to the six other columns by a set of cast-iron stays, which support the floor of the engine-room. This centre column contains the accumulator C, Fig. 1637, and forms the centre pivot on which the bridge rotates.

The weight of the swing bridge is 670 tons. There is no central lifting-press, and the entire weight rests upon a circle of conical live rollers E E, Figs. 1637 and 1640. These are twenty-six in number, as shown in the plan, Fig. 1638; they are each 3 ft. diameter with 14 in. width of tread, as shown in Fig. 1642, and are made of cast iron hooped with steel. They run between the two circular roller-paths D D, 32 ft. diameter and 15 in. broad, which are made of cast iron faced with steel; the axes of the rollers are horizontal, and the two roller-paths are turned to the same bevel.

The turning motion is communicated to the bridge by means of a circular cast-iron rack G, Fig. 1640, 12½ in. wide on the face and 6½ in. pitch, which is shrouded to the pitch-line and is bolted to the outer circumference of the upper roller-path. The rack gears with a vertical bevel-wheel H, which is carried by a steel centre-pin J supported in the lower roller-path; and this wheel is driven by a pinion connected by intermediate gearing with the hydraulic engine. There are two of these engines, duplicates of one another, which are situated at K K in the engine-room, Figs. 1639, 1640; and either of them is sufficient for turning the bridge, the force required for this purpose being equal to about 10 tons applied at the radius of the roller-path. Each hydraulic engine is a three-cylinder oscillating engine, as shown in Figs. 1647, 1648, with simple rams of 4½ in. diameter and 18 in. stroke. These engines work at forty revolutions a minute with a pres-

sure of water of 700 lbs. an inch, and are estimated at 40 horse-power each. The steam-engines for supplying the water-pressure are also in duplicate, situated at L L, Fig. 1639, and are double-cylinder engines driving three-throw pumps of $2\frac{1}{2}$ in. diameter and 5 in. stroke, which deliver

into the accumulator. The steam-cylinders are 8 in. diameter and 10 in. stroke, each engine being 12 horse-power.

The accumulator C, Fig. 1637, shown also in the sectional plan, Fig. 1641, has a ram $16\frac{1}{2}$ in. diameter with a stroke of 17 ft.; it is loaded with a weight of 67 tons, composed of cast-iron segments suspended from a cross-head and working down inside the cylindrical casing formed by the centre cylinder of the pier. A pair of cross-beams M M are fixed to limit the rise of the weight.

For the purpose of obtaining a perfectly solid roadway when the bridge is in position for the passage of trains, and also for securing the perfect continuity of the line of rails, the following arrangement is adopted, shown in Figs. 1643 to 1646. Each extremity of the bridge

is lifted slightly by a horizontal hydraulic press N, Figs. 1643, 1644, acting upon the levers PP which form a toggle-joint; the press has two rams acting in opposite directions upon two toggle-joint levers, which are connected by a horizontal bar Q, and this bar is confined to a

1637.

Section of centre pier and engine-room.

vertical movement by a stud sliding in a vertical guide, so as to ensure an exactly parallel action of the two toggle-joint levers, in order thereby to lift the bridge end exactly parallel. While the end of the bridge is thus held lifted, the three resting-blocks RR, one under each

girder, are pushed home by means of three separate hydraulic cylinders S S, Figs. 1645, 1646; the bridge is then let down upon these resting-blocks by the withdrawal of the toggle-joint levers P P, and the bridge ends are then perfectly solid for trains to pass over. The hydraulic cylinders N and S for working this fixing-gear at the two ends of the bridge are controlled by valves placed upon the centre platform in reach of the bridgeman, the pipes from the valves to the cylinders passing along the side of the roadway of the bridge.

For the purpose of enabling the bridgeman to stop the turning movement of the bridge at the right place, an indicator is provided consisting of a dial with two pointers which are actuated by the motion of the bridge. One of these pointers makes two revolutions and the other forty-two revolutions for one complete rotation of the bridge; they are similar to the hour and minute hands of a watch. The bridge has no stop to its turning movement, and would swing clear past its right position if the turning power were continued; but the bridgeman being guided by the indicator, knows when to stop and reverse the hydraulic engines for the purpose of stopping the bridge at its right place. When this is done, a strong locking-bolt T, Figs. 1643 to 1645, 3 in. thick, pressed outwards by a spiral spring, is shot out at each end of the bridge into a corresponding slot in the fixed girder, so as to lock the bridge; and when the bridge is required to be opened, these two bolts are withdrawn by a wire cord U, Fig. 1645, leading to the platform on which the bridgeman is

1645.

Longitudinal section showing locking-bolt and resting-block.

1647.

Plan of hydraulic engines.

stationed. In consequence of the line of the bridge lying in a north and south direction, the heat of the sun acting alternately on the opposite sides of the bridge produces a slight lateral warping; and in order to bring the ends back into the straight line after swinging the bridge, so as to enable the two locking-bolts to enter their slots, the feet of the toggle-joint lifting-levers P P are bevelled off at 55° on their inner faces, as shown at I I in Fig. 1644, and bear against corresponding bevels V V on the bed-plates. By this means the ends of the bridge when warped are forced back into the correct centre line, in which they are then held secure by the locking-bolts.

As the accumulator is stationary in the centre pier, while the fixing-gear at the ends of the bridge travels with the bridge in swinging, the communication of water-power is effected by a central copper pipe W, Fig. 1640, passing up in the axis of the bridge through the middle of the centre girder, and having a swivel joint at the lower end. Also as the bridgeman's hand-gear rotates with the bridge while the hydraulic turning engines are stationary, the communication for working the valves is made by a central copper rod X, Fig. 1640, passing down through the

1648.

Elevation.

centre of the pressure-pipe W in the axis of the bridge. The hydraulic engines are reversed in either direction by the action of a small hydraulic cylinder, which is governed by the movement of a three-port valve actuated by the rod X from the bridgeman's platform.

The time required for opening or closing the bridge, including the locking of the ends, is only fifty seconds, the average speed of motion of the bridge ends being 4 ft. a second. For the purpose of ensuring safety in the working of the railway line over the bridge, a system of self-acting signals is arranged, which is actuated by the fixing-gear at the two ends of the bridge; and a signal of all right is shown by a single semaphore and lamp at each end of the fixed part of the bridge; but this cannot be shown until each one of the locking-bolts and resting-blocks is secure in its proper place.

39. *Calculation of simple Lattice-girders.—General Methods.*—The triangle is the only articulate polygon which is unyielding; in other words, a triangle composed of inflexible bars cannot yield except by the extension or the contraction of its sides under the influence of the forces applied to them. We shall give the name of *simple lattice* to a network composed of a series of triangles arranged as in Fig. 1649: the whole collection of bars being regarded as a simple figure, the strain upon all the pieces will be determined by the elementary rules of statics. The load consists of distinct weights P, P_1 , applied to the several summits. The reaction Q of the support A is easily obtained by considering the equilibrium of the whole figure. To find the strain borne by any single piece CE, imagine a plane NN' cutting only this piece and two others BC, EG, and seek the conditions of equilibrium of the portion of the system included between the plane NN' and the support A. We obtain three distinct equations—two of projections, and one of moments—which determine the strains upon the three pieces crossed by NN'; for these strains appear as reactions of the right portion of the lattice upon the portion under consideration, and the other forces $Q, P \dots$ are known.

But it is easy to avoid any elimination. If we make the secant plane pass through the point C, the strains upon the pieces BC, EC, will not appear in the equation of moments, and we shall have at once the strain upon the section EG of the side, by dividing the moment of rupture about the opposite summit C, by the perpendicular let fall from C upon EG. The strain upon BC is found in like manner, in terms of the moment of rupture taken with respect to E. Returning to the section NN', we have only to state the equation of the vertical projections of the forces, to obtain the strain upon the bar EC in terms of the strains, already determined, of EG and BC.

If we take the upward direction of the forces as positive, the stress will be positive as long as the sum $P + P_1 + \dots$ of the loads between A and NN' is less than Q , and the moment of rupture will be positive if it tends to turn the figure in the same direction as Q . If we find, for example, the strain T of the bar EC positive, this will indicate that the portion CO of the bar tends to raise the portion EO, and, consequently, the piece CE is subject to a tensile strain; it will be, on the contrary, compressed, if T is negative. These conclusions would change if the bar were placed according to the other diagonal BG.

40. We may also determine the strains by a graphical process, founded upon the observation that at each summit of the triangles the strains upon the pieces which join them are in equilibrio, otherwise this summit would be displaced. Thus, beginning at the abutment, we shall decompose Q in the directions AB and AE, which will give the strains upon these two sides. Then in B we shall take the resultant of the known strain upon AB, and the weight P which is also known, and decompose it between BE and BC; this will give, without the sign, the strains upon these latter pieces. This operation must be continued for the other pieces.

41. A mixed process consists in calculating beforehand the strains upon the exterior sides or sections of flange by means of the moments of rupture, as explained in 39. Then we can at once in any summit, without passing through the preceding ones, determine graphically the strains upon the two inner bars, the function of which is to destroy the known resultant of the strains upon the two sections of flange and the particular load which may be applied to the summit in question.

42. To pass from these general considerations to formulæ more precise, we must begin by fixing the form of the system. Let us consider the case of *straight and horizontal flanges*. On applying the foregoing process to this case, we see immediately that, to find the strain of an interior bar, it is useless to know the absolute strains upon the two sections of flange which join at one of its extremities; it is enough to find the difference of their strains; the function of the two lattice-bars being to counterbalance that one of the two sections which exerts a predominant horizontal thrust, and to support, if necessary, the load which may be applied directly to the summit under consideration.

Now, this difference of strain depends upon the increase of the moment of rupture for a given interval, or, which is the same thing, of the transverse strain. The equation of equilibrium between the vertical forces gives $\frac{F}{\sin. \alpha}$ for the stress upon any interior bar, α being the angle

of this bar with the horizon, and F the stress in the interval which it occupies.

Thus, let $C D N$ be the locus of the transverse strains, Figs. 1650, 1651, the strain upon any bar $E G$ of the girder $A B H$ will be represented graphically by the length of a right line $E' G'$, parallel to $E G$, inscribed between the axis of the abscissæ and the horizontal line representing the stress in the interval occupied by the bar in question.

If the inclination α of the bars is constant, and we reduce in a constant proportion the ordinates of the locus $C D N$, these latter will represent directly to a given scale, either the strains or the sections of the several bars. In the absence of a special plan of strains, the locus $a b c d$ of the moments of rupture is sufficient to determine the strains upon the lattice-bars. For example, the stress relative to the bar $E G$ is nothing but the tangent of inclination of the right line $c d$ with respect to the axis of the x 's, taking into account, of course, the proportion between the scales of the abscissæ and of the ordinates.

43. But the locus of the moments of rupture is specially constructed with regard to the flanges of the girder: it is a polygon the summits of which correspond with the loads P, P' . The volume or the total weight of the lower flange will be proportional to the area comprised between the axis of the x 's and the broken line $a e f g h i k l m$; that of the upper flange will be given by $a' n o p q r s$; and it will be seen from the figure that the whole of the two flanges will be proportional to the area $a b c d \dots$ of the locus of the moments of rupture.

Suppose the girder loaded with equal weights $(p + p') \delta$ placed at equal intervals δ , and the bearing l expressed by $N \delta$. The polygon of the moments of rupture will be parabolic, and its area will be given by the formula obtained in 6. The double of this area, multiplied by $\frac{t}{h}$, t being the ratio $\frac{7800}{R} = 0.0013$ of the weight of the cubic mètre of iron to the admitted resistance, and h the height of the girder, will give for the total weight of the two flanges the value $\frac{(p + p')^2 t (N^2 - 1)}{6 h N^2}$, say the $\frac{2 (N^2 - 1)}{3 N^2}$ of the weight they would have in a girder loaded in a continuous manner, if the greatest section necessary in the middle were preserved throughout the whole length.

This expression does not change whether N be even or odd. But if N be even and we substitute $2m$ for it, the expression becomes $\frac{(p + p')^2 t}{24 h} \frac{4m^2 - 1}{m^2}$, whilst for N odd and equal to $2m + 1$, it assumes the form $\frac{2 (p + p')^2 t}{3 h} \frac{m (m + 1)}{(2m + 1)^2}$.

In practice, this weight of flange should be multiplied by a coefficient U designed to include the joint-plates and other accessories (see 63 and following sections).

In the more general case, when the extreme intervals have a length a different from δ , the bearing being expressed by $2a + N\delta$, the weight of the two flanges together will be

$$\frac{(p + p')t}{6h} (l^3 - N\delta^3 - 2a^3).$$

The total theoretical weight of the lattice-bars may also be represented by the area of a geometrical locus, namely, that having for equation $y = \frac{Ft}{\sin. \alpha \cos. \alpha}$, the inclination α being liable to vary from one bar to another, as well as the stress F . But if there were vertical bars, they would elude this mode of calculation, and we should have to consider them apart.

We are now about to state the formulæ giving the maximum strains and the weight of the several parts of straight girders of regular shape. We call *struts* the bars which are compressed by a load covering all the bridge, and *braces* or *ties* those which are subject to tensile force. But it may happen that a partial load changes the direction of the strains. The struts, or at least some of them, usually require an excess of section to give them the necessary rigidity. We shall take this into account by affecting the theoretical weight with a coefficient the mean value of which is denoted by the letter V (see 68 and following sections).

44. *Girder loaded in one point only.*—The load consists of a single weight P , applied to a point C , Fig. 1652. From A to C the stress has the constant value $\frac{Pb}{a+b}$; the struts, inclined at an angle α , bear in this interval a constant compression $\frac{Pb}{(a+b) \sin. \alpha}$, and the braces, inclined at an angle β , a tension $= \frac{Pa}{(a+b) \sin. \beta}$. In the second interval, from C to B , the stress has the negative value $-\frac{Pa}{a+b}$; the struts and braces affect, therefore, directions opposite to those which they had between A and C , and their strains are found in like manner by dividing the stress by the sine of angle of inclination.

When a girder supports a single weight, economy requires that the height should be increased and that the number of triangles formed by the bars should be reduced. For example, the most economical means of supporting a weight in the middle of the bearing consists theoretically of two bars at 45° resting against each other at their summits, and having their lower extremities supported upon abutments and held by a tie.

If the single weight P is a moving one, the maximum strain upon the bars having the same inclination will vary uniformly according to the same law as the maximum whole stress, which reaches the value P towards the support, and is reduced to $\frac{1}{2}P$ in the middle.

45. *Girders uniformly loaded on the upper side.*—If the load rests directly upon the upper flange, the several sections of the latter will undergo slight partial deflections; but these may be neglected when we regard the load as distributed among the upper summits proportionally to the intervals. This load is of two kinds: one portion denoted by p per lineal metre remains permanently throughout the bearing; the other portion, p' per metre, is moving, that is, it may affect either the whole bearing or only any portion of it; the letter q denotes the ratio $\frac{p'}{p+p'}$. Always supposing that the loaded points are equidistant, we shall consider various particular figures, symmetrical with respect to the middle of the bearing.

First arrangement, Fig. 1653. The intermediate upper summits support each a weight $p\delta$, and

accidentally another weight $p'\delta$; but in the two extreme summits C and D , these weights are reduced to $\frac{p}{2} \left(\delta + \frac{h}{\tan. \alpha} \right)$ and $\frac{p'}{2} \left(\delta + \frac{h}{\tan. \alpha} \right)$.

According to 5, the stress will reach its maximum when the load extends over a portion of the bridge only, and we easily find the following expressions. The several pieces are numbered from the middle to each abutment, for any two symmetrical pieces are in perfectly identical conditions.

A lengthening A C, D B, of the flanges, with upright stays at the ends, will be found useful in practice for a load above; but the formulæ do not include this, unless, indeed, it be included in the coefficient U.

Any strut, the order of which with respect to the others is expressed by n , supports the following maximum strain of compression :

$$(2n-1) \frac{p\delta}{2 \sin. \alpha} + \frac{p'}{4 \sin. \alpha \left(m\delta + \frac{h}{\tan. \alpha} \right)} \left\{ (m+n)(m+n-1)\delta^2 + \left[\frac{h}{\tan. \alpha} + (2m+2n-1)\delta \right] \frac{h}{\tan. \alpha} \right\},$$

except the end strut, the order of which is $m+1$, and which will support only

$$\frac{(p+p')}{\sin. \alpha} \left(m\delta + \frac{h}{2 \tan. \alpha} \right).$$

As to the braces, the tension of the n th reckoning from the middle is given without exception by

$$2n-1 \frac{p\delta}{2 \sin. \beta} + \frac{p'}{4 \sin. \beta \left(m\delta + \frac{h}{\tan. \alpha} \right)} \left\{ (m+n)(m+n-1)\delta^2 + \left[\frac{h}{\tan. \alpha} + (2m+2n-1)\delta \right] \frac{h}{\tan. \alpha} \right\}.$$

The flanges require a full load to produce in them the maximum strain. The compression of the n th upper section is $\frac{(p+p'h)}{2 \tan.^2 \alpha} + \frac{(p+p')\delta}{\tan. \alpha} \left(m-n+\frac{1}{2} \right) + \frac{(p+p')\delta^2}{2h} [m^2-(n-1)^2]$; which gives for the first which is the most heavily loaded $\frac{p+p'}{2} \left[\frac{h}{\tan.^2 \alpha} + \frac{(2m-1)\delta}{\tan. \alpha} + \frac{m^2\delta^2}{h} \right]$.

Tension of the n th lower section = $\frac{p+p'}{\tan. \alpha} \left(m\delta + \frac{h}{2 \tan. \alpha} \right) + \frac{(p+p')\delta^2}{2h} [m^2-(n-1)^2]$; say for the first, $\frac{p+p'}{2} \left[\frac{h}{\tan.^2 \alpha} + \frac{2m\delta}{\tan. \alpha} + \frac{m^2\delta^2}{h} \right]$.

Multiplying the strain upon a strut by its length and by the quantity tV , we shall have its weight. Then, summing the expression obtained, in which n takes the successive values 1, 2, 3, ... m , doubling the result, and adding the two extreme struts (the order of which is $m+1$) calculated apart, we find: Total weight of the 2 ($m+1$) struts

$$= \frac{phtV}{\sin.^2 \alpha} \left[m(m+2)\delta + \frac{h}{\tan. \alpha} \right] + \frac{mp'h tV}{2 \sin.^2 \alpha \left(m\delta + \frac{h}{\tan. \alpha} \right)} \left\{ \frac{\delta^2}{3} (7m^2+12m-1) + \frac{h}{\tan. \alpha} \left[\frac{(m+2)h}{m \tan. \alpha} + 3(m+2)\delta \right] \right\}.$$

We have next, without a coefficient of stiffness: Total weight of the 2 m braces

$$= \frac{m^2 p \delta h t}{\sin.^2 \beta} + \frac{mp'h t}{2 \sin.^2 \beta \left(m\delta + \frac{h}{\tan. \alpha} \right)} \left[\frac{\delta^2}{3} (7m^2-1) + \frac{h}{\tan. \alpha} \left(\frac{h}{\tan. \alpha} + 3m\delta \right) \right];$$

Then with coefficient U, for joint-plates, and so on:

$$\text{Total weight of the upper flange} = m(p+p')\delta tU \left[\frac{h}{\tan.^2 \alpha} + \frac{m\delta}{\tan. \alpha} + \frac{\delta^2}{6h} (4m-1)(m+1) \right];$$

Total weight of the lower flange

$$= \frac{(p+p')h^2 tU}{\tan.^3 \alpha} + m(p+p')\delta tU \left[\frac{3h}{\tan.^2 \alpha} + \frac{3m\delta}{\tan. \alpha} + \frac{\delta^2}{6h} (4m+1)(m-1) \right];$$

$$\text{Total weight of the two flanges together} = \frac{(p+p')tU}{3} \left(\frac{l^3}{2h} - \frac{m\delta^3}{h} - \frac{h^2}{\tan.^3 \alpha} \right).$$

This last result may be obtained directly by means of the area of the locus of the moments of rupture (see end of 6).

46. Particular case $\alpha = \beta$, and consequently $\frac{h}{\tan. \alpha} = \frac{\delta}{2}$, and the bearing $l = (2m+1)\delta$.

$$\text{Strain upon the } n\text{th strut or the } n\text{th brace} = \frac{(2n-1)p\delta}{2 \sin. \alpha} + \frac{p'\delta[4(m+n)^2-1]}{8(2m+1)\sin. \alpha};$$

Except the extreme strut, of order $m+1$, which supports $\frac{(p+p')\delta}{\sin. \alpha} \left(m + \frac{1}{4} \right)$;

$$\text{Compression of the } n\text{th end of upper flange} = \frac{(p+p')\delta^2}{2h} \left(m^2 - n^2 + m + n - \frac{1}{4} \right);$$

$$\text{Maximum strain of upper flange} = \frac{(p+p')\delta^2}{2h} \left(m^2 + m - \frac{1}{4} \right);$$

$$\text{Tension of the } n\text{th end of lower flange} = \frac{(p+p')\delta^2}{2h} \left(m^2 - n^2 + m + n - \frac{1}{4} \right);$$

$$\text{Maximum strain upon lower flange} = \frac{(p + p') \delta^2}{2h} \left(m^2 + m + \frac{1}{4} \right).$$

$$\text{Total weight of the } 2(m + 1) \text{ struts} = \frac{p h \delta t V}{\sin^2 \alpha} \left(m^2 + 2m + \frac{1}{2} \right) + \frac{p' \delta h t V (28m^2 + 18m - 1)}{12 \sin^2 \alpha (2m + 1)};$$

$$\text{Total weight of the } 2m \text{ braces} = \frac{m^2 p h \delta t}{\sin^2 \alpha} + \frac{m p' h \delta t (28m^2 + 18m - 1)}{12 \sin^2 \alpha (2m + 1)}.$$

If we substitute for the coefficient V , with which the struts alone are affected, a coefficient $\frac{1 + V}{2}$ applied to the whole of the lattice, we shall have:

$$\text{Total weight of the lattice} = \frac{(2m + 1)^2 (p + p') \delta h t (1 + V)}{4 \sin^2 \alpha} \left[1 + \frac{m(4m^2 + 6m - 1)}{3(2m + 1)^3} q \right].$$

And for the flanges, we have:

$$\text{Weight of the upper flange} = \frac{m(p + p') \delta^3 t U}{12h} (8m^2 + 12m + 1);$$

$$\text{Weight of the lower flange} = \frac{(p + p') \delta^3 t U}{12h} \left(8m^3 + 12m^2 + 7m + \frac{3}{2} \right);$$

$$\text{Weight of the two flanges together} = \frac{(p + p') \delta^3 t U}{6h} \left(8m^3 + 12m^2 + 4m + \frac{3}{4} \right).$$

If α were of 45° , we should substitute $\frac{1}{\sqrt{2}}$ for $\sin \alpha$, and $2h$ for δ ; we might, besides, substitute for m the value $\frac{l - 2h}{4h}$.

47. Another particular case: $\beta = 90^\circ$. We have $\sin \beta = 1$, $\frac{h}{\tan \alpha} = \delta$; the bearing becomes $2(m + 1)\delta$, say $2m'\delta$, making $m = m' - 1$. In the following values, $\frac{h}{\sqrt{h^2 - \delta^2}}$ may be substituted for $\sin \alpha$.

Strain upon the n th strut (including the last, of order m')

$$= \frac{(2n - 1)p\delta}{2 \sin \alpha} + \frac{(m' + n)(m' + n - 1)}{4m' \sin \alpha} p' \delta;$$

$$\text{Strain upon the } n\text{th brace} = \frac{(2n - 1)p\delta}{2} + \frac{(m' + n)(m' + n - 1)p\delta}{4m};$$

$$\text{Strain upon the } n\text{th end of the upper flange} = \frac{(p + p') \delta^2}{2h} (m'^2 - n^2);$$

$$\text{Maximum strain upon the upper flange} = \frac{(p + p') \delta^2}{2h} (m'^2 - 1);$$

$$\text{Maximum strain upon the } n\text{th end of lower flange} = \frac{(p + p') \delta^2}{2h} (m' + n - 1)(m' - n + 1);$$

$$\text{Maximum strain upon the lower flange} = m'^2 \frac{(p + p') \delta^2}{2h} = \frac{(p + p') l^2}{8h};$$

$$\text{Total weight of the } 2m' \text{ struts} = \frac{h \delta t V}{\sin^2 \alpha} \left[m'^2 p + \frac{7m'^2 - 1}{6} p' \right];$$

$$\text{Total weight of the } 2(m' - 1) \text{ braces} = (m' - 1) \delta h t \left[(m' - 1)p + \frac{7m' - 5}{6} p' \right];$$

$$\text{Total weight of the upper flange} = \frac{m'(m' - 1)(4m' + 1)(p + p') \delta^3 t U}{6h};$$

$$\text{Total weight of the lower flange} = m'(m' + 1)(4m' - 1) \frac{(p + p') \delta^3 t U}{6};$$

$$\text{Total weight of the two flanges together} = m'(4m'^2 - 1) \frac{(p + p') \delta^3 t U}{3h}.$$

48. In the particular case $\alpha = 90^\circ$, the two middle struts will become one. For l and δ constant, this case will be a little less economical than the preceding.

49. Second arrangement, Fig. 1654. This arrangement differs from the preceding only in the fact that the loaded point falls in the middle of the girder. The dotted triangle in the middle resists only beneath the action of a partial load; it offers a defect of symmetry if α is not equal to β . The weights applied to the extreme summits are inferior to the others, as in the preceding arrangements (see 45).

Strain upon the n th strut

$$= \frac{p n \delta}{\sin \alpha} + \frac{p'}{2 \sin \alpha \left(2m \delta - \delta + \frac{2h}{\tan \alpha} \right)} \left\{ \delta^2 (m + n)(m + n - 1) + \frac{h}{\tan \alpha} \left[\frac{h}{\tan \alpha} + \delta (2m + 2n - 1) \right] \right\};$$

$$\text{Except the last (the } m\text{th), which supports } \frac{p + p'}{\sin \alpha} \left[(2m - 1) \delta + \frac{h}{\tan \alpha} \right];$$

Strain upon the n th brace

$$= \frac{p n \delta}{\sin. \beta} + \frac{p'}{2 \sin. \beta \left(2 m \delta - \delta + \frac{2 h}{\tan. \alpha} \right)} \left\{ \delta^2 (m+n)(m+n-1) + \frac{h}{\tan. \alpha} \left[\frac{h}{\tan. \alpha} + \delta (2m+2n-1) \right] \right\};$$

Strain upon the n th section of the upper flange

$$= (m-n+1)(m+n-2) \frac{(p+p') \delta^2}{2 h} + \frac{p+p'}{2 \tan. \alpha} \left[\delta (2m-2n+1) + \frac{h'}{\tan. \alpha} \right];$$

Which gives for the middle section, the most heavily loaded,

$$\frac{m(m-1)(p+p') \delta^2}{2 h} + \frac{p+p'}{2 \tan. \alpha} \left[(2m-1) \delta + \frac{h}{\tan. \alpha} \right];$$

Strain upon the n th section of the lower flange

$$= (m+n-1)(m-n) \frac{(p+p') \delta^2}{2 h} + \frac{p+p'}{2 \tan. \alpha} \left[(2m-1) \delta + \frac{h}{\tan. \alpha} \right];$$

Which gives in the middle the same maximum strain as in the upper flange.

Total weight of the $2m+1$ struts, inclined at an angle α ,

$$= \frac{p h t V}{\sin.^2 \alpha} \left[\frac{h}{\tan. \alpha} + \delta (m^2 + m - 1) \right] + \frac{p' h t V}{6 \sin.^2 \alpha \left(2 m \delta - \delta + \frac{2 h}{\tan. \alpha} \right)} \left\{ \delta^2 (14 m^3 + 3 m^2 - 17 m + 6) + \frac{3 h}{\tan. \alpha} \left[\frac{(2m+3) h}{\tan. \alpha} + \delta (6 m^2 + 6 m - 5) \right] \right\}.$$

Total weight of the $2m-1$ braces, inclined at an angle β ,

$$= \frac{m(m-1) p \delta h t}{\sin.^2 \beta} + \frac{p' h t}{6 \sin.^2 \beta \left(2 m \delta - \delta + \frac{2 h}{\tan. \alpha} \right)} \left\{ \delta^2 (14 m^3 - 21 m^2 + 7 m) + \frac{3 h}{\tan. \alpha} \left[\frac{(2m-1) h}{\tan. \alpha} + \delta (6 m^2 - 6 m + 1) \right] \right\};$$

Total weight of the upper flange

$$= m(4m+1)(m-1) \frac{(p+p') \delta^3 t U}{6 h} + \left[\frac{(2m-1) h}{2 \tan. \alpha} + \left(m^2 - m + \frac{1}{2} \right) \delta \right] \frac{(p+p') \delta t U}{\tan. \alpha};$$

Total weight of the lower flange

$$= m(m-1)(4m-5) \frac{(p+p') \delta^3 t U}{6 h} + \left[\frac{3(2m-1) h}{2 \tan. \alpha} + \left(3 m^2 - 3 m + \frac{1}{2} \right) \delta \right] \frac{(p+p') \delta t U}{\tan. \alpha} + \frac{(p+p') h^2 t U}{\tan.^3 \alpha};$$

Total weight of the two flanges together

$$= (2m-1)(p+p') \delta t U \left[\frac{2m(m-1) \delta^2}{3 h} - \frac{l}{\tan. \alpha} \right] + \frac{(p+p') h^2 t U}{\tan.^3 \alpha}.$$

50. Particular case $\alpha = \beta$, and consequently $\frac{h}{\tan. \alpha} = \frac{\delta}{2}$. The bearing is then $2m\delta$.

$$\text{Strain upon the } n\text{th strut} = \frac{p n \delta}{\sin. \alpha} + \frac{p' \delta}{4 m \sin. \alpha} \left[(m+n)^2 - \frac{1}{4} \right];$$

Except the last (m th), which supports $(p+p') \frac{(4m-1) \delta}{4 \sin. \alpha}$;

$$\text{Strain upon the } n\text{th brace} = \frac{p n \delta}{\sin. \alpha} + \frac{p' \delta}{4 m \sin. \alpha} \left[(m+n)^2 - \frac{1}{4} \right];$$

$$\text{Strain upon the } n\text{th section of the upper flange} = \left(m^2 - n^2 + 2n - \frac{5}{4} \right) \frac{(p+p') \delta^2}{2 h};$$

Strain upon the n th section of the lower flange = $(m^2 - n^2 + n - \frac{1}{4}) \frac{(p + p') \delta^2}{2h}$;

Maximum strain in the middle of the flanges = $(m^2 - \frac{1}{4}) \frac{(p + p') \delta^2}{2h}$;

Total weight of the $2m + 1$ struts (including one side of the middle triangle)

$$= \frac{(2m^2 + 2m - 1) p \delta h t V}{2 \sin.^2 \alpha} + \frac{(56m^3 + 48m^2 - 26m + 3) p' \delta h t V}{48m \sin.^2 \alpha}$$
;

Total weight of the $2m - 1$ braces (including one side of the middle triangle)

$$= \frac{m(m - 1) p \delta h t}{\sin.^2 \alpha} + \frac{(56m^2 - 48m^2 - 2m + 3) p' \delta h t}{48m \sin.^2 \alpha}$$
;

Total weight of the whole lattice, applying the coefficient $\frac{1 + V}{2}$,

$$= \frac{(4m^2 - 1) (p + p') \delta h t (1 + V)}{4 \sin.^2 \alpha} \left[1 + \frac{8m^3 - 2m + 3}{12m(4m^2 - 1)} q \right]$$
;

Total weight of the upper flange = $(16m^3 - 10m + 3) \frac{(p + p') \delta^3 t U}{24h}$;

Total weight of the lower flange = $m(8m^2 + 1) \frac{(p + p') \delta^3 t U}{12h}$;

Total weight of the two flanges together = $(32m^3 - 8m + 3) \frac{(p + p') \delta^3 t U}{24h}$.

The weight of the lower flange exceeds by $\frac{(4m^2 - 1) (p + p') \delta^3 t U}{8h}$ that of the upper flange.

If the inclination of the bars is 45° , the value of the strains upon them will be

$$h\sqrt{2} \left[2pn + \frac{p'}{2m} \left(m + n + \frac{1}{2} \right) \left(m + n - \frac{1}{2} \right) \right],$$

with the exception of the last or n th strut, which will support $\left(2m - \frac{1}{2} \right) (p + p') h\sqrt{2}$. The total weight of the lattice is $(4m^2 - 1) (p + p') h^2 t (1 + V) \left[1 + \frac{8m^3 - 2m + 3}{12m(4m^2 - 1)} q \right]$. In the strains upon the flanges $\frac{\delta^2}{2h}$ should be changed into $2h$, and in their weight $\frac{\delta^3}{h}$ into $8h^2$. And in all the expressions the quantity $\frac{l}{4h}$ may be substituted for m .

51. The particular case $\beta = 90^\circ$, will offer a defect of symmetry in the middle, like the general case. The bearing l becomes $(2m + 1) \delta$.

The strain upon the n th vertical brace is $pn\delta + p'\delta \frac{(m + n)(m + n + 1)}{2(2m + 1)}$, and that of the n th strut is given by the same formula divided by $\sin. \alpha$.

The n th section of the upper or the lower flange supports

$$(m + n)(m - n + 1) \frac{(p + p') \delta^2}{2h}.$$

Total weight of the $2m + 1$ struts = $\frac{m(m + 1) \delta h t V}{\sin.^2 \alpha} \left(p + \frac{7}{6} p' \right)$;

Total weight of the $2m - 1$ braces = $m \delta h t \left((m - 1)p + \frac{7m - 5}{6} p' \right)$;

Total weight of the upper flange = $m(m + 1)(4m - 1) \frac{(p + p') \delta^3 t U}{6h}$;

Total weight of the lower flange = $m(m + 1)(4m + 5) \frac{(p + p') \delta^3 t U}{6h}$;

Total weight of the two flanges together = $\frac{2}{3} m(m + 1)(2m + 1) \frac{(p + p') \delta^3 t U}{h}$.

52. Third arrangement, Fig. 1655. This arrangement differs from the first, in the fact of the struts being equal in number to the braces, which will simplify the formulæ. As the girder ends with a brace, it may be supported on the ends of the upper flange, as shown in the figure.

The weights applied to the upper summits are all equal to $p\delta$ for the permanent portion, and to $p'\delta$ for the moving load. The maximum reaction of the abutment, not including the weight which it bears directly, has the value $\left(m - \frac{1}{2} \right) (p + p') \delta$.

1556.

$$\text{Strain upon any } n\text{th strut} = \frac{\delta}{2 \sin. \alpha} \left[(2n-1)p + (m+n)(m+n-1) \frac{p'}{2m} \right];$$

$$\text{Strain upon the } n\text{th brace} = \frac{\delta}{2 \sin. \beta} \left[(2n-1)p + (m+n)(m+n-1) \frac{p}{2m} \right];$$

$$\text{Strain upon the } n\text{th section of the upper flange} = \frac{(p+p')\delta}{2} \left[\frac{(m^2-n^2)}{h} + \frac{(2n-1)}{\tan. \beta} \right];$$

$$\text{Which gives for the first towards the middle, } \frac{(p+p')\delta}{2} \left[\frac{(m^2-1)}{h} + \frac{1}{\tan. \beta} \right];$$

$$\text{Strain upon the } n\text{th section of the lower flange} = (m-n+1)(m+n-1)(p+p') \frac{\delta^2}{2h};$$

$$\text{Which gives for the maximum strain in the middle, } \frac{m^2(p+p')\delta^2}{2h}, \text{ or } \frac{(p+p')l^2}{8h};$$

$$\text{Total weight of the } 2m \text{ struts} = \frac{\delta h t V}{\sin.^2 \alpha} \left[m^2 p + \frac{7m^2-1}{6} p' \right];$$

$$\text{Total weight of the } 2m \text{ braces} = \frac{\delta h t}{\sin.^2 \beta} \left(m^2 p + \frac{7m^2-1}{6} p' \right);$$

$$\text{Total weight of the upper flange} = m(p+p')\delta^2 \left[\frac{(4m+1)(m-1)\delta}{6h} + \frac{m}{\tan. \beta} \right] t U;$$

$$\text{Total weight of the lower flange} = m(p+p')\delta^2 \left[\frac{(4m-1)(m+1)\delta}{6h} - \frac{m}{\tan. \beta} \right] t U;$$

$$\text{Total weight of the two flanges together} = m(4m^2-1)(p+p') \frac{\delta^3 t U}{3h}.$$

The difference between the weights of the upper and lower flanges is expressed by $m^2(p+p')\delta^2 t U \left(\frac{2}{\tan. \beta} - \frac{\delta}{h} \right).$

53. Particular case in which $\alpha = \beta$. The quantity $\frac{h}{\tan. \beta}$ becomes $\frac{\delta}{2}$.

$$\text{Strain upon the } n\text{th struts and braces} = \frac{\delta}{2 \sin. \alpha} \left[(2n-1)p + (m+n)(m+n-1) \frac{p'}{2m} \right];$$

$$\text{Strain upon the } n\text{th section of the upper flange} = \left(m^2 - n^2 + n - \frac{1}{2} \right) (p+p') \frac{\delta^2}{2h};$$

$$\text{Strain upon the } n\text{th section of the lower flange} = (m-n+1)(m+n-1)(p+p') \frac{\delta^2}{2h};$$

$$\text{Total weight of the } 2m \text{ braces} = (p+p') \frac{m^2 \delta h t}{\sin.^2 \alpha} \left(1 + \frac{m^2-1}{6m^2} q \right);$$

Total weight of the $2m$ struts = the preceding expression multiplied by V ;

$$\text{Volume of the upper flange} = \text{volume of the lower} = m(4m^2-1)(p+p') \frac{\delta^3 t U}{6h}.$$

If the inclination of the bars is 45° , the strains upon them will be calculated by the formula $h \sqrt{2} \left[(2n-1)p + (m+n)(m+n-1) \frac{p'}{2m} \right]$, and their total weight, struts and braces together, by $4m^2(p+p')h^2 t (1+V) \left(1 + \frac{m^2-1}{6m^2} q \right).$

The total weight of the two flanges will be $8m(4m^2-1)(p+p') \frac{h^2 t U}{3}$, and in the expression of their strains $\frac{\delta^2}{2h}$ should be changed into $2h$. We may also substitute $\frac{l}{4h}$ for m .

54. Particular case in which $\beta = 90^\circ$. The strain upon the extreme ends of the upper flange is rendered nul, and the extreme braces are simple suspension-rods, necessary only on the hypothesis that the point of support upon the abutments is taken at the height of the upper

flange. But if these suspension-rods be suppressed and the girder supported by the bottom, we shall have exactly the case in 47. Our present formulæ would give $\delta h t \left(m^2 p + \frac{7m^2 - 1}{6} p' \right)$ as the total weight of the braces, including the suspension-rods; but the suppression of these latter will reduce the weight to $(m - 1)^2 \delta h t \left(p + \frac{7m - 5}{6(m + 1)} p' \right)$, as in the section above referred to.

In the case in which $\alpha = 90^\circ$, the two struts in the middle become one. The hypotheses $\alpha = 90^\circ$ or $\beta = 90^\circ$, introduced into the general formulæ of 52, both give the same total weight for the flanges and for the lattice.

55. Fourth arrangement, Fig. 1656. This figure differs from the preceding, in the fact that the middle of the girder does not coincide with one of the loaded points, but falls in the middle

of an interval. The dotted triangle, in the middle, offers a defect of symmetry, if α differs from β ; it does not resist when the load extends throughout the length; one of the bars which compose it is regarded as a strut, the other as a brace.

$$\text{Strain upon the } n\text{th strut} = \frac{\delta}{\sin. \alpha} \left[n p + \frac{(m + n)(m + n + 1)}{2(2m + 1)} p' \right];$$

$$\text{Strain upon the } n\text{th brace} = \frac{\delta}{\sin. \beta} \left[n p + \frac{(m + n)(m + n + 1)}{2(2m + 1)} p' \right];$$

$$\begin{aligned} \text{Strain upon the } n\text{th upper horizontal section} \\ = (m - n + 1)(m + n)(p + p') \frac{\delta^2}{2h} + (n - 1)(p + p') \frac{\delta}{\tan. \beta}; \end{aligned}$$

$$\text{Strain upon the } n\text{th lower horizontal section} = (m - n + 1)(m + n)(p + p') \frac{\delta^2}{2h};$$

$$\text{Maximum strain in the middle of the flanges} = m(m + 1)(p + p') \frac{\delta^2}{2h};$$

$$\text{Total weight of the } 2m + 1 \text{ struts} = \frac{m(m + 1)\delta h t V}{\sin.^2 \alpha} \left(p + \frac{7}{6} p' \right);$$

$$\text{Total weight of the } 2m + 1 \text{ braces} = \frac{m(m + 1)\delta h t}{\sin.^2 \beta} \left(p + \frac{7}{6} p' \right);$$

$$\text{Total weight of the upper flange} = m(m + 1)(p + p') \delta^2 t U \left[\frac{(4m - 1)\delta}{6h} + \frac{1}{\tan. \beta} \right];$$

$$\text{Total weight of the lower flange} = m(m + 1)(p + p') \delta^2 t U \left[\frac{(4m + 5)\delta}{6h} - \frac{1}{\tan. \beta} \right];$$

$$\text{Total weight of the two flanges together} = \frac{2}{3} m(m + 1)(2m + 1)(p + p') \frac{\delta^3 t U}{h}.$$

56. Case in which $\alpha = \beta$.

$$\text{Strain upon the lattice-bars} = \frac{\delta}{\sin. \alpha} \left[n p + \frac{(m + n)(m + n + 1)}{2(2m + 1)} p' \right];$$

$$\text{Strain upon the } n\text{th upper horizontal section} = (m^2 - n^2 + m + 2n - 1)(p + p') \frac{\delta^2}{2h};$$

$$\text{Strain upon the lower horizontal section} = (m + n)(m - n + 1)(p + p') \frac{\delta^2}{2h};$$

$$\text{Total weight of the lattice} = \frac{m(m + 1)\delta h t (1 + V)}{\sin.^2 \alpha} \left(p + \frac{7}{6} p' \right);$$

$$\begin{aligned} \text{Total weight of the upper flange} &= \text{weight of the lower flange} \\ &= m(m + 1)(2m + 1)(p + p') \frac{\delta^3 t U}{3h}. \end{aligned}$$

If the inclination is 45° , $\frac{1}{\sqrt{2}}$ may be substituted for $\sin. \alpha$, and $2h$ for δ . The quantity m is then equal to $\frac{l}{4h} - \frac{1}{2}$.

57. The case in which $\beta = 90^\circ$ is similar to the corresponding case of the second arrangement in 51. There will be nothing changed except the total weight of the braces, which will amount

here to $m(m+1)\delta h t \left(p + \frac{7}{6}p'\right)$, on account of their number being $2m$ instead of $2(m-1)$, the extreme braces serving only to suspend the girder from the upper points of support.

58. *Girders uniformly loaded on the lower side.*—If we turn upside down the various systems which we have been examining, the load will be transposed to the lower side, and we shall have merely to apply the same formulæ with the signs of the strains changed; the lower flange will have become the upper, the struts braces, and *vice versa*. We must also change α into β , and β into α , the symbol α being always applied to struts and β to braces.

We shall consider only the two arrangements shown in Figs. 1657 and 1658. The first is obtained by reversing the third arrangement of girders loaded on the upper side, Fig. 1655, and the second by reversing the fourth arrangement, Fig. 1656.

The formulæ applicable to these two arrangements and to their particular cases will be found in Table VIII.

59. *Inclination of the Lattice-bars.*—When the inclination α of the bars is quite arbitrary, it should be taken equal to 45° , for a bar crossing an interval δ , will weigh $\frac{F t \delta_1}{\sin. \alpha \cos. \alpha}$, which amounts to $\frac{F t}{\sin. \alpha \cos. \alpha}$ the lineal mètre of girder: now this expression is a minimum when $\alpha = 45^\circ$.

But simple lattice-girders are usually divided into intervals of a given length δ , which form the base of triangles the other sides of which are a strut inclined to an angle α and a brace inclined to β , so that these two angles α and β are an implicit function one of the other, for they are connected by the relation $h(\cot. \alpha + \cot. \beta) = \delta$, whence $\frac{d\beta}{d\alpha} = -\frac{\sin.^2 \beta}{\sin.^2 \alpha}$, δ and h being regarded as given constants. The weight of the two bars of one of the triangles has the value $F h t \left(\frac{V}{\sin.^2 \alpha} + \frac{1}{\sin.^2 \beta} \right)$, and it becomes a minimum when we have $\frac{V \cos. \alpha}{\sin.^3 \alpha} + \frac{\cos. \beta}{\sin.^3 \beta} \cdot \frac{d\beta}{d\alpha} = 0$, whence $\frac{\tan. \alpha}{\tan. \beta} = V$. It would, therefore, be necessary to give the struts an inclination nearer the vertical than the braces.

60. It is easy to solve the question from a more general point of view, by attributing distinct coefficients to each of the two flanges and to each of the two systems of bars, as if, for example, these different parts were made of different materials. On this hypothesis let ξ denote, for the upper flange, the value of the lineal mètre of a prism capable of bearing a net strain of 1 kilogramme, taking into account the joint-plates and other accessories. Let ξ_1 , ξ' , and ξ'' be the analogous quantities relative to the lower flange, the struts, and the braces. And let us take, by way of example, a girder loaded on the lower side of the system of Fig. 1657, in which l is expressed by $2m\delta$.

The total value P of the girder will be given by the formulæ of weights of Table VIII., by suppressing the factor t and the coefficients $U V$, and substituting for them the new coefficients ξ , and so on. If we put

$\left(1 + \frac{m^2 - 1}{6m^2} q\right) \xi' = a$, $\left(1 + \frac{m^2 - 1}{6m^2} q\right) \xi'' = a'$, $\frac{4m^2 - 1}{6m} (\xi + \xi_1) + \frac{1}{2} (\xi_1 - \xi) = c$, and $\frac{4m^2 - 1}{6m} (\xi + \xi_1) - \frac{1}{2} (\xi_1 - \xi) = c'$, and substitute the value $\frac{\delta}{\cot. \alpha + \cot. \beta}$ for h , and $\frac{l}{2m}$ for δ , we shall have $P = \frac{1}{4} (p + p') F \left\{ \frac{1}{\cot. \alpha + \cot. \beta} \left(\frac{\alpha}{\sin.^2 \alpha} + \frac{\alpha'}{\sin.^2 \beta} \right) + c \cot. \alpha + c' \cot. \beta \right\} + \Omega$;

Ω is the additional term intended to include accessory pieces, such as gussets, and so on, regarded as independent of h , as well as of the angles α and β . The quantities a, a', c, c' , are also constants, for δ , and consequently m , is given; the height h is arbitrary, but as it has been eliminated, there remain only the two independent variables α and β . For the minimum expense, the partial derivatives of P , relative to α and to β , must be nul separately, which will give the equations

$$(a + c) \cot.^2 \alpha + (c - a') \cot.^2 \beta + 2(a + c) \cot. \alpha \cot. \beta - a - a' = 0,$$

$$\text{and } (c - a) \cot.^2 \alpha + (a' + c') \cot.^2 \beta + 2(a' + c') \cot. \alpha \cot. \beta - a - a' = 0.$$

Subtracting one from the other, member by member, we obtain an equation of the second degree to determine the proportion of the cotangents or of the tangents. We deduce from it $\frac{\tan. \alpha}{\tan. \beta} = -1$, first value inadmissible, and $\frac{\tan. \alpha}{\tan. \beta} =$

$$\frac{2a + c - c'}{2a' - c + c'} = \frac{2\xi' \left(1 + \frac{m^2 - 1}{6m^2} q\right) + \xi_1 - \xi}{2\xi'' \left(1 + \frac{m^2 - 1}{6m^2} q\right) - \xi_1 + \xi}.$$

Elimination leads to

$$\tan. \alpha = \frac{Z}{2\xi'' \left(1 + \frac{m^2 - 1}{6m^2} q\right) + \xi - \xi_1} \text{ and } \tan. \beta = \frac{Z}{2\xi' \left(1 + \frac{m^2 - 1}{6m^2} q\right) + \xi_1 - \xi},$$

Z denoting the radical

$$\sqrt{4\xi'\xi'' \left(1 + \frac{m^2 - 1}{6m^2} q\right)^2 + 2(\xi_1 - \xi)(\xi'' - \xi') \left(1 + \frac{m^2 - 1}{6m^2} q\right) - (\xi_1 - \xi)^2 + \frac{2(4m^2 - 1)}{3m} (\xi + \xi_1)(\xi' - \xi'') \left(1 + \frac{m^2 - 1}{6m^2} q\right)}.$$

Consequently, the dependent variable h will have, as a minimum, the value

$$h_1 = \frac{lZ}{4m(\xi' + \xi'') \left(1 + \frac{m^2 - 1}{6m^2} q\right)}.$$

In a girder consisting entirely of iron we have not to distinguish different materials, but the distinction of coefficients may exist from other causes. If, for example, we wish to impose upon the upper flange $\frac{1}{K}$ of the coefficient R imposed upon the lower one, we must substitute KUt for ξ , Ut for ξ_1 , Vt for ξ' , and t for ξ'' , P then denoting the total weight of the girder. But it must be remarked that the preceding calculations suppose that we may regard as constant the coefficients U and V , whilst it would be more exact to consider them as functions of the height. With this observation, when both flanges are affected with the same coefficient ($K = 1$), we shall have

$$\frac{\tan. \alpha}{\tan. \beta} = V, h_1 = \frac{l}{2m(V+1)} \sqrt{V + 2m \frac{4m^2 - 1}{6m^2 + (m^2 - 1)q} (V+1)U}.$$

61. Analogous calculations for the case in which $l = (2m + 1)\delta$, Fig. 1539, would give as a minimum

$$\frac{\tan. \alpha}{\tan. \beta} = \frac{2\xi' \left(1 + \frac{1}{6} q\right) + \xi_1 - \xi}{2\xi'' \left(1 + \frac{1}{6} q\right) + \xi - \xi_1}, \text{ and } h_1 = \frac{lZ}{2(2m + 1)(\xi' + \xi'') \left(1 + \frac{1}{6} q\right)},$$

Z denoting the radical

$$\sqrt{4 \left(1 + \frac{1}{6} q\right) \left[\xi'\xi'' \left(1 + \frac{1}{6} q\right) + \xi\xi' + \xi_1\xi'' + \frac{2}{3} (4m - 1)(\xi + \xi_1)(\xi' + \xi'') \right] + (\xi - \xi_1)^2}.$$

For bridges constructed of plate iron, we should make $\xi = \xi_1 = Ut$, $\xi' = Vt$ and $\xi'' = t$; and, consequently, we should take, U and V being regarded as nearly constant,

$$\frac{\tan. \alpha}{\tan. \beta} = V, \text{ and } h_1 = \frac{l}{(2m + 1)(V + 1)} \sqrt{V + \frac{(16m - 1)U(V + 1)}{3 + \frac{1}{2} q}}.$$

But as a function varies little when near a minimum, we need not bind ourselves to follow strictly the rules obtained for the best proportion of the inclinations α and β . Thus they are generally made equal to each other, which is of a more satisfactory aspect.

62. Deflection.—The deflection of a simple lattice under the influence of a certain load will, in general, be easy to determine, when we have the sections of all the pieces and the exact figure of the system under a determinate load given. Then the load, the effect of which we wish to consider, will produce upon the several parts extensions or contractions easy to calculate, so that we can know the length of all the pieces after deflection, and the angles may afterwards be found by trigonometrical formulæ. The determining figure being known, we may deduce the curve of the flanges, the inclination at their extremities, and so on.

Coefficient U applicable to the Flanges.—*Coefficient of stiffness V.*—*Supplementary term Ω .*—*General form of the Formula for Weight.*—63. Coefficient U. This coefficient is intended to take into account the joint-plates of the flanges, and, beyond this, the impossibility, in practice, of reducing the latter exactly to the dimensions given by calculation.

1. *Joint-plates.*—The narrower an iron plate is, the longer it may be, so that small girders will cost proportionally less in joint-plates than large ones. But even for these latter, with plates of 0·80 metre broad, for example, we may reckon upon lengths of 6 metres. If at each joint we have a distinct joint-plate of 0·80 metre long (0·40 metre on each side of the joint), the quantity to be added the metre of plate would be $\frac{0\cdot80}{6} = 0\cdot134$; but we may reduce this figure to 0·11, in

consideration of the fact that the angle-irons of the flange may reach lengths of more than 12 metres, and, consequently, will cost less in joint-plates than the plates of the flanges. This additional quantity of 0·11 may be regarded as the highest limit of the cost of joint-plates in the case of flanges of inconsiderable section composed of a single horizontal plate.

But when the maximum moment of rupture requires a strong section of flange, they are composed of several plates placed one upon another, and in that case a single joint-plate may serve for several joints placed after each other at intervals of 0·40 metre. For example, a joint-plate of 1·60 metre may cover three joints, which will reduce the additional quantity to 0·089. If we consider as an hypothetical limit an extremely low girder, such that the number of flange-plates shall be very great, the joint-plates would be as long as possible, and would have a tendency to weigh, for each joint covered, only the half of the weight of a distinct joint-plate of 0·80 metre. We may thus include the joint-plates in our calculations by applying to the flanges a coefficient varying from 1·06 to 1·11, according as these latter are of great thickness (as if the height were nul), or, on the contrary, reduced to the minimum section that may practically be adopted without depriving the girder of its necessary rigidity; having regard to its other dimensions. These figures may be reduced a little in the case of plates 0·30 or 0·40 metre broad, for example, which would allow us to reckon upon lengths greater than 6 metres.

In heavy girders the number of plates diminishes towards the extremities, and it will be only in the middle that the coefficient may reach the limit 1·06 metre. But, to compensate this, it often happens that at the extremities the first joints of the first plates may be covered by increasing slightly the length of the strengthening plates.

2. *Excesses of Section.*—The section of the flanges cannot be, throughout the length, reduced strictly to the value required by calculation, chiefly on account of the facts that the variation takes place by redans or gradations, and that at those points in which the moment of rupture is inconsiderable, we cannot practically reduce the section below a certain minimum. Instead of a small number of very thick plates, we shall find it a saving of material to employ a larger number of less thickness. But to abstract these thicknesses, let us consider, as above, the limiting cases. If, in the first place, the height were nul, the number of plates of ordinary thickness would be very great, and the redans would be only an imperceptible fraction of the total weight. If, on the contrary, the height reaches a value H, such that the weakest section that we wish to give to the flanges shall be sufficient in the middle, the flange will be prismatic instead of forming a parabolic volume, as the formula for the case of a continuous load suppose. To establish the prism in its integrity, we must multiply the value of the formula by a coefficient of 1·50, affecting generally the joint-plates which increase in the same proportion.

64. Thus the total coefficient U to be applied to the flanges for joint-plates and excesses of section may be taken equal to 1·06 for $h = 0$, and to $1\cdot11 \times 1\cdot50 = 1\cdot66$ for the limiting height H, which renders necessary a constant section in the flanges. We may, therefore, approximatively adopt, for any value of h , $U = 1\cdot06 + 0\cdot60 \frac{h}{H}$.

Usually the volume of the flanges is inversely proportional to h , so that the second term of U will give a quantity independent of h . Consequently, in seeking the most economical height, this constant term will have no influence, and we shall have simply to substitute 1·06 for U.

65. When the load is applied to certain intervals only, we may still admit the preceding expression of U. Yet, from the observation in 43, it will be more exact, if the bearing is divided into N intervals, to multiply the theoretical weight by $1\cdot50 \frac{N^2}{N^2 - 1}$, instead of 1·50, when there is occasion to return to the prismatic form in the case of the limiting height H. The coefficient will then be expressed by the function $U = 1\cdot06 + \left(\frac{1\cdot66 N^2}{N^2 - 1} - 1\cdot06 \right) \frac{h}{H}$.

In simple lattice bridges, U has a tendency to increase slightly on account of the vertical rods serving to fix the bars, for these rods give a certain rigidity to the flanges which affects the resistance by easing the oblique bars, but at the same time by producing in the flanges deflecting strains and an unequal distribution of pressure. The best way to take this into account is to consider the two flanges as forming a solid whole resisting by its summit of resistance.

In girders loaded in a discontinuous manner, theory itself requires that the flanges should vary by sudden leaps from one section to another, but we cannot wholly get rid of the loss occasioned by the redans, on account of the difficulty of making the extra thicknesses prescribed by calculation coincide exactly with the usual thicknesses of plate iron.

66. The limiting height H to be considered in calculating U, may be taken equal to $\frac{(p+p')l^2}{8R s_0}$, s_0 being the minimum section that we wish to give, or that we may give, to the flanges. Consequently the value of U, considering only the case of a continuous load, will be $U = 1\cdot06 + 4\cdot80 \frac{R s_0 h}{(p+p')l^2}$.

In a girder composed of triangles, we may regard as nearly constant the ratios $\frac{h}{l}$ and $\frac{s_0}{h}$; or at least if s_0 has a tendency to be proportionally a little stronger in small girders than in large ones, so that U will decrease slightly when h , and consequently l , increases; on the other hand, small girders cost less in joint-plates, and we may, therefore, regard U as expressed by $1.06 + \frac{c}{p+p'}$, c being a constant independent of l .

67. The preceding remarks concern straight girders. In bow-string girders, the joint-plates will have the same proportional value, but if the lower flange be straight, it will have a constant section, and there will be no loss for redans; besides, the section of the flanges is utilized quite to the extremities, whilst in straight girders there is always an excess of section at the ends. On the other hand, the bow and the chord, or stringer, in a bow-girder are fixed together at the ends by iron plates, which may be considered as forming an integral part of the flanges. When the height is inconsiderable, the strain between the bow and the chord will be great, and the gusset must be very long, but its mean breadth will be less than in a girder having a versed sine or rise of great magnitude. The coefficient U will vary but little in bow-string girders, and may be taken from 1.25 to 1.35.

68. *Coefficient of stiffness V.*—The pieces subject to compression have a tendency to deviate from the straight line when they have a weak section and great length; therefore, we are obliged in such cases to give them an excess of section, that is, instead of calculating them for a pressure of 6000000 kilos, the square metre, we shall calculate them for a less pressure R ; or having calculated them for 6000000 kilos., we must multiply the section so obtained by a coefficient $V = \frac{6000000}{R}$.

For flat bars, simply abutting against others at their extremities, we may, from the results of experience, admit the following figures:—

Ratio of the length to the thickness $\frac{\lambda}{e}$	15	20	25	30	35	40	45	50	55	60	65	70	75	80	90	100
Resistance the square millimetre	6.00	5.30	4.75	4.25	3.90	3.55	3.25	3.00	2.70	2.50	2.30	2.10	2.00	1.80	1.50	1.20
Coefficient of increase V	1.000	1.132	1.263	1.412	1.538	1.690	1.846	2.000	2.222	2.400	2.609	2.857	3.000	3.333	4.000	5.000

The bars of lattice-girders being usually attached at their extremities by several rivets, may be regarded as welded or shut on, and we shall obtain additional security by observing the preceding data.

But flat bars have precisely the worst possible form to resist a strain of compression. This obliges us to increase the number and to place them near together, in order that each isolated part may have the necessary rigidity without giving to V too high a value. But the rivetings at the points where the bars cross each other are not all-sufficient, for the compressed bars are badly supported by being fixed to other bars as flexible as themselves; when the number of lattice-bars becomes great and, in consequence, the sections become very inconsiderable, the struts may yield by numerous deflections, twisting the braces, some in one direction, some in another, an effect similar to the wrinkles which show themselves upon a thin membrane stretched in a frame, when the angles of the frame are distorted. It follows, that we ought to employ flat bars only for girders of small height and heavily loaded, unless, indeed, the rigidity of the vertical middle part of the girder be sufficiently provided for by upright stays. If these stays serve no other purpose than to stiffen the part in question, it will generally be better to suppress them and to strengthen directly the resisting lattice-bars, either by increasing the section, or better, by adopting another form, such as that of angle or T iron. The braces, if nothing prevents it, should be constructed in the same way, because their rigidity, useless to themselves, lends a support to the struts. Sometimes these upright pieces are needed to fix tie-beams on one side only of the girder; it will be sufficient, in this case, if they project upon this same side, which will allow us to construct half of the oblique bars of stiff iron, the mouldings of which shall be turned in the opposite direction, to avoid cutting them away at the points where they cross each other.

69. The influence of the form of the sections being established, it remains to be seen how we can consider the rigidity in the various cases which may present themselves.

Now the curve which a piece under the force of compression tends to assume is a real deflection, which requires, not a certain area of section, but a sufficient moment of resistance. In plate iron we may regard the thickness as being nothing but the ratio of the moment of resistance M expressed by the coefficient $R = 6000000$, to the section S expressed in square millimetres. Thus, to generalize the Table in the preceding section, it is sufficient in the ratio $\frac{\lambda}{e}$, applied to any section,

to substitute the ratio $\frac{M}{S}$ for e , which we may call *reduced thickness*, or *imaginary thickness*, in the direction in which deflection is to be feared, and in which the moment of resistance M is taken.

70. When compressed bars are unsupported throughout their length, as is the case, for example, in girders formed of simple triangles, they should have a section possessing a rigidity equal in all directions. Such would be the round form, but it offers practical difficulties.

The section in the form of a cross with four equal branches, may be advantageously employed; it offers a moment of inertia constant in all directions. As to the moment of resistance, which depends on the distance of the fibre subject to the greatest strain from the centre of gravity, it is

$\sqrt{2}$ times greater in the direction of the lines bisecting the angles than in the direction of the arms; but as deflection will always take place in the weakest part, we can reckon only upon a reduced thickness, exceeding but little the dimension of one of the four arms, when these latter have a constant thickness. Figs. 1659 to 1667 represent some sections in the form of a cross,

composed of angle-iron and plate; this mode of construction causes irregularities of thickness, and the moment of resistance is affected by it according as the material is accumulated towards the centre or towards the extremities. Under each of the sections in the figures will be found the reduced thickness, taken in the direction of least stiffness when the branches are not identical.

71. The single **T** is more convenient for fixing than the section in the form of a cross, and it offers also a slight advantage from the point of view of resistance in the direction of the web. If we consider only the moment of inertia, it is easy to make it rigorously equal in all directions. To effect this, we have merely to proportion the arms and the web so that the moment of inertia in their respective directions *CD* and *AB*, Fig. 1668, shall remain the same. In fact, on account of the symmetry, the directions at 45° *MN* and *M'N'* give equal moments of inertia: the central ellipse of inertia will, therefore, offer two systems of equal rectangular diameters, which is found only in the circle. But, as is the case with the cross, the moment of resistance will be smaller in the principal directions than in the others; and if the reduced thickness is made equal in these two directions, we shall reckon only upon the value which it will so possess as if it remained constant in all directions.

The double **T** cannot be made to resist equally in its two chief directions, because this condition would require flanges of excessive breadth.

72. For bars of small dimension we may employ single angle-iron. This form offers least stiffness in the direction of the line bisecting the angle. If the angle-iron is thin and its branches

have a breadth *c*, we may regard the minimum reduced thickness as equal to $\frac{c}{\sqrt{2}}$ or $0.7c$. The central ellipse of inertia of such an angle-iron has its major axis double the minor; the minimum moment of inertia, a quarter of the maximum, is $\frac{2}{5}$ of the moment of inertia in the direction of one of the branches.

As an application of the foregoing, suppose a bar compressed by a strain of 5 tons, upon a free length of 3 metres. An angle-iron of 0.080 metre broad will give a minimum reduced thickness of about 0.056 metre, and the ratio of the length to this thickness will be $\frac{3}{0.056} = 53$. This value authorizes the adoption of $R = 2 \cdot 8$ per square millimetre, which leads to a section of 1790 square millimetres; this section will be obtained by giving to the angle-iron a mean thickness equal to 0.012 metre. If this thickness did not suit, we should try an angle-iron of a different breadth.

We must proceed thus tentatively for every question of the same kind. We may calculate in advance the compressions which a certain number of model sections will bear, under various lengths, and these data will serve as a guide in determining, at sight, the modified sections which will suit given cases.

When the load is great and the length inconsiderable, we may adopt thicker sections and suppress the coefficient of stiffness. It is advisable, however, in such cases, to preserve an excess of rigidity.

73. In multiple lattice-girders, a compressed bar is fixed, in the points where they cross, to other bars subject to tension, but which generally act more effectually against a deflection in the plane of the vertical because they cannot resist a deviation normal to this plane; in fact, if the braces are flexible bars, they will resist perfectly a strain of tension directed in the direction of their length, but very badly a transverse strain, which would bend them in a very marked manner. Thus, with regard to deflection in the plane of the vertical, we may consider the compressed bar as subdivided into shorter portions which may be stiffened separately; and as to deviation out of the plane of the vertical, it will be better not to reckon upon the tension of the braces, but only upon their rigidity which will supply what is wanting to the strut. The connection at the points where they cross each other may, therefore, improve the relation of the length to the reduced thickness, in the plane of the vertical because it reduces the length, and in the direction normal to

this plane because the rigidity of the braces assists that of the struts. However, this must not induce us, from the point of view of rigidity, to multiply the lattice as much as possible, for so we weaken each bar taken individually, and we should at length produce a girder the vertical portion of which would be liable to crumple up like a thin sheet of iron.

74. Let us consider the case of a *simple cross* formed by two bars of the same length and the same section: the strain of deviation which tends to throw the centre of the cross out of the plane of the vertical meets with an equal resistance from each of the two bars, omitting the special effect due to the tension of the brace; consequently the strut will be required to furnish only a moment of resistance or a reduced thickness, less by half than in the case in which it is isolated. Although its resisting section is not increased, it will be regarded as having the same reduced thickness as a single piece formed by the superposition of the two branches of the cross.

When the brace has less rigidity than the strut, the latter must be more rigid in the direction normal to the vertical. We may give it a reduced thickness equal to the sum of its own and that of the brace.

75. The vertical bars which are sometimes applied to a lattice to consolidate it, act in an analogous manner. Having no longitudinal strain to bear, the area of their section is of little consequence; they act only by their moment of resistance.

Suppose, for example, Fig. 1669, a flexible bar *AB*, held in its middle *C* by a rigid vertical bar *DE*. If the latter were absent, the bar *AB* could be subjected to a compression of 6 kilogrammes a square millimetre only under the condition that the ratio of its length λ to its reduced thickness $\frac{M}{S}$ (see 69) did not exceed 15; which is equivalent to saying that it should

have a moment of resistance at least equal to $\frac{\lambda S}{15}$ (the section *S* being expressed in square milli-

mètres), precisely as if the point *C* were subjected to a transverse strain equal to $\frac{4S}{15}$; but as the

bar is, of itself, incapable of resisting this strain, we may impose it upon the vertical bar which on this account should possess a moment of resistance equal to $\frac{\lambda' S}{15}$, the section *S* being, not its own, but that of the bar to be strengthened. Thus, by its less length, the vertical bar may furnish a determinate rigidity with a less moment of resistance: it is, however, generally better to increase the section itself of the bar and to suppress the vertical, for by that means we diminish the pressure per unity of surface, which requires less rigidity.

If the bar *AB* already possesses of itself a certain rigidity, it may take a portion x of the strain of deflection in *C*. It will then be deflected by a quantity $\frac{x \lambda^3}{48 EI}$ (E = modulus of elasticity, I = moment of inertia) which, on account of their being fixed together, must be equal to the versed sine of the arc assumed by the vertical bar; this condition gives the equation $x \left(\frac{\lambda^3}{I} + \frac{\lambda'^3}{I'} \right) = \frac{48 \lambda'^3}{15 I'}$, whence we deduce x . Consequently the vertical bar will be required to furnish only a supplementary moment of resistance equal to $\left(\frac{4S}{15} - x \right) \frac{\lambda'}{4}$.

We might apply analogous considerations to the less simple case in which *C* is not the middle either of the oblique or of the vertical bar.

For a cross formed of two bars of the same section and the same free length λ , we shall have $x = \frac{2S}{15}$, and each bar will furnish, as we have already seen, a moment of resistance equal to the half of that which the compression-bar ought to have, if it were deprived of all assistance.

76. In a multiple lattice with flexible braces, the struts must be capable of greater transverse resistance in the direction normal to the vertical part of the girder than in the direction of the vertical part. Figs. 1670 to 1684 give as examples various sections, with their reduced thicknesses in the direction of greatest resistance; it will be seen that the forms in **U** or double **T** are very good, for they give reduced thicknesses which exceed by much the apparent dimension.

If, for instance, we have to construct a piece 8 mètres long, capable of resisting a maximum strain of compression of 10 tons only, the fifth section gives as the ratio of the length to the reduced thickness $\frac{8}{0.159} = 50$. According to the Table in 68, the piece ought to bear a strain of only

3 kilogrammes a square millimetre, and it is capable of bearing $3500 \times 3 = 10500$ kilogrammes, which is something more than sufficient. Adopting this section, the coefficient of stiffness would be 2.10; but it would be more advantageous to adopt a **U** iron of less weight.

77. The principle of increased section in the middle applied to the connecting-rods of machines, may also be adopted for the struts of very important girders. This may be effected by applying plates to the middle of the piece, precisely as in the case of girders loaded transversely.

It is always useful, in multiple lattices, to give to the tension-bars sections with projecting mouldings, at least as much as possible without making the area of the section exceed the value corresponding to a strain of 6 kilogrammes the square millimetre. When the length becomes so great that this condition of area, applied to the struts and braces, does not allow us to realize a sufficient

	1670.	1671.	1672.	1673.	1674.	1675.	1676.	1677.
Areas in sq. millimètres. Reduced thickness.								
Areas Reduced thickness.								
	1678.	1679.	1680.	1681.	1682.	1683.	1684.	

rigidity, we must have recourse to a coefficient of increase V , which may be exclusively applied to the struts, or divided between these and the braces when nothing prevents us from giving to the latter continuous projecting mouldings.

Sometimes accessory arrangements contribute to stiffen the vertical portion of girders; such is the case, for instance, Figs. 1580, 1585, where the cross-girders are placed in the middle of the height.

These various considerations no doubt are not exhaustive, but they will be sufficient to enable us to choose, in every case, the best forms; and when it may be done at a small cost, it will always be prudent to have an excess of rigidity.

78. When we wish to find as near as possible, without going through a complete calculation, the weight which a girder fulfilling certain given conditions would have, we may proceed as follows to find the value of the mean coefficient V to be applied to the parts of the lattice under compression.

We calculate the strains Q_1 and Q_2 upon the strut which bears the least strain (in the middle), and upon the one which bears the greatest strain (at the end); then, having regard to their length, we consider what sections it would be necessary to give them, and we deduce the coefficients of stiffness v_1 and v_2 , special for these two bars. The total weight of the struts will then be nearly proportional to the mean $\frac{1}{2} (Q_1 v_1 + Q_2 v_2)$, whilst if the question of rigidity did not interfere, it would be proportional to the mean $\frac{1}{2} (Q_1 + Q_2)$ of the limiting strains; we may thence conclude approximatively $V = \frac{Q_1 v_1 + Q_2 v_2}{Q_1 + Q_2}$.

79. If some of the end struts could support a strain of 6 kilogrammes, the general coefficient would be smaller still. We should then seek the least section under which a strut can bear 6 kilogrammes, having regard to its free length and other circumstances, and determine the load Q_3 which it would carry with this section; then we should make approximatively

$$V = \frac{Q_2^2 - Q_1 Q_3 + Q_1 v_1 (Q_3 - Q_1)}{Q_2^2 - Q_1^2}.$$

80. The mean coefficient V may also be expressed by means of the variable coefficient v applicable to the successive bars, by making $V = \frac{\sum F v}{\sum F}$. We might obtain from section 6 the values of F and $\sum F$, but to calculate $\sum F v$, we should have to express the law of variation of v according to that of the strains. Now this law would be too complicated or too arbitrary to lead by this method to a satisfactory result, and it is preferable to trust to the approximative formula in section 78.

81. By increasing the height of a girder we weaken its middle, or vertical portion, and this obliges us to raise the value of the coefficient V in order to preserve a sufficient rigidity.

To find the mode of variation of V with the height h of the girder, we may remark in the first place that, according to the values of the Table in 68, as long as the ratio $\frac{\lambda}{e}$ does not exceed 50 or 55, V will be accurately enough represented by the function $0.57 + \frac{1}{35} \frac{\lambda}{e}$, with the condition, however, that it cannot become less than unity. In this expression, the reduced thickness e depends on the form and area of the section, and this area is a function of the load Q which the piece supports and of the coefficient V : it is expressed by $\frac{Q V}{R}$.

If the section vary in such a way that on dividing it by the reduced thickness, the quotient b is constant, we shall have $e = \frac{QV}{Rb}$, and consequently $V = 0.57 + \frac{1}{35} \frac{R\lambda b}{QV}$, whence

$$V = 0.29 + \sqrt{0.082 + \frac{R\lambda b}{35Q}}.$$

For example, for girders composed of triangles or crosses, expressing the length λ of the bars and their strain Q by means of the height h of the girder and the whole strain F , we shall have

$$V = 0.29 + \sqrt{0.082 + \frac{Rb}{35F} h}. \text{ For a multiple lattice of the } i \text{ degree, we have only to change } F \text{ into } \frac{F}{i}.$$

If the section varied while remaining similar to itself, the quotient of the square of the section by the reduced thickness would be constant, and V would be determined by an equation of the third degree.

Thus, keeping to the simplest case first considered, V will be expressed in terms of the height by formulæ of the form $a + \sqrt{b + ch}$. But as there is nothing absolute in the value of this coefficient, nor in the relation of the section to the reduced thickness, on account of the great diversity of form, we may content ourselves, in the investigation of the most economical heights, with replacing V by a rational function of the first degree $a + bh$, determined by means of two particular values of this coefficient for heights differing not too widely, but including between them the height sought. This is equivalent to replacing an arc by its chord.

82. Circumstances other than the condition of rigidity may oblige us to increase the weight of the vertical portion of a girder beyond the limits prescribed by theory. For example, in a multiple lattice in which the bars are very numerous, their section is not made to vary in a perfectly continuous manner, but only by successive groups; so that the greater portion of them will possess a slight excess of weight. Then again in the parts in which the stress is inconsiderable, it often happens that we cannot in practice make the bars so slender as they are required to be by calculation. Besides, when the section is inconsiderable, a single rivet-hole weakens it in a proportionally great degree. This is another reason for increasing the dimensions. These several augmentations might give occasion for a new coefficient applied to the whole of the vertical portion of the girder, but it will simplify the matter to include them in the coefficient V by raising its value sufficiently high.

83. *Supplementary term Ω .*—To complete the computation of the weight of a girder, we must include certain accessory pieces the dimensions of which are nearly independent of the height of the girder, and which may be represented by a constant additional term Ω . Such are, for example, in lattice-girders, the gussets at the points where the bars cross each other, joint-plates and other contrivances for making the rivets offer a double section to the strain upon them. On the other hand, these special pieces are partly compensated by the fact of the lattice-bars ending at the edge of the longitudinal angle-irons of the flanges, so that their length is slightly inferior to that supposed in the formulæ. Sometimes certain accessory pieces may be considered as increasing in a certain proportion with the height; in these cases we may include them in the coefficients U or V according as they belong to the flanges or to the vertical portion.

84. *General form of the Formulæ giving the Weight of Girders, and the most advantageous Heights.*—The total weight of a girder is obtained by adding the terms referring respectively to the flanges, to the vertical portion and to the accessories independent of the height. Dividing by the length of bearing, we shall have the mean weight of the lineal metre.

In this mean weight, the flanges will appear as a quantity expressed by $\frac{2GtU}{h}$, G denoting the mean ordinate of the locus of the maximum moments of rupture (that is, $\frac{1}{12}(p+p')l^2$ in the case of a single bay and a continuous load). As U is of the form $a + b\bar{h}$ (64), the flanges are divided into a part inversely proportional to $\bar{h}$, and a part which is constant.

In girders composed of simple triangles or crosses, δ being constant, the inclination of the bars is a function of the height, and the pieces of the vertical portion generally make, a metre of length, a weight of the form $\frac{G't(1+V)}{l\delta} \left(\bar{h} + \frac{\delta^2}{4\bar{h}} \right)$, G' denoting the mean ordinate of the locus of the maximum stress, the value of which ordinate is $\frac{1}{4}(p+p')l \left(1 + \frac{1}{6}q \right)$ in the case of a continuous load. Admitting that $1 + V$ is expressed by $a + b\bar{h}$ (81), the weight in question will give rise to terms in $\bar{h}^2$, in $\bar{h}$, in $\frac{1}{\bar{h}}$, and to a constant term.

In multiple lattice-girders in which the inclination of the bars is 45° , or else keeps a certain other constant value, as in the case of solid girders, the theoretical vertical position would have a constant weight. But, in such cases, the rigidity is usually obtained by the addition of special stays, vertical or inclined, the section and length of which increase with $\bar{h}$, so that their weight will be expressed under the form $(u + u'\bar{h})\bar{h}$.

85. Thus, the weight of the lineal metre of girder will be generally given by formulæ of the following form: $\frac{P}{l} = \frac{A}{\bar{h}} + B + C\bar{h} + D\bar{h}^2$. The corresponding height at the minimum expense

will be given by the equation of the third degree: $A = (C + 2Dh)h^2$, whence we deduce the real value:

$$h = \sqrt[3]{\frac{1}{4D}} \left\{ \sqrt[3]{A - \frac{C^3}{54D^2}} + \sqrt[3]{A^2 - \frac{AC^3}{27D^2}} + \sqrt[3]{A - \frac{C^3}{54D^2}} - \sqrt[3]{A^2 - \frac{AC^3}{27D^2}} \right\} - \frac{C}{6D}.$$

But as it is always enough to know this height within 1 décimètre, it will be a saving of time to solve the equation tentatively. As a function varies but little when near a minimum, we may without much increasing the expense adopt heights less than those given by calculation, and we find an additional reason for doing this in the fact that the ties or cross-pieces generally increase with the height. We might, it is true, seek directly the conditions of the minimum of weight for the whole flooring, instead of a single girder.

86. Sometimes, for the sake of simplicity, we may regard V as a fixed coefficient which may conveniently be forced a little; in this case, V being constant, we shall arrive for simple lattices

at formulæ of the form $\frac{P}{l} = \frac{A}{h} + B + Ch$, and taking $h = \sqrt{\frac{A}{C}}$, we shall have as the mini-

mum value, $\frac{P}{l} = 2\sqrt{AC} + B$. It is evident that an alteration of height, even if considerable,

has but a small influence; for if, by way of example, instead of $\sqrt{\frac{A}{C}}$, we take $h = \kappa \sqrt{\frac{A}{C}}$, the

term $2\sqrt{AC}$ will be merely changed into $2\sqrt{\frac{A}{C}} \frac{1+\kappa^2}{2\kappa}$.

Now $\kappa = 0.9$ gives $\frac{1+\kappa^2}{2\kappa} = 1.0056$				And $\kappa = 1.1$ gives $\frac{1+\kappa^2}{2\kappa} = 1.0045$				
"	0.8	"	"	1.0250	"	1.2	"	1.0167
"	0.7	"	"	1.0643	"	1.3	"	1.0346
"	0.6	"	"	1.1333	"	1.4	"	1.0571
"	0.5	"	"	1.2500	"	1.5	"	1.0833
"	0.4	"	"	1.4500	"	2.0	"	1.2500

An increase of height above $\sqrt{\frac{A}{C}}$ produces a less loss than an equal diminution, but in almost every case it will be a diminution that we shall have to make.

It will be well to make a verification afterwards to ascertain whether the height $\sqrt{\frac{A}{C}}$, or at least the reduced height adopted, does not require a value of V superior to that which we have introduced into the calculation.

This method gives too great height, and, therefore, the reduction which it will be necessary to make will be more considerable than when we employ the more exact method of the preceding section.

87. *Girders of Simple Triangles.*—Formulæ of the Weight a lineal metre, in the case of Bars of Equal Inclination.—To find the total weight P of girders of simple triangles, formed by bars of equal inclination, we have only to add together the weights of the flanges, the struts, and the braces, given by the formulæ p , for the particular cases in which $\alpha = \beta$. As the total length of the girder exceeds its bearing, we shall give only the weight per lineal metre, found by dividing P by the bearing l , and it is understood that when the total weight, including the ends, is required, the weight of the lineal metre is to be multiplied, not by the bearing, but by the total length, say by $1.045l$ or $1.097d$, d being the free span, according to what was said in §7.

1. *Load on the lower side.*—If $l = 2m\delta = N\delta$, we shall have, Ω being an additional term for the accessories independent of h ,

$$\frac{P}{l} = \frac{1}{2} m(p+p')t \left(1 + \frac{m^2-1}{6m^2}q\right) \left\{ \frac{\delta^2}{h} \left[\frac{(4m^2-1)U}{3m + \frac{m^2-1}{2m}q} + \frac{1+V}{4} \right] + h(1+V) \right\} + \Omega,$$

or

$$\frac{P}{l} = \frac{1}{4} (p+p')t \left(1 + \frac{N^2-4}{6N^2}q\right) \left\{ \frac{l}{N\delta} \left[\frac{2}{3} \cdot \frac{N^2-1}{N} \cdot \frac{U}{1 + \frac{N^2-4}{6N^2}q} + \frac{1+V}{4} \right] + \frac{N\delta}{l} (1+V) \right\} + \Omega,$$

a formula applicable when N is even.

When $l = (2m+1)\delta = N\delta$, we have

$$\frac{P}{l} = \frac{m(m+1)}{2m+1} (p+p')t \left(1 + \frac{1}{6}q\right) \left\{ \frac{\delta^2}{h} \left[\frac{2}{3} (2m+1) \cdot \frac{U}{1 + \frac{1}{6}q} + \frac{1+V}{4} \right] + h(1+V) \right\} + \Omega;$$

or

$$\frac{P}{l} = \frac{1}{4} \cdot \frac{N^2-1}{N} (p+p')t \left(1 + \frac{1}{6}q\right) \left\{ \frac{l}{N\delta} \left(\frac{2U}{3 + \frac{1}{2}q} + \frac{1+V}{4N} \right) + \frac{h}{l} (1+V) \right\} + \Omega,$$

a formula applicable when N is odd.

The flanges do not change whether N be even or odd; but the lattice decreases slightly when N is odd, in the proportion of $N^2 - 1$ to N^2 .

2. *Load on the upper side.*—For $l = 2m\delta = N\delta$, we shall have

$$\frac{P}{l} = \frac{1}{48m} (p + p') t \left[6(4m^2 - 1) + \left(4m^2 - 1 + \frac{3}{2m}\right) q \right] \\ \left\{ \frac{\delta^2}{h} \left[\frac{(32m^2 - 8m + 3)U}{6(4m^2 - 1) + \left(4m^2 - 1 + \frac{3}{2m}\right) q} + \frac{1+V}{4} \right] + h(1+V) \right\} + \Omega,$$

which amounts nearly to

$$\frac{P}{l} = \frac{N^2 - 1}{4N} (p + p') t \left(1 + \frac{1}{6} q \right) \left\{ \frac{l}{N h} \left[\frac{2U}{3 + \frac{1}{2} q} + \frac{1+V}{4N} \right] + \frac{h}{l} (1+V) \right\} + \Omega,$$

a formula identical with the last of the case in which the load is on the lower side, except that here N is even.

And if $l = (2m + 1)\delta = N\delta$, we have

$$\frac{P}{l} = \frac{1}{12} (p + p') t \left[3(2m + 1)^2 + m \cdot \frac{4m^2 + 6m - 1}{2m + 1} q \right] \\ \left\{ \frac{\delta^2}{2h} \left[\frac{32m^3 + 48m^2 + 16m + 3}{3(2m + 1)^2 + m(4m^2 + 6m - 1)q} U + \frac{1+V}{2} \right] + \frac{h(1+V)}{2m + 1} \right\} + \Omega;$$

or

$$\frac{P}{l} = \frac{1}{4} (p + p') t l \left(1 + \frac{1}{6} q \right) \left\{ \frac{l}{N h} \left[\frac{2}{3} \cdot \frac{N^2 - 1}{N} \cdot \frac{U}{1 + \frac{1}{6} q} + \frac{1+V}{4} \right] + \frac{N h}{l} (1+V) \right\} + \Omega,$$

a formula in which N is odd, and which is obviously the same as the first of case 1.

88. *Examples.*—*Girder of 28 metres bearing*, supporting, on the upper side, a load of 3500 kilogrammes to a metre, Figs. 1685 to 1689; $p = 1100^k$ (the girder itself weighing 400), $p' = 2400^k$, $q = 0.686$, $m = 4$, and, consequently, $\delta = 3^m.50$, $h = 3^m.30$.

As the girder is lightly loaded, we must seek to diminish as much as possible the least section of the flanges, without, however, reducing too much their breadth, which we will fix at $0^m.400$. To diminish the breadth of the vertical ribs, projecting gussets are placed at intervals, to which the struts and braces may conveniently be attached. Those struts which are most heavily loaded have a section in the form of a cross, favourable to rigidity in all directions; one of the angle-irons passes behind the gusset to avoid the necessity of cutting it away at the extremities; and, consequently, some of the rivets offer a double section. Instead of filling the whole of the space above the gusset to make this angle-iron solid with the rest of the bar, it is sufficient to fill it in part only. The middle bars require fewer rivets, but it has been necessary to increase their theoretical section to obtain the required rigidity.

The lower vertical rib is only $0^m.300$ broad; but the upper could not be reduced below $0^m.350$, because the flange should be rigid to resist compression, because in the present case it might be required to serve as a minor longitudinal girder, and because we might have occasion to affix to it a light corbel, in which case this breadth of $0^m.35$ is barely sufficient. The brackets may be placed in the middle of the intervals to be out of the way of the bars. It is solely for the purpose of forming a minor longitudinal girder that the upper flange has been produced, and the vertical supports added at the ends.

We find by calculation the total weight of the girder to be 11200 kilogrammes, say 380 kilogrammes the lineal metre.

The flanges weigh together 8070 kilogrammes, including the gussets for fixing the bars; but to determine the value of U , it is better to consider only the weight of 7400 kilogrammes, which we obtain by deducting the projection of the gussets, and reckoning with the vertical rib only the joint-plates which would be needed if it were not interrupted at short intervals by the gussets. Dividing by the whole length $29^m.40$, we find that the flanges make together 252 kilogrammes

the lineal metre. The formula would give $177.3 U$; we shall, therefore, have $U = \frac{252}{177.3} = 1.42$,

a value which includes the extensions at the ends.

However great the height of the girder might be, we could hardly compose the flanges of less than two angle-irons of 100/100/12 millimetres, a vertical rib of 300/10, and a horizontal plate of 350/8; this would form a sufficient section in the middle if the height were $5^m.50$, and it would remain constant throughout the bearing. By the formula of 64, we should find again

$$U = 1.06 + 0.60 \frac{3.30}{5.50} = 1.42.$$

The extra weight of 670 kilogrammes occasioned by the presence of the gussets, is reduced to 500 kilogrammes when diminished by the saving effected by the fact of the real length of the bars being a little less than their theoretical length, since they terminate at the edge of the angle-irons of the flanges. Hence we conclude that Ω is here equal to $\frac{500}{29.40} = 17$ kilogrammes the

lineal metre of girder, say the 0.047 of the total weight of the principal pieces. This is a great deal, but we may reduce this value by giving the gussets a thickness of 8 millimetres only.

The oblique bars weigh 2600 kilogrammes, but the saving effected in their length has just been attributed to the term Ω , we must, therefore, suppose them to possess the weight 2770

kilogrammes, which they would have with their theoretical length. Comparing with the formula, $V = 1.34$.

If we wished to compute V approximately, without going through a complete calculation, we should have considered only one extreme and one middle bar. The latter, for a maximum strain of $Q_1 = 9\frac{1}{2}$ tons, gives $V_1 = 2.26$ with the section adopted; and the other, for a strain $Q_2 = 52.6$ tons, gives $V_2 = 1.07$, including the filling. The formula

$$\text{of '78 then gives } V = \frac{Q_2 V_2 + Q_1 V_1}{Q_2 + Q_1} = 1.29,$$

a value which we must increase a little, because in the formulae one of the bars of the middle triangle has been regarded as a brace, and, on this account, exempted from the coefficient V , whilst in reality both bars of this triangle should be able to serve, each in its turn, either as strut or as brace.

To discuss the height of the girder, we must first seek an approximative expression of V in terms of the height. To this end, let us consider, by way of example, a height of 5 metres; we shall then have $Q_2 = 48.6$ tons and $Q_1 = 8.7$ tons, and the free length of the bars between the gussets will be about 4 metres. For the one which is the most heavily loaded, a section in the form of a cross with four arms of 150/10, held together by four angle-irons of 70/70/10, will give $V_2 = \text{about } 1.40$; and for the weakest bar, a cross composed only of a bar of 140/6 and of two angle-irons of 70/70/10, will give $V_1 = 2.40$. We thence conclude $V = 1.55$, say 1.60 on account of the observation made above. Knowing the values of V for two different heights, it is evident that we may adopt nearly $1 + V = 1.70 + 0.19 h$.

Substituting this expression in the formula of the preceding section (case 2 for N even), we find that the minimum expense is given by a height of about 4^m.40. In fact, with this height, we should have $1 + V = 2.54$, $U = 1.54$, and, consequently, the weight of the lineal metre descends to 350 kilogrammes, Ω included; whereas with $h = 3^m.30$, $1 + V = 2.33$, $U = 1.42$, the formula gives 370 kilogrammes. These weights should be increased a little to take sufficiently into account the end upright pieces, which really form no portion of the girder, but serve only to support the rail upon the abutment. It is obvious that if the height allowed permits, it may be of some use to increase slightly the height of the plan, to carry it to 3^m.60, for instance, but it would be useless to go beyond that, for the cross-pieces would increase without giving any sensible advantage to the girder. We might, in a more general manner, have sought the most advantageous height, by considering the whole of the flooring, and expressing the cross-pieces themselves as a function increasing with h .

89. *Girder of 56 metres bearing, with a load on the lower side of 7000 kilogrammes the metre, Figs. 1690 to 1700: $p = 3000^k$ (the girder itself weighing 1300^k), $p' = 4000^k$, $q = 0.572$, $m = 4$ or $N = 8$, $\delta = 7^m$, $h = 7^m$.*

The load supposes both lines loaded simultaneously; otherwise, for one line only, p' would not exceed 3000 kilogrammes, and we might reduce by about $\frac{1}{3}$ the weight of the girder, allowing it a strain of 7 instead of 6 kilogrammes in the exceptional case of two heavily-laden trains crossing the bridge at the same time.

Cross-bracing behind the compression-bars.

The interval δ can be raised to 7 mètres only on the supposition that there are two cross-girders for each section or division of flange, which subjects the bottom flange to a deflecting strain; but this strain may be neglected, having regard to the form of the section and to the other arrangements adopted.

The following Table gives the strains upon the pieces:—

	Upper Flange.				Lower Flange.				Struts or Braces.			
	1	2	3	4	1	2	3	4	1	2	3	4
Numbers of the divisions, or of the bars... ..	392	369	294	172	386	337	239	92	51	94	141	192
Maximum strain, in tons..												

The flanges are hollow and have a double vertical rib, which allows the bars to be very firmly fixed. The two triangles next the abutment are besides provided at their extremities with joint-plates forming a kind of fork, which enables the rivets, or at least many of them, to offer a double section. By this means we may place upon each rib thirty rivets, twenty-four of which offer a double section. This gives for the foot of the end brace, for example, a total of 108 shearing sections, capable of resisting a strain of 216 tons if the rivets have 0^m.025. The thickness of the double vertical ribs is 0^m.012. In the last triangle it is well to strengthen them to increase their resistance to a shearing force; this is accomplished by adding broad gussets of 0^m.012. At the foot of the end brace there is no projecting gusset; but the thickness of the rib is doubled by the projecting of a joint-plate.

For the intermediate triangles, it is useless to have recourse to double shearing sections.

The struts have a hollow form, very favourable to resistance to compression, as the moment of resistance is rendered as great as possible in the two directions. The transverse plate of 400/8 is not reckoned in the resisting section; it has been added to connect the other pieces of the bar so as to render them solid, and this plate or flat bar constitutes the principal element of the coefficient V. Its effect is completed by three triangles or rods placed on the other side, at equal intervals.

The braces are composed of two pieces left unconnected, except in the middle bar, which is as much a strut as a brace, and which, for this reason, has been stiffened by a continuous strip of plate iron connecting the two pieces. It would have been somewhat more economical to have substituted a light lattice for this continuous plate; but it has the advantage of giving more body to the pieces and of diminishing the pressure on each unit of surface.

The girder weighs 75 tons, say 1293 kilogrammes a lineal mètre of length (58 mètres).

The flanges with their joint-plates weigh 50 tons, say 862 kilogrammes the mètre, which gives $U = 1.29$.

The plates or gussets added to the end bars to obtain a double section of rivet, are in part covered by the saving resulting from the fact of the lengths of the bars being a little less than their theoretical lengths.

The excess, 2050 kilogrammes, increased by the angle-iron forming a hand-rail, becomes 2400 kilogrammes; say $\Omega = 42$ kilogrammes a lineal mètre, or the 0.032 of the whole weight.

The bars themselves make up a weight of 22600 kilogrammes, not including the accessories reckoned in Ω . Hence we deduce $V = 1.25$.

Here the form favourable to rigidity given to the struts, would allow of the height being increased without much augmenting V.

It would be reckoning liberally to take, for example, $1 + V = 1.55 + 0.10h$ when near a height of 7 mètres. The best height is then theoretically given by the equation $h^2(h + 7.75) = 1946$, and is about 9 mètres. Indeed, with this value we should have $V = 1.43$, $U = 1.36$, and, consequently, the weight = 1.250 kilogramme per mètre, Ω included; whereas with $h = 7$, $V = 1.25$, $U = 1.29$, and $\Omega = 42$, the formula gives 1295 kilogrammes, which agrees with the direct calculation.

These two weights, however, differ but little, which justifies the adoption of the height 7 mètres as being the more convenient.

90. The object of formulæ of weight is to enable us to compute the cost of a girder subject to given conditions, without making a plan and a calculation of it. But, if we wish to attain a certain exactness, it will be well to consider approximatively arrangements which may be adopted, and which affect U and V.

By way of example, let us suppose it is required to find the weight of a girder of the same form as that of 56 mètres which we have been considering, but the load of which is reduced by one-half (3500 kilogrammes instead of 7000). It will be advisable to retain the hollow form of the struts and the double-ribbed flanges; but these ribs may be, for example, 0^m.400 broad by 0^m.012 thick, for only half the former number of rivets will be required. If the least section of flange comprises besides a horizontal plate of 550/8 and four angle-irons of 100/100/12, it will become sufficient in the middle when the height of the girder rises to 12 mètres; so that we may consider

$$U = 1.06 + 0.60 \frac{7}{12} = 1.41.$$

The strongest strut supporting 96 tons = Q_2 , will have sufficient rigidity if we give it the hollow form composed of two side plates of 350/11, a back plate of 350/8, and four angle-irons of 100/100/12; this would give to the bar a coefficient $v_2 = 1.22$. The weakest strut, for the strain $Q_1 = 25\frac{1}{2}$ tons, may be formed of two side plates of 220/6 and back plate of 350/6, and four angle-irons of 60/60/8; this will make $v_1 = 1.96$. Consequently we shall compute the general coefficient

$$\text{of stiffness at } V = \frac{Q_2 v_2 + Q_1 v_1}{Q_2 + Q_1} = 1.38.$$

With the values thus found for U and V, the formula will give 680 kilogrammes as the weight

92. In large bridges, we may usually give sufficient dimensions to the vertical ribs of the flanges to enable us to reduce to a comparatively trifling matter, or to avoid altogether, the addition of special gussets. Thus the additional term Ω , occasioned by the accessories, for 1 metre of girder, will increase less rapidly than the bearing, whilst the weight of the metre of girder increases as the bearing. It follows from this that the ratio of Ω to the total weight diminishes when the bearing increases. For light girders, we must add to the numbers of the first Table a sum varying, for example, from 5 to 2 per cent., according as the bearing varies from 20 to 80 metres, and for the heavy girders of the second Table, from 6 to 3 per cent.

In the case of spans of 20, 60, and 80 metres, we may allow the following loads for girders carrying either one or two rails:—

	$l = 20$ m. Girders carrying		$l = 60$ m. Girders carrying		$l = 80$ m. Girders carrying	
	One Rail.	Two Rails.	One Rail.	Two Rails.	One Rail.	Two Rails.
	kilos.	kilos.	kilos.	kilos.	kilos.	kilos.
p { Exterior dead weight	700	1400	700	1400	700	1400
p { Weight of the girder itself ..	300	500	900	1400	1200	2100
Moving load p'	2500	5000	2000	4000	2000	4000
Total load a metre, $p + p'$..	3500	6900	3600	6800	3900	7500

Let us suppose besides $N = 7$ for bridges of 20 metres, 8 for those of 30 to 60 metres, 9 for 70 metres, and 10 for 80 metres; and let us add the sums for Ω indicated above. We shall have the following approximative weights:—

Spans	Mètres. 20	Mètres. 30	Mètres. 40	Mètres. 50	Mètres. 60	Mètres. 70	Mètres. 80
Weight a metre of a girder carrying one rail ($\frac{h}{l} = 0.11$)	Kilos. 265	Kilos. 405	Kilos. 545	Kilos. 680	Kilos. 820	Kilos. 1000	Kilos. 1220
Weight a metre of a girder carrying two rails ($\frac{h}{l} = \frac{1}{8}$)	460	685	910	1140	1365	1690	2090

These weights offer a saving of 0.20 to 0.40 upon those of solid girders satisfying the same conditions, see 119 to 135. This saving is due to the fact that, by taking precautions to ensure the rigidity of the struts, we may have girders of great height without having a too heavy vertical portion.

93. *Girders having Vertical Bars.*—If we suppose $\beta = 90^\circ$ in the girder, Fig. 1657, with a load on the lower side, and express the bearing by $N\delta$ (N being even), we shall have a girder with vertical braces, which will weigh for each metre

$$\frac{P}{l} = \frac{(p+p')t}{24N} \left\{ \frac{l^2}{N^2h} [4NU(N^2-1) + 6N^2V + V(N^2-4)q] \right. \\ \left. + (1+V)[6N^2 + (N^2-4)q]h \right\} + \Omega.$$

If, on the other hand, α be taken equal to 90° , we shall have a girder with vertical struts, weighing

$$\frac{P}{l} = \frac{(p+p')t}{24N} \left\{ \frac{l^2}{N^2h} [4NU(N^2-1) + 6N^2 + (N^2-4)q] \right. \\ \left. + (1+V)[6N^2 + (N^2-4)q]h \right\} + \Omega.$$

In one respect, this latter weight will be less than the preceding because the coefficient V affects fewer terms, but in another respect, Ω will be greater, for it must include the lengthening of the lower flange, which, according to theory, would have a total length of only $(N-2)\delta$, whilst in practice it is absolutely necessary that it reach the abutments, even if the strain upon the extreme sections should be nul.

The other analogous cases in which N would be odd, or those in which the load would be applied to the upper part, will be easily calculated by the aid of the formulæ given, 39 to 62. But, as these girders with vertical bars are less advantageous than those having bars at an equal inclination, we shall not consider them further.

94. *Girders of Crosses, or Double Lattice.*—Girders of simple crosses, with or without vertical stays, should be considered as a double lattice, and may be calculated by imagining that they result from the juxtaposition of two simple lattices. Now in every multiple system in which several pieces simultaneously combine to resist a certain distortion which may be prevented by a single piece, there takes place a distribution of strains that it is not always easy to discover exactly when the conditions are complex; it may be computed, however, with some degree of certainty when we take care to render the conditions of strain equivalent or comparable. The general rule is that the various pieces should undergo equal proportional extensions, and that,

consequently, they distribute among each other the total strain proportionally to their sections; the strain a unit of section will be equal upon the several bars, with the exception of slight differences which may proceed from unequal tension given at the time of fixing. But in the case in which the strain acts by compression, the area of the sections does not alone influence the distribution, rigidity interferes, and if the forms of the sections are different, it is difficult to know to what degree a certain bar will yield, and another, and stronger one, to concentrate the load upon itself. The way to avoid these uncertainties is to make identical the multiple pieces which replace a single piece. However, with regard to multiple lattice-girders, this equal distribution must not be considered from bar to bar, but from system to system, because the pieces brought together being more or less distant from each other, the stress may vary from one to the other. If the whole is composed of n simple lattices, each of them will be calculated as belonging to a girder supporting only the $\frac{1}{n}$ of the given load.

95. *Girders of Crosses and Vertical Rods.*—If we consider first a girder of crosses and vertical rods, for a load applied to the lower part, Fig. 1701, it is obvious that it may be resolved into two simple girders, one with vertical braces, the other with vertical struts, and the formulæ of which for the case of N even are given in 93. But the weight will be less than the arithmetical mean of these formulæ, for these vertical rods belonging at once to the two simple component lattices, are subject to a compressive strain on one side and to a tensile strain on the other; and the maximum strain upon them will be a constant tension $\frac{1}{2} (p + p') \delta$. The two end vertical

bars must be excepted, the strain upon them, which is one of compression, being $\frac{1}{4} (N - 1) \delta (p + p')$; so that these two bars alone make up the same theoretical weight as all the others, or rather more; for, resisting compression, they receive the coefficient V . We have thus as the total weight of the $N + 1$ vertical bars the value $\frac{1}{2} (N - 1) (1 + V) (p + p') \delta t h$, and the main weight of the lineal mètre of girder will be

$$\frac{P}{l} = \frac{(p + p') t}{24 N} \left\{ \frac{l^2}{N^2 h} \left[4 N U (N^2 - 1) + (1 + V) \left(3 N^2 + \frac{N^2 - 4}{2} q \right) \right] + (1 + V) \left[3 (N^2 + 4 N - 4) + \frac{N^2 - 4}{2} q \right] h \right\} + \alpha.$$

If the load be placed above the girder, the intermediate vertical bars will still support a maximum strain of $\frac{1}{2} (p + p') \delta$, but it will be one of compression which will necessitate the application of the coefficient of stiffness; and as to the two extreme bars, they, too, will be strengthened a little, for they will have to support directly the weight $\frac{1}{2} (p + p') \delta$ placed upright with the abutment, a weight which we had not to consider when the load was below, because it rested immediately upon the masonry without passing through the vertical bar. Consequently we shall have, for the case of a load on the upper side, and N even,

$$\frac{P}{l} = \frac{(p + p') t}{24 N} \left\{ \frac{l^2}{N^2 h} \left[4 N U (N^2 - 1) + (1 + V) \left(3 N^2 + \frac{N^2 - 4}{2} q \right) \right] + (1 + V) \left(3 N^2 + \frac{N^2 - 4}{2} q \right) h + 24 N V h \right\} + \alpha.$$

When N is odd, we have for the case of a load on the lower side,

$$\frac{P}{l} = \frac{(N - 1) (p + p') t}{24 N} \left\{ \frac{(N + 1) l^2}{2 N^2 h} [8 N U + (1 + V) (6 + q)] + (1 + V) h \left[12 + \frac{N + 1}{2} (6 + q) \right] \right\} + \alpha;$$

and the changing of the load from the lower side to the upper will occasion an increase of expense, because the intermediate vertical bars will have to be stiffened, and the end bars will have the additional strain of a partial weight resting through them upon the abutment.

But we shall see presently that a saving may be effected by suppressing the intermediate vertical bars or rods, when possible; and if their presence is necessary, it will be for the purpose of affixing the cross-pieces, or for other purposes foreign to the resistance of the girder, so that it will be more logical to consider them as an accessory addition, their section being supposed as given according to the duty they have to fulfil (see 100).

96. *The wooden girders of Howe's system* have the form of girders of crosses with vertical rods; but an essential difference from the point of view of resistance is, that the wooden crosses, merely abutting the bearing-blocks, cannot resist by tension; under a given load, there is only one of the bars of each cross that resists, whilst the vertical rods, each composed of several smaller ones,

always take a tensile strain; the system resists as a simple yielding lattice, that is, its form changes according as the strain comes upon one or the other piece of each cross.

97. *Girders of Crosses without Vertical Rods.*—If we consider a lattice of crosses without intermediate vertical rods, loaded on the upper side, Fig. 1702, we see that it may be resolved into two simple systems given by Figs. 1703 and 1704. Now the system of Fig. 1703 corresponds to the case $\alpha = \beta$ in 53 by changing δ into 2δ , m into $\frac{N}{4}$, and reducing the load by half. Besides this, we must add the two end vertical bars, the strain upon which is nearly $\frac{N}{4} (p + p') \delta$; they will weigh together $\frac{1}{4} (1 + V) (p + p') l h t$, if we apply to them, instead of V , the coefficient $\frac{1 + V}{2}$, which

will simplify a little the general formula, and which is warranted by the fact that the theoretical resistance being considerable, there is no need of a large coefficient of stiffness; besides, the end vertical bars have already been taken into account by the fact that the total weight of the girder is obtained by multiplying the weight of the lineal metre by the whole length and not by the bearing only.

The system of Fig. 1704 will come under the case of $\alpha = \beta$ of section 50, but only under the condition that the extreme weight be made equal to the other weights, instead of being $\frac{3}{4}$ only. On

this hypothesis, the strain upon the n th strut or the n th brace will be $\frac{\delta'}{\sin. \alpha} \left[n p + \frac{(m + n)^2}{4m} p' \right]$, a value which extends to brace No. 0, as well as to the n th strut, and which supposes that the weights applied to the several summits are equal to $p \delta'$ or to $(p + p') \delta$, according to the case.

The total weight of the oblique bars will consequently be $\frac{2m^2 (p + p') \delta' h t}{\sin.^2 \alpha} \left[1 + \frac{2m^2 + 1}{12m^2} q \right]$,

a formula in which δ' will be changed into 2δ , m into $\frac{N}{4}$, and in which the load will be divided by 2. For the flanges of this figure, we must also, in the formulæ of 50, take into account the modification of the load in the extreme summit.

Adding together the weights of the two component lattices, and dividing by the bearing, we shall obtain as the weight of the lineal metre of girder, Fig. 1702,

$$\frac{P}{l} = \frac{1}{24} (p + p') t \left\{ \frac{l^2}{N h} \left[4U \cdot \frac{N^2 - 1}{N} + 3(1 + V) \left(1 + \frac{N^2 - 4}{6N^2} q \right) \right] \right. \\ \left. + 3h(N + 2)(1 + V) \left(1 + \frac{N - 2}{6N} q \right) \right\} + \alpha.$$

This formula obviously remains the same when the load is on the lower side instead of the upper. It supposes N even, but may also be applied approximatively for N odd; however, in this latter case, it is better to employ the formula in 99.

98. The point of view from which we have considered the question in the preceding section offers the difficulty of a certain complication in calculating the strains upon the various pieces, and as a multiple system leaves the distribution of the loads arbitrary, we take advantage of it in this case to adopt a more convenient process. In the preceding method a brace bore the same strain as one of the struts to which it was fixed at the extremities, but now we shall suppose that both bars

of a cross are subject to a strain $\frac{F}{2 \sin. \alpha}$, F being the stress in the interval occupied by the cross.

It follows from this that in the two flanges, the sections or divisions situate perpendicularly to each other will support also the same strain (on account of the condition of equilibrium relative to the horizontal projections of the forces), which was not the case on the preceding hypothesis; this strain is calculated by the moment of rupture with respect to the centre of the cross; the total weight, however, of the two flanges together remains the same as before. As to the lattice, not including the end vertical bars, it is represented by $\frac{(1 + V) h t}{2 \sin.^2 \alpha} \Sigma F$, an expression in which ΣF

denotes the sum of the absolute maxima strains in the successive intervals, for the whole bearing, the value of which sum is given in 6 for the two cases of N even or odd. Adding the end vertical bars, the

strain upon which is $\frac{1}{4}(N+1)(p+p')\delta$, including the weight they directly support, and which will, therefore, weigh together $\frac{N+1}{4N}(p+p')t\ell h$, we obtain as the total weight of the lattice per lineal metre, in the case in which N is even, the following expression :

$$\frac{1}{8}(1+V)(p+p')t\left\{\left(N+2\frac{2}{N}+\frac{N^2-4}{6N}q\right)h+\left(1+\frac{N^2-4}{6N^2}q\right)\frac{t^2}{N}h\right\},$$

which differs only by a slight increase of the end vertical bars, from the value which enters into the formula of the preceding section. This difference proceeds from the fact of our having, in 97, attributed to these bars a mean strain between the cases of a load on the upper and a load on the under side.

99. For N odd, we obtain the following weight of the lineal metre of girder, the latter being calculated in the manner we have just alluded to :

$$\frac{P}{\ell} = \frac{N^2-1}{24N}(p+p')t\left\{\frac{t^2}{N^2}h\left[4UN+(1+V)\left(3+\frac{1}{2}q\right)\right]+3h(1+V)\left(\frac{N+1}{N-1}+\frac{q}{6}\right)\right\}+\Omega.$$

This formula may be admitted for a load on the upper or on the under side, for the situation of the load occasions but a slight difference in the weight of the end vertical bars.

On comparing the formulæ of the lattice composed of crosses, with those of girders of simple triangles with bars at an equal inclination, we see that the difference consists essentially in this fact, namely, that with crosses the weight of the lattice is modified as if the length of the intervals δ had been doubled, and, consequently, their number reduced by one-half. We ought, in general, to adopt that one of the two systems which brings the inclination of the bars nearest to 45° .

100. *Vertical Rods considered as a supplementary term.*—On comparing girders of crosses without intermediate vertical rods with those which possess them, we find that these latter have an excess of weight represented by these additional rods, which thus form, from the point of view of the resistance of the girder, a superfluous addition. Their use is, in fact, limited to distributing the load among all the summits both at the top and at the bottom, instead of affecting directly only one of the flanges ; but there is no advantage in this, because the horizontal space between the points of application of the strains remains the same.

But these rods are useful in certain cases, chiefly in girders loaded on the lower side, to stay the vertical portion and maintain its perpendicularity. We are justified, therefore, in considering this kind of girder ; only, as the reason for introducing intermediate vertical rods is foreign to the theoretical resistance, we shall reckon them as a supplementary addition, represented for the

mètre of girder by the term $\frac{rN}{\ell}h$, in which r denotes the weight of the lineal metre of rod. These rods, which usually need be placed upon one side only of the vertical portion of the girder, may have the form of a single **T** composed of a projecting strip of plate iron and two angle-irons. If, for instance, for heights of 2 to 5 metres, these sections are composed in the following manner :—

Height h of the girder	2 ^m	3 ^m	4 ^m	5 ^m
Mean section of a { Projecting plate of ..	130/10 ^{mm}	200/10	260/10	260/10
vertical rod .. { Two angle-irons of ..	80/80/10	80/80/10	110/70/10	130/75/12

we shall conclude that r may be represented by $8(2+h)$, and, consequently, the additional term for vertical rods will be $\frac{8Nh(2+h)}{\ell}$. The rest of the girder will be regarded as expressed by the formulæ for lattices composed of crosses without intermediate vertical rods.

101. *Examples.*—*First Example.*—*Girder of Crosses without intermediate Vertical Rods*, Figs. 1705 to 1707.—Data : $\ell = 24^m$, $\delta = 3^m$, $N = 8$, $h = 2^m.50$, $p = 1000^k$ (the girder itself weighing 300), $p' = 2400^k$ (one rail), $p+p' = 3400$, $q = 0.706$.

Following the method of calculation set forth in 98, the strains upon the successive divisions of the flanges will be, reckoning from the middle, 94.9, 82.6, 58.2, 21.4 tons ; those upon each of the two bars forming the successive crosses will be 8.2, 14.1, 20.6, 27.9 tons ; and that upon the end vertical bars 23 tons.

The braces are, like the struts, made of double angle-irons, in order that the rigidity of the compressed bar may be identified with that of a cross composed of four angle-irons by joining the sections of the brace and the strut. For a bar in the middle, for example, the reduced thickness of a cross of four angle-irons of 70/70/8 millimètres will be 0^m.08 ; the ratio of the free length to this thickness is $\frac{2.80}{0.08}$ or 35, which requires a coefficient of stiffness = 1.56. With the section adopted, this coefficient is 1.55, a value which is all the more sufficient because the rivetings at the extremities of the bar amount to a joining of the metal.

The fixing of the extreme bars requires the application of joint-plates to give the rivets a double resisting section : we obtain by this means twenty sections, which is amply sufficient.

Direct calculation gives for the whole girder :—

Flanges	{ Angle-irons and vertical ribs with their joint-plates ..	2750	} 5600*
	{ Horizontal plates	2850	
Bars ..	{ Braces and struts	1550	} 7500*
	{ Joint-plates and filling-plates affixed to the bars at the		
	{ point where they cross	140	
	{ Two end vertical bars	210	

Say 300 kilogrammes per metre of girder.

The flanges weighing 224 kilogrammes the metre of girder, whilst the formula in 97 gives them 167 U, we have U 1·34.

The bars amount to 1900 kilogrammes, 140 of which are for the special pieces for fixing the end

1705.
Scale 0·01.

bars and the plates which are affixed to the bars at the points where they cross each other; but these 140 kilogrammes are nearly compensated by the saving resulting from the fact that the bars have not quite their theoretical length; so that we may suppose α nul, and take then $V = 1·30$, at which we arrive from a comparison of the weight $\frac{1900}{25} = 76$ kilogrammes, resulting from the calculation, with that of $33(1 + V)$, furnished by the formula.

If we admitted $1 + V = 1·95 + 0·15h$, the best height would result from the equation $120 = (2·65 + 0·408h)h^2$, and would be about 5 metres, a great value which proceeds from the extreme lightness of the lattice; but it is prudent not to exceed the height of $4^m·50$, near which we cannot practically reduce the section of the flanges.

A greater diminution of the height is warranted by the small variation of the weight and by the advantage of diminishing the importance of the exterior tie-pieces. Yet, if the height allowed be unlimited, we shall do well to take a height of 3 metres, instead of $2·50$ as in the plan.

If the load were doubled and made 6800 kilogrammes the metre, everything included, it would be easy to reduce U to $1·25$, and V to $1·15$, even if the height were carried up to $3^m·50$.

102. *Second Example.*—Girder of Crosses and without Vertical Rods, for a Tubular Bridge of 72 metres span, Figs. 1708 to 1717.—Data: $l = 72^m$, $\delta = 8^m$, $N = 9$, $h = 9^m$, $p = 3000^k$ (the girder itself weighing 1700), $p' = 4000^k$, $p + p' = 7000^k$, $q = 0·5714$.

When one line of rails only is loaded, p' amounts to only 3000 kilogrammes, which will allow us to reduce by $\frac{1}{2}$ the weight of the girder if we do not object to raise R to 7 kilogrammes the square millimetre for the very exceptional case of two heavily-laden trains crossing the bridge at the same time.

The strains upon the portions of the flanges, reckoning from the middle to the ends, are:—498, 473, 398, 274, and 100 tons; the strains upon each of the two bars of the crosses = 24, 52, 82, 115, and 150 tons; the end vertical bars support 112 tons.

In the elevation of this girder and some others we have been obliged to exaggerate slightly the thicknesses of the horizontal plates of the flanges in order to render the arrangement of them perceptible.

The struts have a double T section, offering a great moment of resistance in the direction normal to the vertical portion of the girder. In the plane of this vertical portion, the free length being only half, the rigidity is sufficient with the sections adopted. We might, if necessary, take the sections of a hollow form, as in Figs. 1690 to 1700.

The braces are composed of two equal and parallel pieces enclosing the strut, and are fixed externally to the vertical ribs of the flanges; but the two bars of the middle cross are identical and in the form of a double T.

In fixing the end bars, the double rib allows us to place eighty rivets of $0^m·025$; so that it is useless to double the shearing sections. The thickness of $0^m·012$ given to the ribs renders tearing away impossible.

The gussets at the point where the bars cross each other serve not only to connect the brace and the strut, but as joint-plates for these pieces. But for several bars at the end, composed of two thicknesses of plate, this gusset can cover the joint of only one plate; the joint of the second plate is then made to fall in another place where it has special joint-plates. The angle-irons of the bars may be continuous throughout the length.

The following is the result of the calculation:—

Flanges	{	Angle-irons { principal 10505	}	87840, say 879000 ^k	}	122500 ^k
		border 2835				
		Double vertical ribs 22380				
		Special joint-plates for angle-irons, and so on .. 3550				
		Horizontal plates with their joint-plates .. 48120				
Bars	{	Plates between the vertical ribs, at the ends of each cross-girder 450	}	34000	}	600
		Struts and braces 27630				
		Two end vertical bars 4270				
		Plates at the point of crossing and joint-plates .. 2100				
		Hand-rails				

It follows from this that the mean weight of the lineal metre of girder will be 1630 kilogrammes.

We might make up an additional term Ω by taking, in the flanges, the border angle-irons which do not enter into the theoretical resistance, and the plates at the ends of the cross-girders; and in the bars, the plates at the points of crossing and the joint-plates; to this might be added the hand-rails. But we should have to deduct the saving in the length of the bars, which does not reach the theoretical length; and this saving more than compensates the weight of the light pieces of railing. The plates upon the bars and their joint-plates may enter into V , for these pieces are a function of h in this sense that a less height would allow us to suppress the joint-plates and reduce the dimension of the plates. The accessories of the flanges may be introduced into the coefficient U . From this point of view, we shall regard Ω as nul, $U = 1.36$, and $V = 1.25$.

If we admit that when near the most economical height, $1 + V$ increases according to the law $1 + V = 1.35 + 0.10 \frac{h}{h_0}$, and that U is reckoned as only 1.06, according to the rule given in 64, the best height will result from the equation $0.807 h^3 + 5.45 h^2 = 2726$, and will be 13 metres. Indeed we shall then have $V = 1.65$, $U = 1.50$, and the weight of the girder a metre will be brought down to 1510 kilogrammes, whilst for $h = 9$, $V = 1.25$ and $U = 1.36$, the formula gives 1626 kilogrammes.

103. *Third Example.*—Girder of Crosses and with Vertical Rods, of 40 metres span, Figs. 1718 to 1725.—Data: $\delta = 40$ m, $\delta = 4$ m,

1709.
Transverse section G.H.

Scale 0.005 for the elevation and transverse section, 0.025 for the details.

1709.

$N = 10$, $h = 4^m \cdot 50$; $p = 2500^k$, $p' = 3200$ (one line of rails loaded), $p + p' = 5700^k$, $q = 0 \cdot 56$.

In the exceptional case in which both lines are simultaneously loaded at the rate of 4300 kilogrammes a metre each, the bridge will be subjected to a strain of about $7^k \cdot 2$, and this may be allowed.

Successive strains upon the portions of the flanges = 248, 228, 188, 127, and 46 tons;

Successive strains upon the bars = 16, 28, 41, 54, and 68 tons;

Strain upon the end vertical bars = 51 tons.

In order to fix properly the struts in the double I form, whose greatest stiffness is in the direction normal to the vertical portion of the girder, double vertical ribs to each flange have been adopted, as in the preceding example. The braces are of flat, equal and parallel bars enclosing the struts, except in the two middle crosses, in which the flat bars are replaced by two angle-irons of 110/70/11 millimètres, because, in certain positions of the load, these braces may have to bear slight compression.

The bars bearing the greatest strain are fixed without having recourse to double shearing sections, for 20 or 24 rivets may be placed upon each of the two ribs, and this is amply sufficient.

The intermediate vertical rods serve for affixing the cross-girders. The following is the result of calculation:—

Two flanges	{	Angle-irons and vertical ribs with their joint-plates ..	13300	} 23500	} 34000 ^k .
		Horizontal plates and their joint-plates	10200		
		Oblique bars (including 100 ^k for plates)	7200		
Lattice ..	{	Two end vertical bars with their gussets	1450	} 10500	
		Nine intermediate vertical rods	1850		

Thus the girder weighs 815 kilogrammes per mètre, its whole length being $41^m \cdot 80$.

The term Ω will be nul, for the bar-plates amounting to only 100 kilogrammes, do not even compensate the saving upon the length of the bars.

The flanges amount, according to calculation, to 563 a mètre, and according to the formula 435 U; hence $U = 1 \cdot 30$.

The oblique bars = 207 according to calculation, and 90 $(1 + V)$ according to the formula. Therefore $V = 1 \cdot 30$.

Supposing $1 + V = 1 \cdot 75 + \frac{1}{8} h$, and expressing the vertical rods by an additional term $\frac{8 N h (2 + h)}{l}$, (100), the most economical height will be $5^m \cdot 90$, which will allow us to construct a tubular bridge, and to suppress the intermediate vertical rods. Thus for bridges of two girders of more than 40 mètres span, we may adopt the tubular system in preference to girders loaded on the lower side, if we desire to obtain greater stability in the girders.

104. *Tables of the Weights of Girders.*—The best height to adopt is an implicit function of the load in virtue of the coefficient V, so that the height of heavy girders may be increased a little.

If for girders lightly loaded we suppose $h = 0 \cdot 11 l$, $U = 1 \cdot 40$, $V = 1 \cdot 35$, and for girders

heavily loaded $h = \frac{1}{8} l$, $U = 1 \cdot 35$, and $V = 1 \cdot 30$, these coefficients will allow us to suppose Ω

nul, and by applying the general formulæ (97 and 99), we may construct the Tables on p. 827, giving the values of $\frac{P}{(p + p')^2}$; that is, the weight of the lineal mètre of girder will be found by multiplying the numbers of the Tables by $(p + p') l$.

The least expense corresponds to $N = 8$ in the first Table, and to $N = 7$ in the second. These values give, having regard to the heights adopted, directions to the bars a little less than 45° upon the horizontal, since the Tables decrease with N.

If there be intermediate vertical rods, they must be added as we have seen in 100, which is equivalent to adding to the numbers in the Tables the quantity $\frac{8 N h (2 + h)}{(p + p')^2}$.

105. Supposing loads similar to those which were taken for girders of triangles (92), the weight of the girders themselves only being slightly reduced in a few cases, and taking the same values of N, namely, 7 for a span of 20 mètres, 8 for spans of 30 to 60 mètres inclusive, 9 for 70 mètres, and 10 for 80 mètres, we shall have the following approximative weights for girders without intermediate vertical rods.

Spans	Mètres. 20	Mètres. 30	Mètres. 40	Mètres. 50	Mètres. 60	Mètres. 70	Mètres. 80
Weight of the lineal mètre of girder carrying one rail ($h = 0 \cdot 11 l$)	Kilos. 260	Kilos. 385	Kilos. 520	Kilos. 650	Kilos. 780	Kilos. 940	Kilos. 1140
Weight of the lineal mètre of girder carrying one line of rails ($h = \frac{1}{8} l$)	445	670	880	1100	1310	1590	1900

It will be seen that in large spans these girders of crosses without vertical rods offer a small saving over those of simple triangles (92), because the supposed values of N allow of the bars being placed nearer the inclination of 45° , and because in the double lattice the strains upon the

	0.003264	0.003239	0.003236	0.003238	0.003258	0.003274	0.003306	0.003332	0.003370	0.003402	0.003445

struts and braces are less, and, therefore, the several parts may be fixed without the addition of supplementary pieces.

106. For girders with vertical rods calculated as in 100, the Table will become on the hypothesis of the same heights, although there may be occasion to reduce them a little in this case:—

Spans	Mètres. 20	Mètres. 30	Mètres. 40	Mètres. 50	Mètres. 60	Mètres. 70	Mètres. 80
Weight of the lineal carrying one rail	285	420	565	700	840	1020	1235
mètre of girder { „ one line of rails	475	720	940	1170	1390	1690	2020

being weights differing but little from those of girders of simple triangles (92).

107. *Double Crosses.*—In cases of limited height, or in those of small girders, if we happen to have $h < \frac{\delta}{\sqrt{2}}$ we may place two crosses in an interval δ comprised between two successive points of application of the load. In this case, the weight of the diagonals will be modified, $\sin^2 \alpha$ being changed into $\frac{1}{2} \sin^2 \alpha'$, α' representing the greater inclination obtained by the doubling of the crosses. The flanges depend only on the distance apart of the loaded points; the vertical rods, if there are any, will be placed square with the cross-girders, in every second cross, Fig. 1726.

Confining ourselves to the case of N odd, the weight of the metre of girder may be computed by the formula

$$\frac{P}{l} = \frac{(N^2 - 1)(p + p')t}{48N} \left\{ \frac{l^2}{N^2 h} \left[8NU + 3(1 + V) \left(1 + \frac{1}{6} q \right) \right] + 12h(1 + V) \left[\frac{N + 3}{N + 1} + \frac{1}{6} q \right] \right\} + \alpha,$$

when the load is placed upon the lower part; and by

$$\frac{P}{l} = \frac{(N^2 - 1)(p + p')t}{48N} \left\{ \frac{l^2}{N^2 h} \left[8NU + 3(1 + V) \left(1 + \frac{1}{6} q \right) \right] + 12h \left[\frac{4NV}{N^2 - 1} + (1 + V) \left(1 + \frac{1}{6} q \right) \right] \right\} + \alpha,$$

if the load is on the upper part. The coefficient V is applied to the end vertical bars as well as to the other bars under compression.

108. *Multiple Lattice-girders.*—*General Observations.*—A multiple lattice may usually be considered as resulting from the superposition of several simple lattices, at least if we omit to consider the connection at the points where they cross each other. The component simple lattices may be of different systems, as it happened in the case of girders of crosses; sometimes, in such cases, certain bars participate simultaneously in the composition of two elementary lattices; and if they are acted upon on one side by a force of compression and on the other by a force of tension, their resulting maximum strain may be limited to a small value, as in the case of vertical rods considered in section 95.

We are now about to consider exclusively another kind of multiple lattice, resulting from the union of several simple lattices, identical in form, but placed one before another. Thus, in Fig. 1727, the system $A B C D$ is a simple lattice, but we shall form a double one by superposing the parallel lattice $A' B' C'$, and this duplication will enable us to distribute the load applied to the girder over a double number of points, without subjecting the portions of the flanges to a deflecting strain. The load may be applied to all the summits or only to some of them. But even if all the loaded summits should belong exclusively to one of the elementary lattices, all the bars will take part in the resistance, for in virtue of the rigidity of the portions of the flanges a parallelogram such as $B C E D$ cannot be distorted by the lengthening or shortening of the bars $B C$, $D E$, without producing a change in the intermediate bar $C' D'$. Thus it is usual to calculate first the strains in a simple system as $A B C D$, and then to divide them equally among the whole of the bars. The flanges are regarded as loaded in a continuous manner.

The connection at the points of crossing enables a bar to receive variable strains at the same instant in its several subdivisions, and the vertical portion of the girder thus possesses a certain moment of resistance. But these secondary considerations are never taken into account.

The theoretical weight of a multiple lattice must, therefore, be obviously the same as that of a simple lattice the bars of which have the same inclination. But in practice each system has its advantages and its disadvantages, and may modify the expense in one direction or in another. By multiplying the bars we incur excesses of section, because the theoretical strains become very

small and would require dimensions which the importance of the girder would not allow; the plates, too, on the points where the bars cross each other increase in proportion. On the other hand, a multiple lattice may always be traced near 45° , whatever the interval between the cross-girders may be, whilst with simple bars we may be obliged to have recourse to less advantageous inclinations. From the point of view of rigidity, if the multiplicity of the points of crossing offers the advantage of subdividing the bars into portions of inconsiderable length, on the other hand the sections decrease, the vertical portion of the girder acquires a tendency to twist like a thin sheet of iron, and we are obliged to remedy this disadvantage by the addition of stiffening vertical rods. At the ends of the girder, a certain number of the elementary lattices terminate by fragments of bars which are fixed at different points in the height of the end vertical bar. This bar would, therefore, have a tendency to bend if the precaution were not taken of replacing it by a broad piece of solid plate iron stiffened by projecting ribs.

It seems, therefore, preferable not to multiply beyond a moderate degree the systems of lattice, but to construct them of bars possessing the greatest possible rigidity. It is only in cases in which the rivetings become difficult that we should have recourse to the multiple system, for then the bars, being weakened, may be fixed by a very small number of rivets. This is the principal consideration which should decide the degree of multiplicity.

As to the comparative security of simple and multiple lattices, provided the joints and rivetings are equally solid, they may be regarded from this point of view as equal. If the bars were of cast iron or of wood, it might be objected that a defect in a single piece would be sufficient to ruin a simple system, whilst in a multiple system the resistance never falls upon a single piece. But in bridges of malleable iron, this objection would be specious, for a bar should have such a section that it may be composed, in almost all cases, of several pieces riveted together; consequently, a defect in one of the pieces will be protected by the other sound parts, and it may happen that all the elementary pieces may be defective without the whole breaking, if the defective portions are isolated by the rivetings; the only result in such a case being a greater strain upon the sound portions than was anticipated. In those parts in which the strains are inconsiderable, a multiple system will offer in general a great excess of resistance, but it will be at the price of an excess of material, and we might, if we chose, increase the sections in a simple system to obtain an equal additional security.

109. If the inclination of the bars remains constant when the height varies, the lattice will have, theoretically, a nearly constant weight; in order that the flanges may be supported at the same intervals, the multiplicity of the lattice must increase with the height. Indeed, even when the general rigidity of the vertical portion of the girder resides chiefly in the addition of projecting ribs, we must reckon upon a surplus expense for the local rigidity of the several portions of the compressed bars, and for other conditions which must be fulfilled, principally not to reduce the sections below a certain minimum, not to make a continuous variation from bar to bar, but only by successive groups, to take into account in certain cases the weakening occasioned by the rivet-holes, and so on. We may affect the whole of the lattice with a coefficient V , but in analogy with the notations employed for girders of triangles or crosses, in which V was specially applied to the struts, we will denote the general coefficient by $\frac{1+V}{2}$, (82).

110. The stiffening vertical rods may serve also for affixing the cross-girders, and the vertical cross-bracing. Their section increases with the height, but may be taken nearly constant with the load in the ordinary cases of railway bridges, for they will thus add, as they should do, a relative increase of strength which will be the greater as the lattice becomes weaker and more liable to distortion. For the same reason they may be made to vary but little in the several points in the length of a given girder.

Instead of placing only one vertical rod in a line with each cross-girder, it may be advantageous, if the distances δ are great, to have two for each interval, placing them alternatively on each side of the vertical portion of the girder when nothing prevents. Or we may place principal rods in a line with the cross-girders, and other weaker rods in the middle of the intervals.

Let us suppose adopted as a mean, for the case of one rod to the interval δ , the sections given in Fig. 1728.

The weights given by this figure may be put into the formula $15h$, so that the weight of the rods a lineal metre of girder will be represented by $\frac{15h^2}{\delta}$.

111. *Formulae of Weight.*—The flanges will make up a weight $\frac{(p+p')^2 t U}{5h}$ a lineal metre of girder, regarding the load as continuous. The bars at 45° give $\frac{1+V}{24} (p+p') (6+g) l t$.

The end vertical bars transmit to the abutments the strains upon the bars which are fixed at different points in their length; their section should theoretically increase from the top to the bottom, and as their mean compression is equal to half the reaction of the abutment, that is to $\frac{1}{4}(p+p')l$, their total weight will be $\frac{1}{2}(p+p')t\ell h$, say $\frac{1}{2}(p+p')t\ell h$ per metre of girder. But, in practice, this is insufficient, and, as we shall see by the examples hereafter, it is necessary to add to each extreme bar two vertical stiffening rods similar to those described in the preceding section; we thus obtain at once the necessary rigidity, and an increase such that the section will be everywhere superior to the theoretical value, and will, therefore, not need to vary from the bottom upwards.

This addition of four vertical rods will give, to a metre of girder, a term $\frac{60h^2}{l}$, admitting the sections of Figs. 1729 to 1731; and if there are already intermediate rods to the number of $\frac{l}{\delta} - 1$, the term including all these additions will be $15h^2 \frac{l-3\delta}{l\delta}$.

To sum up, we shall have the weight of the lineal metre of a lattice-girder with vertical rods, by the formula

$$\frac{P}{l} = (p+p') \frac{t^2 U}{6h} + \frac{1+V}{24} (p+p') (6+q) l t + \frac{1}{2} (p+p') t h + 15h^2 \frac{l-3\delta}{l\delta} + \Omega.$$

112. Suppose $1+V = a + b h$, this formula becomes

$$\frac{P}{l} = (p+p') \frac{t^2 U}{6h} + \frac{a}{24} (p+p') (6+q) l t + \frac{1}{2} (p+p') t h + \left[1 + \frac{b l}{12} (6+q) \right] h + 15h^2 \frac{l-3\delta}{l\delta} + \Omega.$$

If the ratio $\frac{h}{\delta}$ were regarded as constant, and we made $\frac{h(l-3\delta)}{(p+p')l\delta t} = \theta$, the most advantageous height would be $h_1 = l \sqrt{\frac{U}{3 + \frac{1}{4} b l (6+q) + 90\theta}}$, and it would reduce the weight of the metre of girder to the minimum value,

$$\frac{P_1}{l} = (p+p') l t \left\{ \frac{1}{3} \sqrt{U \left[3 + \frac{1}{4} b l (6+q) + 90\theta \right]} + \frac{a}{24} (6+q) \right\} + \Omega.$$

If, instead of h_1 we adopted a different height $h = \kappa h_1$, the term of the radical in the preceding expression would be multiplied by $\frac{\kappa^2 + 1}{2\kappa}$.

But usually δ is a fixed quantity, unconnected with h , and the most economical height is then determined by an equation of the third degree.

113. When the lattice-bars have sufficiently rigid forms to allow the vertical rods to be suppressed, the weight of the girder will be found by the formula

$$\frac{P}{l} = \frac{1}{2} (p+p') t \left[\frac{U t^2}{3h} + \frac{1}{12} (1+V) (6+q) l + h \right] + \frac{60h^2}{l} + \Omega.$$

114. *Examples.—First Example.—Flat-bar Lattice-girder with Vertical Rods*, Figs. 1729 to 1731.—Data: $l = 27^m \cdot 50$, $\delta = 3^m \cdot 00$, $p = 1100^k$, $p' = 2400^k$, $p+p' = 3500^k$, $q = 0 \cdot 686$.

The flat form which the bars have in this case is the least favourable to rigidity, but it enables us to place the vertical rods in a projecting position upon each side of the vertical portion of the girder, without weakening in any part the section of the bars. The lattice is multiplied eight times; the bars of which it is composed vary from 130/14 millimètres to 60/12, both for compression and tension; for here, the bars being weak, it is well to give, even to those subject to tension, an excess of section on account of the loss occasioned by the rivet-holes. In a line with the cross-girders, at intervals of 3 mètres, the lattice is enclosed by vertical rods formed of two angle-irons of 80/120/10 millimètres, one on each side; and in the middle of the intervals there are single rods formed of one angle-iron. The weight of all these rods to each lineal metre of girder is 42 kilogrammes; this result agrees with the formula which, for $\delta = 3$, gives $\frac{15h^2}{\delta} = 45$, the weight

42 kilogrammes, not including certain pieces used to fill up the hollows in fixing the rods. The figure contains plans or diagrams of the resistance of the flanges and the lattice: the former shows the arrangement of the horizontal plates and their joint-plates. In the diagram of the lattice the ordinates of the curve represent the strain upon a bar to the scale of $2\frac{1}{2}$ millimètres a ton or the necessary theoretical section, abstracting the rigidity to the scale of $1\frac{1}{2}$ millimètre a square centimètre; the broken line is the locus of the sections really adopted, or the strains to which the bars would be liable if they could be subjected to a stress of 6 kilogrammes a square millimètre.

The weight of a girder is made up of the following quantities:—

Flanges, including joint-plates	7600 ^k	} 12970, say 13000 ^k , or 2070 } 455 a metre.
Bars at 45° (including 270 ^k for plates)	3300	
Vertical rods (including 70 ^k for filling)	1210	
End vertical pieces	860	

The formula of 111 will be made to agree with the results by supposing $U = 1.39$, $V = 2.16$, and $\Omega = 12$ kilograms say the 0.026 of the total weight. The term Ω includes the plates upon the bars at the points of crossing and the filling used in fixing the vertical rods. The value of V is high, because the tension-bars have been increased, as well as those subject to compression; the discontinuous variation of section by groups of bars is also a source of loss. Yet, notwithstanding this high value of V , the rigidity of the lattice is to us less satisfactory than in the girders of the following examples, in which the bars have a better form. If the load were double, V could be reduced easily to 1.90. The vertical rods agree with the hypotheses of the formula by taking $\delta = 3$ metres, that is, by considering the single rods as borrowed from the double or principal rods, which are to an equal extent weakened.

The end solid vertical pieces are also conveniently represented by the formula, for the term $\frac{1}{2}(p+p')lth$ gives 188 kilogrammes, four rods give 60 h^2 or 540, and the 860 kilogrammes of the calculation will be completed by the fact that the total weight of the lattice proper is calculated for the whole length of girder instead of for the bearing only.

If we suppose $V + 1 = 2 \cdot 35 + 0 \cdot 27 h$, the most advantageous height will be obtained from the equation $608 = (11 \cdot 69 + 13 \cdot 27 h) h^2$, whence h is about $3^m \cdot 30$. Reckoning in this case $U = 1 \cdot 42$, the minimum weight will be 452 kilogrammes, including 12 kilogrammes for Ω .

It will be seen that the reduction of the height to 3 metres has not increased the weight in any sensible degree.

115. *Second Example.—Girder with Rigid Struts and with Vertical Rods, Figs. 1732 to 1741.*—Data: $l = 64^m$, $\delta = 4^m$, $h = 8^m$, $p = 3000^k$, $p' = 3000^k$ (for the case of a single line loaded with 4000^k), $p + p' = 6000^k$, $q = 0.50$.

Here we adopt a mixed system, better than the preceding; the vertical rods are placed upon one side only of the lattice, which enables us to place on the other side oblique bars with projecting ribs, and arranged to resist compression; in the middle only, a few braces are made of angle-iron, because in certain cases they may be subject to compression. These angle-irons are then cut away in a line with the vertical rods; but their resisting section remains intact in the portions of their length where they have of themselves to resist compression, producing a deflecting strain.

This system is of itself sufficiently rigid to allow the adoption of a more open lattice than in the case of flat bars; and, in fact, notwithstanding the considerable height of the girder, we have multiplied it only ten times. The vertical rods weigh only 145 kilogrammes a metre of girder, instead of 240 kilogrammes, which the formula of 111 would allow. This gain is due to the rigidity which the struts already possess.

The following is the result of direct calculation:—

Flanges	Angle-irons and vertical ribs with their joint-plates	20000 ^k	55500	96000, say 1435 ^k a mètre of girder.
	Horizontal plates with their joint-plates	35500		
Bars at 45°, including 1000 ^k for plates and joint-plates		25200	34500	
	Vertical rods, with their filling	9300		
End solid vertical pieces		6000		

These quantities correspond with $U = 1.25$, $V = 1.80$, $\Omega = 15$ (for plates on the bars), or 0.01 of the total weight.

For the end vertical pieces, the term $\frac{1}{2}(p + p') l h t$ gives 2000 kilogrammes, four vertical rods according to the formula will amount to 3840; these two amounts added to the weight furnished by the hypothesis that the lattice extends along the bearing upon the abutments, will give more than the 6000 kilogrammes obtained by direct calculation.

If the height be increased, and the same degree of multiplicity, and the same distance between the vertical rods retained, the latter being suitably strengthened, V will vary but slowly on account of the rigid form of the compression-bars. Suppose, for example, $1 + V = 2.40 + 0.05 h$,

$U = 1.06 + 0.024 h$, $\Omega = 15$, and reduce to $10 h^2 \frac{l + 3 \delta}{l \delta}$ the term for the rods, the weight of the metre of girder with the present data, but for an indeterminate height, will be

$$\frac{P}{l} = 5645 \frac{1}{h} + 10.66 h + 2.97 h^2 + 468.$$

The minimum is for $h =$ about 9^m.30, and its value is 1430 kilogrammes, whilst for the height of 8 mètres the same formula gives 1450 kilogrammes. The height may, therefore, be again slightly reduced, without much disadvantage: taking it at 7 mètres, for example, the weight would not exceed 1495 kilogrammes a metre.

116. *Third Example.*—Rigid Lattice-girder without Vertical Rods, Figs. 1742 to 1747.—Data: $l = 40^m$, $h = 4^m.50$, $p = 2200^k$ (the girder itself weighing 900), $p' = 3800^k$ (the contiguous line only being loaded at the rate of 4300^k a metre), $p + p' = 6000$, $q = 0.633$.

The lattice is only sixfold. All the bars are of a rigid form, and the connection at the points of crossing utilize the rigidity of the braces in favour of the struts. The bars on one side of the lattice keep the same direction throughout the length of the girder, so that no projection is cut away. Calculation gives

Flanges	Vertical ribs and angle-irons with their joint-plates	7500 ^k	24400	37200 ^k , say 890 a mètre of girder.
	Horizontal plates with their joint-plates	16900		
Lattice-bars (including 300 ^k for gussets at the points of crossing)		10300		
End vertical pieces		2500		

These quantities correspond with $U = 1.26$, $V = 1.90$, and $\Omega = 7^k$, say the 0.008 of the total weight; V might be reduced if, instead of having only four series of sections for the bars, we varied them in a continuous manner.

If, when h varies, we suppose $U = 1.06 + 0.046 h$, and $1 + V = 1.55 + 0.30 h$, the formula of 113 will become with the other data of the present example, $\frac{P}{l} = \frac{2205}{h} + 29.8 \cdot h + 1.5 h^2 + 236$. The minimum for a height of 6^m.70 will be 831 kilogrammes a metre, instead of 890 as for the girder in the plan.

117. *Tables of Weights.*—We will suppose generally the following loads, which differ from those of 92 only by a small increase in the weight of the girders:—

Girders carrying one rail.					Girders carrying two rails.		
$l =$	20 ^m	60 ^m	80 ^m		20 ^m	60 ^m	80 ^m
$p + p' =$	3600 ^k	3600 ^k	4000 ^k		7000 ^k	6900 ^k	7600 ^k
$q =$	0.695	0.556	0.500		0.714	0.580	0.576

Let us suppose again for girders carrying one rail, $h = 0.11 l$, $U = 1.40$, $V = 2.20$, $\Omega = 10$; and for girders loaded with two rails, $h = \frac{1}{8} l$, $U = 1.30$, $V = 1.90$, and $\Omega = 15$. The formula of 113 will give us the following Table.

Generally girders carrying two rails may be relieved of a portion of their load, if we allow a strain greater than 6 kilogrammes the square millimètre for the accidental case of two heavily-laden trains crossing the bridge at the same time.

The weights in this Table exceed those of girders with simple crosses (105), but are considerably below those for girders with a solid rib (129, 130, 133).

118. For lattice-girders of flat bars, with stiffening vertical rods, V can receive hardly any reduction, and the weight will increase by the addition of the rods. The latter form a rather arbitrary element; but on the hypotheses made in section 110, and by giving to δ a value varying from 2 to 5 mètres, according as the span varies from 20 to 80 mètres, we may admit the following figures, which suppose the adoption of the same heights as in the preceding section.

Weight of the mètre of a flat lattice-girder, stiffened by vertical rods.

We may, in the case of vertical rods, adopt heights a little less; but the weights will change only in a very small degree.

When the vertical rods are on one side only of the lattice, as in Fig. 1732, we may make half the bars at 45° rigid, and reduce in consequence the weight of the rods. The value of the girder will then be between those of the Tables in 117 and 118.

119. *Solid Girders.—Vertical Portion.*—The solid rib or web is exclusively employed for all kinds of girders of small dimensions, such as cross-girders and minor longitudinal girders. We have already given in 13 to 19 the rules applicable to these kinds of pieces.

We purpose now to examine girders of greater importance; for there is an appreciable interest, in this case, in submitting the plates of the vertical portion and the pieces which give it rigidity to a more minute discussion.

Denoting the height of the girder by h , and the variable thickness of the vertical portion by e , the theoretical volume of the latter will be expressed by $h \int e dx$, or by $\frac{1}{R_1} \int F dx$, according to the value of e given in section 1. Replacing the area $\int F dx$ of the locus of the stress by the value in section 4, we shall have for the whole bearing: theoretical volume of the vertical portion

$$= \frac{1}{4R_1} (p + p') \left(1 + \frac{1}{6} q\right) l^2.$$

120. Comparing this expression with the theoretical volume of a multiple lattice at 45° without vertical rods, namely, $\frac{1}{4R_1} (p + p') \left(1 + \frac{1}{6} q\right) (1 + V) l^2$, we see that if R_1 were equal to R , the solid rib would have only a volume equal to that of the braces in a multiple lattice, or equal to half the volume of this lattice, supposing V reduced to unity.

We may conceive this fact by imagining the solid rib split into a great number of strips at 45°, placed so as to form the tension-bars of a multiple lattice: these bars in mutual contact will press each other laterally, and these pressures will render useless the addition of struts; for a rod subject to a tensile strain at the rate of R kilogrammes the unit of section, may also be compressed at the same coefficient normally to its length without the resulting pressure exceeding R in any direction.

But the coefficient R_1 of resistance to shearing force is usually taken equal to 4000000, whilst R rises to 6000000. The vertical portion, or rib, will therefore already reach the $\frac{3}{4}$ of the theoretical volume of a lattice at 45°. Besides this, the joint-plates and the pieces added to give rigidity, joined to the circumstance that the vertical portion itself cannot be strictly reduced everywhere to the theoretical thickness, render it in reality more expensive than the lattice, at least when the girder acquires a certain importance. Stiffening pieces, or the application of a sufficient coefficient V_1 , are, it is true, necessary for a multiple lattice also; but if it be a very open one, and bars of a proper form be adopted, a certain fraction of the required rigidity will be already furnished by the theoretical volume, which will reduce in an equal degree the supplementary additions.

The continuity of the rib, or vertical part, prevents it from resisting exactly as a lattice; the strains, too, vary in a continuous manner from one point to another, instead of remaining constant throughout the length of the imaginary strips of which we have spoken. If the plate were very thin, compression would produce corrugations, while tension would be concentrated in certain points; the plate would wrinkle in directions near 45° , and the wrinkles thus formed would show the direction of the greatest tensile strains, or the positions of the braces in the lattice offering the greatest resistance, which might be cut out of the vertical plate, having regard to the mode of loading.

This continuity of the vertical portion allows it to be introduced into the calculation of the moment of resistance; but generally it will raise it only by a very small value, especially as the thickness is reduced to a minimum precisely in the middle, where the moment of resistance should be great. It is, therefore, not necessary to compute exactly the part taken by the vertical portion in the moment of resistance; it is well even to undervalue it slightly, on account of the influence of the joints, which diminish the resistance a little.

121. *Flanges.*—The variable section s of the flanges is given by the following equation, which expresses the equality of the moment of rupture M to the moment of resistance: $M = R h \left(s + \frac{F}{6 R_1} \right)$, see section 14. Substituting for M and F the values given in section 4, we deduce

$$s = \frac{1}{2} (p + p') \left(\frac{x(l-x)}{R h} - \frac{l-2x}{6 R_1} \right) - \frac{p' x^2}{12 R_1 l}.$$

The maximum for $x = \frac{1}{2} l$ will be $s_1 = \frac{(p + p') l^2}{8 R h} - \frac{p' l}{48 R_1}$.

From this maximum value, the theoretical section s decreases as the ordinate of a parabola as we approach the abutments; it becomes nul at the point where the vertical portion alone possesses a sufficient moment of resistance to be in equilibrio with the moment of rupture, and beyond this it becomes negative even. But it cannot in reality be thus: not only must s not become nul, it must not even descend below a certain minimum s_2 which may be fixed in each case. If x_2 is the abscissa (reckoned from the abutment) which gives to s this value s_2 , the total volume of the flanges will be $2 \left[l s_2 + \frac{2}{3} (s_1 - s_2) (l - 2x) \right]$.

122. But this formula would be inconvenient, and it is better to consider simply the volume of the two flanges as equal to $\frac{4}{3} l s_1$, that is, as if the section varied parabolically from s_1 in the middle to 0 at the extremities, and the coefficient U may serve to correct nearly the divergence between the form thus conceived, and the one occurring in practice. And, as the least thickness of the vertical rib in the middle is never less than $0^m \cdot 006$, we may compute its moment of resistance for this thickness, neglecting the surplus if the plate is stouter; s_1 will then have the value $\frac{(p + p') l^2}{8 R h} - 0 \cdot 001 h$, and consequently, total weight of the two flanges

$$= \frac{t l U}{3} \left(\frac{(p + p') l^2}{2 h} - 0 \cdot 004 R h \right).$$

123. *Accessories.*—To complete the weight of the girder, there yet remain to be computed the accessories of the vertical portion, namely, 1, the excess of material occasioned by the fact that the thickness varies by redans or gradations and not in a continuous manner, and also by the fact that it cannot descend in any part below a certain minimum, $0^m \cdot 006$ for instance; 2, the joint-plates of the rib; and 3, the pieces intended to give it rigidity.

In girders heavily loaded, we may suppose that the redans and the surplus thickness, indispensable in the middle, are equivalent to an extra continuous thickness of about $0^m \cdot 0027$ applied to the whole vertical rib.

124. As to the *joints*, they may be placed widely apart when the height of the girder does not exceed the breadth of the iron plates, and this is one of the causes which make the solid rib economical for small girders. But when the height becomes considerable, a case which we are now discussing, we must not reckon upon distances greater than $0^m \cdot 90$ between the successive joints. In order that the rivets may offer a double shearing section, for the purpose of reducing the breadth of the joint-plates, the latter are composed of double plates placed on each side of the vertical rib; these plates will nearly always be of $0^m \cdot 006$, for a less thickness is seldom employed in the construction of bridges, and on the other hand that of $0^m \cdot 006$ is sufficient when the rib consists of stout plate of $0^m \cdot 012$. The breadth of the joint-plates may, at least over a certain portion of the girder, be limited to $0^m \cdot 160$, placing only one row of rivets upon each side of the joint. But if the stress reaches a high value near the supports, it may be necessary to place a double row of rivets, and to increase the breadth of the joint-plates to $0^m \cdot 300$, so that there may

always be on each side of the joint a number of rivets at least equal to $\frac{F}{2 R_1 \sigma}$, F being the stress, R_1 the resistance to a shearing force, and σ the section of a rivet. If, as a mean, we reckon $0^m \cdot 200$ for the breadth of the joint-plates, they will be equivalent to an extra continuous thickness of $0^m \cdot 0027$, which, added to that of the preceding section, gives $0^m \cdot 0054$.

This amount may be retained for girders lightly loaded; for if on the one hand the breadth of all the joint-plates is reduced to $0^m \cdot 160$, which produces an extra thickness of only $0^m \cdot 0022$; on the other hand, in small girders especially, calculation will assign thicknesses too far below the limit.

125. The pieces added to give rigidity are usually vertical and are applied to the joint-plates;

they thus form vertical rods, which are made use of in fixing the cross-girders, or brackets. Their section is not determined by rigorous laws, it is necessary only that their projecting ribs should increase with the height, to ensure rigidity. It is often advantageous to increase those situated in a line with the cross-girders at the expense of the intermediate ones. Let us, for example, suppose adopted, for heights of 2 to 5 mètres, the arrangements shown by Figs. 1748 to 1751, which gives the horizontal section of a certain length of vertical rib.

With these forms, the angle-irons and transverse plates, not including the joint-plates, will weigh 12 h kilogrammes a square mètre of vertical rib, and this is equivalent to a reduced thickness equal to 0.00154 h . We will put it at 0.002 h , to be able to increase the rigidity of the vertical rib again towards the ends. This value is considered as applicable to strong as well as to weak girders; it will constitute for these latter an addition of strength relatively greater, as, indeed, should be the case, for it is the weak vertical ribs which are most liable to twist. We may, within certain limits, modify the distance of the vertical stiffening pieces apart by modifying inversely their section. Sometimes we shall do well to fix the transverse plates by means of a single angle-iron, and to rivet to the exterior edge a second angle-iron. The intermediate stiffening pieces will have a U form instead of a T, and the border angle-iron will give a gratuitous increase of rigidity.

126. *Formula and Table of Weights for Solid Girders.*—Adding the weight of the theoretical vertical rib (119) and that of the flanges (122), reduced to the lineal mètre of girder, as well as the accessories equivalent to extra thicknesses of 0.0054 (124) and of 0.002 h (125), we obtain the following formula as the expression of the weight of the girder a lineal mètre :

$$\frac{P}{l} = \frac{1}{6} (p + p') l t \left\{ \frac{U l}{h} + \frac{3}{8} (6 + q) \right\} + h (42 \cdot 12 - 8000 t U + 15 \cdot 6 h).$$

As q has but a small influence, we may substitute for it the value 0.60 from which it will generally not differ much, and we shall then have

$$\frac{P}{l} = (p + p') l \left\{ 0.0002167 U \frac{l}{h} + 0.0005363 \right\} + h (42 \cdot 12 - 10 \cdot 4 U + 15 \cdot 6 h).$$

Substituting for the coefficient U in this expression the value assigned to it in 64 and seeking the condition of the minimum of expense, we find that the most advantageous height h_1 must satisfy the equation : $0.23 (p + p') l^2 = (31510 + 31200 h) h^2$.

127. The loads $p + p'$ do not vary much with the span, because the moving load p' decreases, while the dead weight of the girder increases. For spans of 20 and 55 mètres, we may adopt the following loads, according as the girder is to carry one or two rails :—

		Girders carrying	
		One Rail.	Two Rails.
20 mètres span ..	Exterior dead weight	kilos. 700	kilos. 1400
	Weight of the girder	400	600
	Moving load p'	2500	5000
	Total load $p + p'$	3600	7000
55 mètres span ..	Exterior dead weight	700	1400
	Weight of the girder	1300	2000
	Moving load	2000	4000
	Total load	4000	7400

Substituting these quantities in the equation of the preceding section, we find that, for 20 mètres span, the most economical height will be 1^m·90 if the girder supports only one rail, and 2^m·45 if it supports two rails. For 55 mètres span, we obtain respectively 4^m·20 and 5^m·20.

Thus, for girders the least loaded, the ratio of the most advantageous height to the span would vary from 0·095 in small spans, to 0·076 in long ones; and for heavy girders from 0·12 to 0·095. We may alter these heights a little without the weight changing sensibly, and it will often be advantageous to reduce them, either to lessen the vertical cross-bracing and cross-ties if the bridge is loaded on the upper side, or to increase the stability if the girders are loaded on the lower side, or again, to satisfy conditions of limited thickness. In the following Tables we give heights reduced by about $\frac{1}{10}$.

128. It remains to compute U , which, according to 66, may be expressed by $1\cdot06 + 4\cdot80 \frac{R s_0 h}{(p+p') l^2}$, or $1\cdot06 + \frac{1\cdot10 R s_0}{h (31510 + 31200 h)}$ by replacing $\frac{h^2}{l^2}$ by the value obtained from the equation which ends section 126. From this U may be regarded as independent of the load; it diminishes when h increases, but only by the factor between parentheses, for $\frac{s_0}{h}$ will be nearly constant, since it is necessary to adopt a minimum section of flange s_0 greater in proportion to the dimension of the girder.

For example, if the girder is 1^m·80 high (bridge of 20 mètres), we may make s_0 of one plate of 3/508 millimètres and of two angle-irons of 80/80/10; for a girder of 4 mètres high ($l = 55$), we may take a plate of 550/8 with four angle-irons of 100/100/12, two of which are placed next the vertical rib and two at the edges of the flange. In both cases this would give $\frac{1\cdot10 R s_0}{h} =$ about 22000, and consequently $U = 1\cdot31$ for $h = 1\cdot80$, and $1\cdot20$ for $h = 4$. We shall, therefore, vary this coefficient from 1·30 to 1·20, according as the span varies from 20 to 55 mètres.

129. The several hypotheses made in the preceding sections lead to the following Table for the weight of the lineal metre of solid girders, the heights adopted being a little under those which would correspond rigorously with the minimum expense.

Span		Mètres. 20	Mètres. 25	Mètres. 30	Mètres. 35	Mètres. 40	Mètres. 45	Mètres. 50	Mètres. 55
Girders carrying one rail ($p + p' = 3600$ to 4000 kilogrammes, accord- ing to the span) ..	Height	1·70	2·00	2·30	2·60	2·90	3·20	3·50	3·80
	Weight a metre	Kilos. 370	Kilos. 485	Kilos. 610	Kilos. 735	Kilos. 870	Kilos. 1000	Kilos. 1140	Kilos. 1285
Girders carrying one line of rails ($p + p' = 7000$ to 7400)	Height	2·25	2·60	2·95	3·30	3·65	4·00	4·35	4·70
	Weight a metre	Kilos. 570	Kilos. 750	Kilos. 940	Kilos. 1125	Kilos. 1320	Kilos. 1525	Kilos. 1730	Kilos. 1940

We may compute by interpolation the weight of girders supporting intermediate loads. If, for example, for a bridge of 55 mètres span we had $p + p' = 6400$ kilogrammes, we should find that by adopting a height of 4^m·45 the weight of the lineal metre would be about 1750 kilogrammes. This weight would be substituted for that of 1940 kilogrammes for a girder carrying one line of rails; if, instead of a load of 4000 kilogrammes, which supposes both lines loaded simultaneously, we considered a load of only about 3000 kilogrammes for the ordinary case of the passage of one train, the strain a square millimètre would then exceed 6 kilogrammes in the exceptional case of two heavily-laden trains crossing at the same time.

130. *Other Formulae.*—In the foregoing discussions we have distinctly stated that the thickness of the vertical rib should not descend below a certain minimum, which may be fixed at 0^m·006, but this condition has not been positively expressed in the formula; we have contented ourselves with providing for it by the aid of an approximative extra thickness. This condition is, however, easily expressed, as we shall see; but to do this we must distinguish two cases, that in which this minimum thickness of 0^m·006 is sufficient throughout the length of the girder, and the contrary case. The vertical rib being calculated for a strain of 4 kilogrammes a square millimètre, the two cases in question are equivalent to those in which the quantity $(p + p') l$ is less or greater than 48000 h .

First Case: $(p + p') l < 48000 h$.—The vertical rib has a constant thickness of 0^m·006, and it requires joint-plates with a single row of rivets on each side of the joint. We shall then have, remarking that the joint-plates are equivalent to an extra thickness of 0^m·0022,

$$\frac{P}{l} = (p + p') \frac{P^2 U}{6 h} + h (64 + 15\cdot6 h - 8000 t U).$$

This formula may be applied to girders carrying only one rail, provided the height be not too small. On the contrary, the formula of section 126 supposed tacitly that the height was not great, in order that the vertical rib should not become too weak. With the new expression of $\frac{P}{l}$ the most

economical height will be a little less than hitherto: thus for the bridge of 20 metres loaded with 3600 kilogrammes a metre, it will be only $1\cdot 15$ instead of $1\cdot 90$; and for the bridge of 55 metres loaded with 4000 kilogrammes, it will be $3\cdot 95$ instead of $4\cdot 20$. But retaining the same heights, loads, and values of U introduced into the Table in 129, the present formula gives the following weights, which hardly differ from the preceding. This Table ends with 35 metres span, because beyond this the condition of the present case would not be fulfilled.

Span	Mètres. 20	Mètres. 25	Mètres. 30	Mètres. 35
Weight a mètré of girder carrying only one rail ($p + p' = 3600$ kilograms for 20 mètres span, to 3770 kilogrammes for 35 mètres) .. }	Kilos. 370	Kilos. 480	Kilos. 600	Kilos. 725

131. *Second Case: $(p + p')l > 48000 h$.*—This will always be the case with girders carrying one line of rails, it will also be the case with girders carrying only one rail, if their height is below a certain value.

Fig. 1752 represents the plane of the theoretical vertical rib, throughout half the bearing, the thicknesses being exaggerated. If the plate had everywhere only $0\text{m}\cdot006$, its volume for the whole bearing would be $0\cdot006\text{ } l\text{ } h$; but we must add to it the triangular prisms one of which is shown in the figure. These prisms should have rigorously a curvilinear face, but we may neglect the influence of q , for it is perceptible only in the middle, upon the focus of the stress. The maximum

stress requires at the ends a thickness $e_1 = \frac{(p+p')l}{2 R_1 h}$ or $\frac{(p+p')l}{8000000 h}$ supposing $R_1 = 4000000$.

Consequently, the volume of the two additional prisms will be $\frac{[(p+p')^2 - 48000h]^2}{16000000(p+p')}$.

But as the thickness, instead of varying uniformly, decreases by redans or gradations of $0\text{m}\cdot002$, we must add a mean thickness of $0\text{m}\cdot001$ to the part over which the prisms extend; it may be increased to $0\text{m}\cdot0012$ even, to take into account various circumstances, especially that of having neglected q , and it will give a new supplementary volume equal to $\frac{0\cdot0012\ h}{p+p'} [(p+p')l - 48000\ h]$.

We shall have besides:—

$$\left. \begin{array}{l} \text{Joint-plates and stiffening rods in the part} \\ \text{where the vertical rib is only } 0^{\text{m}}\cdot006 \end{array} \right\} = \frac{48000 h^2}{p + p'} (\xi_1 + \xi'_1 h);$$

$$\left. \begin{array}{l} \text{Joint-plates and stiffening rods in the part} \\ \text{where the vertical rib is strengthened} \end{array} \right\} = \frac{(p+p')l - 48000h}{p+p'} (\xi_2 + \xi_2' h) h.$$

132. Collecting the various elements of the vertical portion, as they have been computed, adding to them the flanges according to section 122, then transforming the volumes into weight, and dividing by the bearing, we shall have

$$\frac{P}{l} = \begin{cases} \frac{t U}{6 h} [(p + p')^2 - 0.008 R h^2] \text{ (flanges).} \\ + 46.8 h + \frac{0.0004875}{(p + p') l} [(p + p') l - 48000 h]^2 \text{ (vertical rib according to Fig. 1752).} \\ + \frac{9.36 h}{(p + p') l} [(p + p') l - 48000 h] \text{ (redans in the strengthened portions of vertical rib).} \\ + \frac{48000 h^2}{(p + p') l} (\xi_1 + \xi'_1 h) + \frac{(p + p') l - 48000 h}{(p + p') l} (\xi_2 + \xi'_2 h) h \text{ (joint-plates, and so on, of the vertical rib).} \end{cases}$$

Making $R = 6000000$; $t = 0.0013$:

Weight of the joint-plates a square mètre of vertical
rib in the extreme strengthened portions $\xi_2 = 0^m \cdot 0035 \times 7800^k = 27^k \cdot 3;$

$$\text{Weight of the vertical rods a square metre in the extreme strengthened portions} \left\{ \begin{array}{l} \xi'_2 h = 0.0024 \times 7800 h = 18.72 h; \\ \end{array} \right.$$
$$\left. \begin{array}{l} \text{extreme strengthened portions} \quad \dots \dots \dots \\ \text{Weight of the joint-plates a square m\`etre in the in-} \\ \text{termediate portion} \end{array} \right\} \xi_1 = 0^m \cdot 0022 \times 7800^k = 17^k \cdot 16;$$
$$\left. \begin{array}{l} \text{intermediate portion} \dots\dots\dots \\ \text{Weight of the vertical rods a square metre in the} \\ \text{intermediate portion} \dots\dots\dots \end{array} \right\} \xi'_1 h = 0\text{m}\cdot0016 \times 7800 h = 12\cdot5 h;$$

the formula will become

$$\frac{P}{l} = (p + p') l \left(\frac{13 U l}{60000 h} + 0.0004875 \right) + h (36.66 - 10.4 U + 18.72 h) - \frac{h^2}{(p + p') l} (298560 h - 187200).$$

133. The most economical height will here be given by the following equation of the fourth degree (U being replaced by the expression in 64):

$0.0002297 (p + p')^2 l^3 = 25.64 (p + p') l h^2 + 37.44 [(p + p') l + 10000] h^3 - 895680 h^4$, which ought to give values a little greater than hitherto, since we have expressed the fact that, in proportion as the height increases, the lengths of the portions of vertical rib which need to be strengthened are reduced. And, in fact, for $l = 20$ mètres, and $p + p' = 7000$ kilogrammes, we obtain $2^m.70$, instead of $2^m.45$, found by the first formula; and for $l = 55$, and $p + p' = 7400$, we find 5.45 , instead of 5.20 .

By increasing the heights, therefore, a little, we shall form by means of the last formula the following Table, in which $p + p'$ varies from 7000 to 7400, and U from 1.30 to 1.20, in proportion as the bearing increases from 20 to 55 mètres. These loads refer to girders carrying two rails, a test which in general is realized in a complete manner only when both lines are simultaneously loaded.

	Mètres.	Mètres.	Mètres.	Mètres.	Mètres.	Mètres.	Mètres.	Mètres.
Span	20	25	30	35	40	45	50	55
Height	2.50	2.85	3.20	3.55	3.90	4.25	4.60	5.00
	Kilos.	Kilos.	Kilos.	Kilos.	Kilos.	Kilos.	Kilos.	Kilos.
Weight of the mètre of girder .. .	535	710	890	1070	1265	1460	1670	1870

These weights are a little less than those obtained by the first method.

134. *Example of Solid Girder*, Figs. 1753 to 1757: $l = 35$ mètres, $p + p' = 7000$ kilogrammes.—According to a direct calculation, this girder weighs only 1030 kilogrammes a lineal mètre. The arrangements shown in the plan for the joint-plates of the flanges allows us to reduce the coefficient U to the value 1.20.

135. *Girders with Inclined Stays*.—When vertical stays or rods are not deemed necessary for the purpose of affixing cross-girders or brackets, they may be replaced by oblique pieces crossing the flat joint-plates, which would remain vertical and would be interrupted in the line of these pieces. The latter would be inclined to 45° , nearly normally to the wrinkles which would be produced if the plate were not stiffened. This arrangement is alluring; however, the economical advantage of it appears doubtful, because for the same normal distance between the consecutive pieces the diminution of their number would be compensated by the increase in their length; or rather the distance between the oblique bars may be greater, but their section should be increased to an equal degree, for these pieces, concentrating upon themselves by the effect of their rigidity the strains of compression, may be considered as the struts of a lattice which would be completed by the tension of the plate in the direction of one of the diagonals of each panel. Now for one direction given to these diagonal tensions of the plate, we may replace two vertical stays AB, CD, Fig. 1758, by a single stay AD, which would be equivalent to them, for with the inclination of 45° , for example, it would have its strain and its length multiplied by $\sqrt{2}$. Thus between the imaginary lattice A B C D E F G, and the lattice A D E H, there would be this essential difference only, namely, that in the second, the plate will be relieved of the diagonal tensions BC, FG, in the rectangular panels occupied by the oblique bars. But there is small advantage in this, since this plate must resist equal strains in other panels, and besides, these stays were not intended to reduce these strains.

The adoption of oblique pieces will in no degree change the form of the formulæ of weight given, 119 to 135. It would be sufficient to introduce other values for the weight of the stays a square mètre of vertical rib, if it were thought a reduction might be made.

136. *Formulæ applicable to Bow Bridges*.—Bow-girders are metallic frames consisting of two curved flanges more or less distant from each other in the middle, and approaching each other towards the extremities where they are bound together by strong wrought-iron plates. If we consider any vertical section, the action of the flanges, having an inclined direction, will produce a vertical force capable of resisting, in part at least, the stress upon the bridge. The lattice connecting the flanges at certain intervals may thus be greatly relieved.

If the lattice is a simple one, the bars, or at least some of them, must necessarily possess sufficient rigidity to resist compression. This is doubtless a great disadvantage, for the theoretical strains being small we shall obtain the rigidity only at the cost of a great increase of section. This increase, however, is confined within rather narrow limits, even if we do not bring into play the rigidity of the bow itself; since the coefficient of stiffness, if it has a high value, is applied to only a small fraction of the total weight. We may, therefore, not hesitate to adopt for this coefficient a value of 2.50, for instance, which raises to 60 the ratio of the length to the reduced thickness (68). But, by doubling the diagonals of the lattice, we may in certain cases entirely suppress the compressions in the vertical portion, or at least render them unworthy of consideration, as we shall see in 144 and 157. As an expenditure of material, this will amount to nearly doubling the theoretical weight of simple diagonals not possessing rigidity; for we arrive at this elimination of the compressions only by supposing, in any cross, that one of the diagonals of which it is composed remains inactive at a given moment. The compression is always thrown upon the vertical rods, where it is destroyed or very much reduced by a permanent tension due to the dead weight of the flooring.

These considerations allow us to study bow bridges as simple articulate systems, which will lead us to formulæ for the computation of their weight more precise and simple than the method

of introducing the rigidity of the bows themselves, and, consequently, the form of their section, could do. When a scheme is devised in which this rigidity plays an important part, it is because something is to be gained by it, and then our computations will still be useful if we consider them as forced a little.

It is generally more convenient to make only the upper flange or bow arched, the lower flange or stringer being straight and provided with points for fixing the cross-girders. We shall designate more specially this particular form by the name of *arched girder*.

137. *Parabolic Arched Girder, divided into an odd number of intervals*, Fig. 1759.—Let $l = (2m+1)\delta$ be the bearing and h the height in the middle. The bars, whether vertical or oblique, are num-

bered from the middle. The bow is a polygon, having its summits upon a parabola with a vertical axis, and the sides of which have a constant horizontal projection equal to δ .

The n th vertical rod has a length expressed by $h \left[1 - \frac{n(n-1)}{m(m+1)} \right]$, and the value of the sum of the lengths of the $2m$ rods is $\frac{2h}{3}(2m+1)$ or $\frac{2}{3} \frac{lh}{\delta}$. The length of the n th section EF of the curved flange is $\frac{1}{m(m+1)} \sqrt{m^2(m+1)^2\delta^2 + 4(n-1)^2h^2}$, and makes with the vertical an angle γ given by $\cotan. \gamma = \frac{2h(n-1)}{m(m+1)\delta}$.

The length of the n th diagonal shown by the full line is

$$\frac{1}{m(m+1)} \sqrt{m^2(m+1)^2\delta^2 + [m(m+1) - n(n-1)]^2h^2},$$

and makes with the horizon an angle α the sine of which is

$$\text{Sin. } \alpha = \frac{m(m+1) - n(n-1)}{\sqrt{m^2(m+1)^2\delta^2 + [m(m+1) - n(n-1)]^2h^2}}.$$

The length of the n th diagonal shown by the dotted line is

$$\frac{1}{m(m+1)} \sqrt{m^2(m+1)^2\delta^2 + [m(m+1) - n(n-1)(n-2)]^2h^2},$$

and the sine of the angle of inclination is

$$\text{Sin. } \alpha' = \frac{m(m+1) - (n-1)(n-2)}{\sqrt{m^2(m+1)^2\delta^2 + [m(m+1) - (n-1)(n-2)]^2h^2}}.$$

138. 1.—Let us first suppose a simple lattice formed by the vertical rods and the diagonals shown by the full lines.

If the framing is subjected only to a permanent load uniformly distributed according to the horizontal, in such a manner that a weight equal to $p\delta$ is applied to the foot of each vertical rod, this weight will express the constant tension of all the rods, which act as simple suspension-rods to transmit the load to the several summits of the polygonal arc. Their total theoretical weight will be $= \frac{2}{3}(2m+1)p\delta ht$, t denoting as before the ratio of the weight of the cubic mètre of iron to the admitted resistance R.

The n th section of the bow is subject to the following strain of compression:

$$\frac{p\delta}{2h} \sqrt{m^2(m+1)^2\delta^2 + 4(n-1)^2h^2};$$

whence we deduce for the total weight of the bow the value $U(2m+1)p\delta t \left[\frac{m(m+1)\delta^2}{2h} + \frac{2h}{3} \right]$.

The lower flange, or stringer, bears a constant tension equal to $\frac{m(m+1)p\delta^2}{2h}$, which gives it a total weight $= \frac{U m(m+1)(2m+1)p\delta^2 t}{2h}$. The letter U still denoting the coefficient for joint-plates and other accessories.

It is useless to enlarge upon these formulæ, well known in the theory of suspension bridges.

With the present mode of loading, the parabolic form given to the bow assimilates it to a funicular polygon, that is, its several elements have precisely the directions which they would of themselves assume if they were left free to turn about their summits. It is, indeed, easy to prove that the action of any section has a vertical projection equal to the stress, so that the diagonal is inactive.

139. It will not be the same in the case of a moving load which, although distributed uniformly in the proportion of $p' \delta$ a vertical rod, may exist on a certain portion only of the length.

To find the maximum strains upon the several sections of the flanges, the load must be extended over the whole bridge; for these strains depend only upon the moments of rupture about certain summits, and these moments increase always in proportion as we add new loads upon a certain point in the bearing. The strains and weight of the flanges will, therefore, be obtained by the formulæ of the preceding section by substituting $p + p'$ for p .

But the strains upon the bars are at once functions of the moment of rupture and the stress.

Let T be the strain upon the diagonal ED , Fig. 1759, M the moment of rupture about the point D , the abscissa of which is $(m - n + 2) \delta$, and F the stress between C and D . The strain

upon the section EI of the bow will be equal to $\frac{M}{D I \sin. \gamma}$, and, consequently, considering the portion of the girder situate to the left of the line GH , the condition of equilibrium relative to the vertical forces will give, supposing T to be a tension, $T = \frac{F}{\sin. \alpha} - \frac{M \cotan. \gamma}{D I \sin. \alpha}$.

This expression is of the form $BF - AM$, A and B being given quantities. Therefore, from section 7, it will become a maximum when the load is applied to the point D and to all those on the right. Taking this maximum value, and substituting the values of $\cotan. \gamma$, $\sin. \alpha$ and DI (the length of the $(n - 1)$ th vertical rod), we find that the diagonal should be capable of resisting a strain of tension,

$$T = \frac{p' \delta}{2(2m + 1)h} \sqrt{m^2(m + 1)^2 \delta^2 + [m(m + 1) - n(n - 1)]^2 h^2}.$$

We know that if we complete the load by adding weights $p' \delta$ at the bottom of the vertical rods situate to the left of GH , the diagonal will be relieved of its strain. Therefore, this complementary load placed alone in its turn should produce a compression equal to the preceding tension. Thus, applying a coefficient of stiffness V , the weight of the diagonal in question will be

$$\frac{p' \delta t V}{2m(m + 1)(2m + 1)} \left\{ m^2(m + 1)^2 \frac{\delta^2}{h} + [m(m + 1) - n(n - 1)]^2 h \right\}.$$

To find the total weight of the $2m - 1$ diagonal bars, we must scan the preceding expression in which n takes the successive values 1, 2, ... m , double the result, and then subtract what the above expression becomes for $n = 1$, in order not to reckon twice the middle diagonal. We shall be induced, for the sake of symmetry, to divide this diagonal into two pieces to form a central cross, but the strain will be distributed between the two bars of this cross, and there will be no increase of weight. We obtain:

Total weight of the $(2m - 1)$ diagonals shown by the full lines,

$$\frac{p' \delta t V}{2(2m + 1)} \left[m(m + 1)(2m - 1) \frac{\delta^2}{h} + \frac{h}{15} (16m^3 + 9m^2 + m + 4) \right].$$

140. Analogous calculations may be applied to the n th vertical rod CE . Cutting it by a section $G'H'$, supposing it to be subject to a compression T' , and calling M' the moment of rupture about a point C , the abscissa of which is $(m - n + 1) \delta$, we shall have by the equation of equilibrium relative to the projections of the vertical forces, $T' = F - \frac{M' \cotan. \gamma'}{EC}$; γ' is the angle of the $(n + 1)$ th section of the bow with the vertical, and EC the length of the n th rod.

This expression is also of the form $BF - AM'$. Treating it by the rule in section 7, we obtain for the maxima compression of the rod, $T' = \frac{(m - n)(m + n - 1)}{2(2m + 1)} p' \delta$.

Here F was the stress taken beyond the point to which the moment M' is referred. It follows that this maximum strain T' is produced when the load is applied to the point D , and to those following it as far as B . This compression will be wholly or partly neutralized by the permanent tension due to the dead weight.

When the load is completed, the vertical rod, instead of being subject to a strain of compression T' , is, on the contrary, subject to a strain of tension $p' \delta$. Therefore the complementary load placed alone in its turn should subject the rod to a tension

$$T'' = p' \delta + T' = \frac{(m + n + 1)(m - n + 2)}{2(2m + 1)} p' \delta,$$

which always greatly exceeds the maxima compression, especially when we add the permanent tension $p' \delta$, due to the dead weight.

It may happen that this latter tension is always sufficient to destroy the compressions which the load may produce. We may, therefore, from this point of view dispense with a coefficient of stiffness, and calculate the rods by tension only. Adding the dead to the moving load, and denoting the ratio $\frac{p}{p + p'}$ by q , the weight of the n th rod will be

$$(p + p') \delta t h \left[1 - \frac{n(n - 1)}{m(m + 1)} \right] \left[1 + q \frac{(m + n - 1)(m - n)}{2(2m + 1)} \right],$$

an expression which being doubled, then summed from $n = 1$ to $n = m$ inclusive, leads to

$$\text{Total weight of the } 2m \text{ vertical rods} = \frac{2(p+p')\delta t h}{3} \left[2m+1+q \cdot \frac{(m-1)(2m-1)}{5} \right].$$

141. Adding the weight of the flanges, of the diagonals and of the vertical rods, substituting for δ its value in l , and dividing by l , we obtain for the mean weight of the lineal metre of girder,

$$\frac{P}{l} = (p+p') t l^2 \frac{m(m+1)}{(2m+1)^2} \left[U + qV \frac{2m-1}{2(2m+1)^2} \right] \frac{1}{h} + \frac{(p+p') t h}{3} \\ \left\{ 2(U+1) + \frac{q}{10(2m+1)^2} [16m^3(1+V) - m^2(16-9V) - m(4-V) + 4(1+V)] \right\} + \Omega.$$

The term Ω includes accessories independent of h .

Substituting N for $2m+1$, we may write also

$$\frac{P}{l} = (p+p') t l^2 \cdot \frac{N^2-1}{4N^2} \left(U + qV \cdot \frac{N-2}{2N^2} \right) \frac{1}{h} + \frac{(p+p') t h}{3} \\ \left\{ 2(U+1) + \frac{q}{40N^2} [8N^3(1+V) - 5N^2(8+3V) + 8N(6+V) + 15V] \right\} + \Omega.$$

Such is the formula applicable, N being odd, to a bow-girder with simple rigid diagonals. If the height is great, the vertical rods may with advantage possess rigidity, because they may furnish resting points for fixing the vertical cross-bracing which is needed to maintain the verticality of the girder. In such cases we may either subject them to a coefficient V , or retain the preceding formula, by adding to it a term $\frac{2}{3} \frac{N \theta h^2}{l}$ for the addition, to each rod, above the theoretical section, of a projecting rib weighing θh a lineal metre.

The first method would have the advantage of simplifying the formula by reducing it to

$$\frac{P}{l} = (p+p') t \left\{ \frac{N^2-1}{4N^2} \cdot \frac{l^2}{h} \left(U + qV \cdot \frac{N-2}{2N^2} \right) + \frac{h}{3} \left[2(U+1) + \frac{qV}{40N^2} (16N^3 - 55N^2 + 56N + 15) \right] \right\} + \Omega.$$

142. 2.—If the diagonals shown by the full lines of Fig. 1759 are now suppressed and replaced by the diagonals shown by the dotted lines, we shall have another system of simple lattice, which will give occasion to analogous calculations. The value of the strain either by tension or by compression upon the n th diagonal is

$$\frac{p' \delta}{2(2m+1)h} \sqrt{m^2(m+1)^2 \delta^2 + [m(m+1) - (n-1)(n-2)]^2 h^2},$$

and consequently we have:

Total weight of the $2m-1$ diagonals shown by the dotted lines =

$$\frac{p' \delta t V}{2(2m+1)} \left\{ \frac{m(m+1)(2m-1) \delta^2}{h} + \frac{h}{15(m+1)} (16m^4 + 55m^3 + 70m^2 - 85m + 4) \right\}.$$

The vertical rods are subject to the same strains, and make up the same total weight as with the first system of diagonals.

143. 3.—Generally a single system of diagonals will not be sufficient, and a girder of complete crosses will be adopted. The strains are then indeterminate, and we are free to calculate the pieces from one or the other of the two following points of view.

We may, in the first place, consider the complex system as resulting from the superposition of two simple lattices, each comprising a certain portion of the section of the flanges and vertical rods, plus one of the systems of diagonals, to the exclusion of the other. It is natural to attribute a half of the load to each of these two constituent parts; and, consequently, the diagonals will have their strains and their weights given by the same formulæ as if they were simple, by changing p' into $\frac{1}{2} p'$. The flanges retain the same weight; as to the vertical rods, the present hypothesis divides them into two portions, one of which is subject to a strain of compression and the other to a strain of tension, under the action of a determinate load extending over a part only of the flooring. For example, if the load be applied only to the rod under consideration and to all those to the right, it will produce upon this rod on the one hand a tension $\frac{p' \delta}{4(2m+1)} (m^2 + 3m - n^2 + n + 2)$, and

on the other hand a compression $\frac{p' \delta}{4(2m+1)} (m^2 - n^2 - 3m - n - 2)$. The resultant is a tension $\frac{3m+n+2}{2(2m+1)} p' \delta$, the maximum of which is $p' \delta$ for $n = m$. Now this maximum is required of all the vertical rods when the bridge is completely loaded. They must, therefore, be all calculated for a tension equal to $(p+p') \delta$, without taking into account their mode of participating in the resistance of the two component simple lattices.

We therefore give:

$$\text{Total weight of the } 2m \text{ vertical rods} = \frac{2}{3} (2m+1) (p+p') \delta t h.$$

The total weight of the metre of girder is then

$$\frac{P}{l} = \frac{(p+p') t}{(2m+1)^2} \left\{ m(m+1) l^2 \left(U + \frac{qV}{2(2m+1)} \right) \frac{1}{h} + \frac{2}{3} \left[(U+1)(2m+1)^2 \right. \right. \\ \left. \left. + qV \cdot \frac{4m^4 + 10m^3 + 10m^2 - 10m + 1}{5(m+1)} \right] h \right\} + \Omega,$$

or, if l is expressed by $N \delta$ (N being odd),

$$\frac{P}{l} = (p + p') t \left\{ \frac{N^2 - 1}{4 N^2} l^2 \left(U + \frac{q V}{2 N} \right) \frac{1}{h} \frac{2}{3} \left[U + 1 + \frac{q V}{10} \left(N + \frac{1}{N} - \frac{30(N-1)}{N^2(N+1)} \right) \right] \right\} + \Omega;$$

a formula to which we shall generally have to add (141) a term $\frac{2}{3l} N \theta h^2$, allowing us to enlarge the vertical rods by means of projecting ribs or gussets for the purpose of maintaining the verticality of the girder.

144. But the diagonals being very long and subject to small strains, can be stiffened only by means of a high value of V . Now, considering them as very flexible rods, unable to resist any compression, they will of themselves elude this kind of strain by yielding, and the lattice will assume another mode of resistance, in virtue of which the strains of compression will always be thrown upon the vertical rods. Choosing diagonals which at any instant are prepared for a tensile strain, the whole framing will offer a constant resistance. From this point of view, the two systems of diagonals will be calculated each for the whole load, which is equivalent to making $V = 2$, in the formula of the preceding section. It is true that in this case the vertical rods may be required to resist compression, but it will be to a very small coefficient, for the permanent tension $p \delta$ neutralizes in a great measure, if not altogether, the strains in the opposite direction. The real strain of

compression, if such be produced, is limited to $\frac{p' \delta}{2(2m+1)} (m-n)(m+n-1) - p \delta$, whilst under

a complete load the maximum tension reaches $(p + p') \delta$. If, therefore, p be not less than $\frac{m(m-1)}{2(2m+1)} p'$ the vertical rods can never be subject to compression, in which case we obtain this

remarkable result, that all the lattice-bars have to resist tensile strains only, which obviates the necessity for rigidity. This allows us to adopt great heights for girders, and to make the arched form more advantageous than the straight. These favourable conditions still exist when the maxima compression of the vertical rods, without being always nul, remains at least within certain limits; and if there is occasion for applying to these rods a coefficient V , as we are about to do, it is much less on account of the possible compression, than for the purpose of maintaining the vertical position of the girder by means of suitable arrangements; such, for instance, as the vertical cross-bracing fixed to the rods in Fig. 1762, which rods must furnish sufficiently firm points. By adding this coefficient V applied to the vertical rods (but no longer affecting the diagonal bars), the addition of a term $\frac{2}{3} \frac{N \theta h^2}{l}$ as in the preceding case, is rendered superfluous. It is the same addition expressed under another form.

It is evident that there will be an advantage in bringing the pieces of the vertical portion of the girder into accordance with the second hypothesis rather than with the first, whenever the latter would require for the rigidity of the diagonals the application of a coefficient V greater than 2. But it is scarcely necessary to remark that, although freed from all compression according to the second hypothesis, the diagonals will offer greater security if we give them all the rigidity which, with a convenient form, the area of their theoretical section admits, for we shall thus render them capable of resisting at pleasure in two different ways; the mode of effective resistance will be a kind of mean which will limit the real strains to a figure smaller than the admitted limits.

145. From the considerations in the preceding section, the weight of the lineal metre of arched girder with complete crosses may be represented by

$$\frac{P}{l} = \frac{(p + p') t}{(2m+1)^2} \left\{ m(m+1) l^2 \left(U + \frac{q}{2m+1} \right) \frac{1}{h} + \frac{2h}{3} \left[(U + V)(2m+1)^2 + \frac{2q}{5(m+1)} (4m^4 + 10m^3 + 10m^2 - 10m + 1) \right] \right\} + \Omega;$$

or, if l is expressed by $N \delta$ (N being odd),

$$\frac{P}{l} = (p + p') t \left\{ \frac{N^2 - 1}{4 N^2} l^2 \left(U + \frac{q}{N} \right) \frac{1}{h} + \frac{2h}{3} \left[U + V + \frac{q}{5} \left(N + \frac{1}{N} - \frac{30(N-1)}{N^2(N+1)} \right) \right] \right\} + \Omega.$$

146. *Parabolic Bow-girder divided into an even number of intervals.*—We will now suppose that the bearing l is expressed by $2m \delta$, and we shall consider the general case of a bow both flanges of which are curved, as in Fig. 1760.

The total height in the middle is the sum of the versed sines h and h' of the curve above and below the horizontal A B, drawn through the points of meeting at the ends. The various pieces are, as before, numbered from the middle.

If the flooring were placed according to the tangent to the lower flange, we should have to lengthen the vertical rods to this tangent and to add a horizontal longitudinal girder. But nothing prevents us from placing the flooring at the height of the line A B, and saving, if not the longitudinal girder, at least the lengthening of the vertical rods; unless the upper bow be, as in the bridge at Saltash, formed of a single tubular section projecting over the space occupied by the flooring, an arrangement which requires the extremities A and B to be kept at a sufficient height above the rails. But two distinct framings well tied and braced together, leaving, of course, a free passage for the trains, may constitute a sufficiently rigid whole; and we shall, consequently, consider only the pieces represented in the figure, except the casual addition of a longitudinal beam tying together the vertical rods at the height of the flooring, this piece being regarded as included in the term Ω independent of the height.

We have as geometrical data:

$$\text{Length of the } n\text{th vertical rod} = \frac{m^2 - (n-1)^2}{m^2} (h + h');$$

$$\text{Sum of the lengths of the } 2m - 1 \text{ vertical rods} = (h + h') \frac{(4m^2 - 1)}{3m};$$

$$\text{Length of the } n\text{th section of upper flange} = \frac{1}{m^2} \sqrt{m^4 \delta^2 + (2n-1)^2 h^2};$$

$$\text{Length of the } n\text{th diagonal shown by a full line} = \frac{1}{m^2} \sqrt{m^4 \delta^2 + [(m^2 - n^2)(h + h') + (2n-1)h']^2}.$$

This diagonal is inclined upon the horizon at an angle α given by

$$\sin. \alpha = \frac{(m^2 - n^2)(h + h') + (2n-1)h'}{\sqrt{m^4 \delta^2 + [(m^2 - n^2)(h + h') + (2n-1)h']^2}}.$$

The n th section of upper flange makes with the vertical an angle γ such that $\cotan. \gamma = \frac{(2n-1)h}{m^2 \delta}$.

We shall obtain the analogous quantities, relative to the lower flange and to the diagonals shown by the dotted lines, by simply changing h into h' , and h' into h .

147. The flanges should always be calculated under a full load, whatever the diagonals adopted may be. The value of the strain upon the n th section of the upper flange is

$$\frac{(p + p') \delta}{2(h + h')} \sqrt{m^4 \delta^2 + (2n-1)^2 h^2},$$

and that upon the n th lower section is found by the same formula modified by interchanging h and h' , which only alters the second term under the radical. If we cut these two corresponding sections according to the radical, their action will furnish a vertical resultant projection equal to $\frac{(p + p') \delta}{2} (2n-1)$, which is exactly in equilibrio with the stress; thus, when the load is complete throughout the length of the bridge, the diagonals do not resist.

The weight of the n th section of the upper flange being expressed by

$$\frac{(p + p') \delta t}{2m^2(h + h')} [m^4 \delta^2 + (2n-1)^2 h^2],$$

we conclude that the total weight of this flange will be $\frac{(p + p') \delta t}{h + h'} \left[m^3 \delta^2 + (4m^2 - 1) \frac{h^2}{3m} \right]$, and adding the coefficient U , the two flanges together will weigh

$$\frac{(p + p') \delta t U}{h + h'} \left[2m^3 \delta^2 + (4m^2 - 1) \frac{(h^2 + h'^2)}{3m} \right].$$

148. The load still extending over the whole bearing, the strain upon the vertical rods will be found by remarking that, for the equilibrium of the point I , the rod DI must destroy the resultant of the strains from the two sections LI and EI , abutting at this point, the diagonals being inactive, as we have just seen. We have:

Tension of the n th rod = $(p + p') \delta \frac{h}{h + h'}$, a constant value whatever n may be.

In the case in which the maximum strain is always limited to this value, the total weight of the $2m - 1$ rods will be independent of h' , and will have as its expression $(p + p') \delta t h \frac{4m^2 - 1}{3m}$.

This supposes that the load is applied to the bottom of the vertical rods. If, on the contrary, the flooring is on a level with the line AB , the upper portion of each rod will have the same

tensile strain as before, but the lower portion will bear a compression $(p + p')\delta \frac{h'}{h + h'}$, and if we give different sections to the two portions, the total weight will be expressed by

$$(p + p')\delta t \cdot \frac{4m^3 - 1}{3m} \cdot \frac{h^2 + V h'^2}{h + h'},$$

V being a coefficient of stiffness applied to the compressed portions, and which may be extended to the upper portions for the purpose of adding rigidity to the bridge considered as a whole.

149. If the diagonals shown by the full lines alone existed, we should find the strain T upon the n th diagonal ED , Fig. 1760, by cutting it by a plane GH , and expressing the nullity of the sum of the vertical projections of the forces applied to the portion of the framing comprised between A and the section GH .

But the n th section of the upper flange, cut by the line GH , is subject to a strain of compression = $\frac{M}{ID \times \sin. \gamma}$, M being the moment of rupture about the point D . The section CD is

subject, on the contrary, to a tensile strain = $\frac{M'}{EC \times \sin. \gamma'}$, M' being the moment of rupture at the point E or C . Consequently, if F = the stress in the interval CD , we shall have

$$T \sin. \alpha = F - \frac{M \cotan. \gamma}{ID} - \frac{M' \cotan. \gamma'}{EC}.$$

This expression being of the form $F - A M - A' M'$, will be a maximum when the load goes from D (inclusive) to the abutment B , according to the observation made in section 7. Applying the general rule, and replacing $\cotan. \gamma$, $\cotan. \gamma'$, and the lengths ID , EC , of the n th and $(n + 1)$ th vertical rods by their values, we arrive at the maximum tensile strain upon the diagonal, namely, $T = \frac{p' \delta}{4m(h + h')} \sqrt{m^4 \delta^2 + [(m^2 - n^2)(h + h') + (2n - 1)h]^2}$. The weight of this bar is

$$= \frac{p' \delta t}{4m^3(h + h')} \{m^4 \delta^2 + [(m^2 - n^2)(h + h') + (2n - 1)h]^2\}.$$

Summing this expression, in which n takes the successive values $1, 2, \dots, m - 1$, then doubling that the result may include the whole bearing, we obtain as the total weight of the $2(m - 1)$ diagonals in full lines,

$$\frac{p' \delta t}{60 m^2 (h + h')} \left\{ 30 m^3 (m - 1) \delta^2 + (16 m^4 - 15 m^3 - 1) h^2 \right. \\ \left. + \left(16 m^4 + 15 m^3 - 120 m + 119 - \frac{30}{m} \right) h^2 + 8 (4 m^4 - 5 m^2 + 1) h h' \right\}.$$

In a simple lattice, we must multiply this weight by a coefficient of stiffness; for the bars are subject, under a partial complementary load, to compressions as great as the tensions T .

A load extending from one abutment to any point in the flooring, causes a strain of compression upon all the diagonals (full lines) in the half-bay contiguous to this abutment, and one of tension upon all those of the opposite half-bay.

150. Having still only the diagonals shown by the full lines, a partial load upon the right side will cause upon the n th vertical rod a strain of compression, the value of which will be found by considering a section such as $G'H'$, Fig. 1760, and writing again the equation of the vertical projections of the forces. Into this equation will enter the stress after the point D , and the moment of rupture about this point, a moment upon which depend the strains upon the divisions EI , DS , crossed by the section GH . We shall find as the maximum of the compression sought, due to the load p' , $\frac{p' \delta (m + n - 2)}{4m(h + h')} [(m - n)(h + h') + 2h]$, a formula which does not apply to the middle bar, for which $n = 1$.

The effective compression which may be produced will be only the difference between the above value and that of the permanent tension $\frac{p \delta h}{h + h'}$.

The maxima tension will exceed the compression by the whole value $\frac{(p + p') \delta h}{h + h'}$; for the special effect of a partial load upon the left side, complementary of the preceding, should be to annul, in the first place, the compression produced by the load on the right, and then besides this to raise the tension to the value which it possesses when the weights $p' \delta$ are applied to all the vertical rods. Thus this complementary load, acting above, will produce, adding the permanent strain, a tension $\frac{(p + p') \delta}{h + h'} \left\{ h + q \frac{(m + n - 2)}{4m} [(m - n)(h + h') + 2h] \right\}$, according to which the weight of the vertical rods should be calculated, if the diagonals shown by the full lines exist alone, and the load be applied to the bottom of the rods.

151. But if the load be placed at the height of the line AB , passing through the points of junction of the flanges, the lower portion of the vertical rod will be subject to less tension and to greater compression, for the stress will not be the same when the line $G'H'$ cuts the rod above or below the points where the flooring is affixed. When the weights $p' \delta$ are applied only to the n th vertical rods and to all those on the right, the lower portion of this n th rod will be subject to a strain of compression = $p' \delta \frac{m + n}{4m} \cdot \frac{(m - n)(h + h') + 2h'}{h + h'} + \frac{p \delta h'}{h + h'}$.

152. The middle vertical bar is an exception to the preceding formulæ, because a secant plane cannot cross it without cutting a diagonal also. But the strain upon this rod is determined by the condition of being in equilibrio with the resultant, always vertical, of the compressions borne by the two sections of the upper flange. When the bridge is completely loaded, the rod supports a maxima tension of $\frac{(p+p')\delta h}{h+h'}$ in its upper portion; and below the point where it receives the

cross-girder, it is at the same time subject to a strain of compression of $\frac{(p+p')\delta h'}{h+h'}$; but the compression will be greater if we unload the bridge entirely, with the exception of the middle rod under consideration, and in this case it reaches the value $\frac{(p+p')\delta h'}{h+h'} + p'\delta \frac{(m-1)h}{m(h+h')}$ or $\frac{(p+p')\delta h'}{h+h'} \left[1 + \frac{(m-1)h}{mh} q \right]$. If, on the contrary, the load were over the whole of the bridge,

except upon the middle rod, the lower portion of this rod would support only $\frac{p\delta h'}{h+h'} - \frac{p'(m-1)\delta h}{m(h+h')}$ which may be changed into tension if the sign becomes negative.

153. If now we exclude the diagonals shown by the full lines and adopt those shown by the dotted ones, it is easy to see that we shall obtain the strains and the weights of the latter by the formulæ found for the former in 149, by merely changing h into h' and h' into h , as if the girder were turned upside down.

As to the vertical rods, the n th one will bear, at least in its upper portion, a maxima tension $= \frac{p\delta h}{h+h'} + p'\delta \frac{(m+n)(m-n)(h+h') + 2h}{4m(h+h')}$; and if the load be applied to a certain point in the height of the rod, the portion below this point may be compressed by a force equal to $p'\delta \frac{m-n+2}{4m} \cdot \frac{(m+n)(h+h') - 2h}{h+h'} + \frac{p\delta h'}{h+h'}$, which will be produced when the rod in question and those on the left support alone weights $p'\delta$.

It is easy to see *a priori* that this last strain may be deduced from the last formula of 150 by simply changing h into h' and h' into h . The maxima compression of 151 is also connected with the maxima tension of the present section by virtue of the same symmetry. Indeed, if we turn the bow upside down, the lower portion of the vertical rod will become the upper, the system of diagonals will have changed, h and h' will have interchanged, and the signs of all the forces will also have changed. The middle rod is subject to the same considerations.

154. The preceding formulæ enable us to find easily the net cost of a simple lattice, but we shall stop to consider only the case in which the diagonals are doubled and form complete crosses.

On account of the indeterminateness of the strains in a multiple lattice, we may consider the resistance in either manner explained in 143 and 144 (rigid or flexible crosses). But, without omitting to give to the diagonals the rigidity which their theoretical section allows, by way of an additional precaution we shall follow the second method which consists in throwing the strains of compression upon the vertical rods. They will, indeed, need to be stiffened on account of their theoretical strains being more considerable than those of the diagonals, and the necessity which will nearly always exist of giving them a surplus section for the sake of the general effect of the flooring. It is obvious that if we suppose the flooring placed towards the middle of the vertical rods, the latter must possess rigidity; thus they will be able to resist compression, whether they be required to do so throughout their length or not. The diagonals, on the contrary, will require a coefficient of stiffness greater than 2; it is not too much, therefore, to double them, reckoning at each instant only upon those which resist by tension; and as additional security, those subject to compression will not remain quite useless, for they may be stiffened.

155. Before establishing formulæ of the total weight, we must point out exactly the strains which the vertical rods have to resist.

We must remark, in the first place, that under the action of a partial load moving from one of the abutments to a given point, the diagonals subjected to a tensile strain, which alone are considered as acting, will all be inclined in the same direction, from one end of the framing to the other; they will be those the feet of which are inclined towards the abutment affected by the partial load. It follows from this that, under such a mode of loading, any vertical rod may be cut by a plane which does not cross any active diagonals, and its strain will be determined as if the lattice were a simple one. The middle bar itself will come into the general formulæ, for there will no longer be in this point the forced inversion of resisting diagonals which was produced in the simple lattices with the forms adopted.

The upper portion of the rods will be calculated generally for a constant strain $\frac{(p+p')\delta h}{h+h'}$, which is no other than the tension produced under a complete load. A partial load might produce a compression equal to $\frac{p'\delta(m+n-2)}{4m(h+h')} [(m-n)(h+h') + 2h'] - \frac{p\delta h}{h+h'}$ (see 150); but in order that this strain may exceed the preceding, h' must become great and h small. For $h = h'$, the first formula, is sufficient so long as m does not exceed the limit $\frac{1}{2} \left(3 + 4 \frac{p}{p'} + \sqrt{\left(3 + 4 \frac{p}{p'} \right)^2 + 1} \right)$; for example, for $q = 0.60$ or $\frac{p}{p'} = \frac{2}{3}$, m may reach the value 5. For h' nul, it is sufficient if m be less than $6 + 8 \frac{p}{p'}$, which is always the case, and even then it may happen that no compression is

manifested, if the permanent tension always predominates over the compressions which the load may produce. Usually m is less than 5; if it exceeded this slightly, a few of the rods would be subject to a strain of compression a little greater than the tensile strain, but this small difference might be neglected on account of the surplus section which will be given in every case. We shall affect the weight of the vertical rod with a coefficient V , designed to give the rigidity necessary to resist compression and to add to the transverse stability of the structure.

If now we pass on to the lower portion of the rods, situate below the point where the load is applied to them, the strain of compression would be $\frac{(p+p')\delta h'}{h+h'}$ considering only the complete load. But under a partial load, this strain will reach the greater value (153)

$$\frac{p\delta h'}{h+h'} + p'\delta \cdot \frac{m-n+2}{4m} \cdot \frac{(m+n)(h+h')-2h}{h+h'},$$

according to which the piece should be calculated. We obtain the weight of the lower portion of the n th rod, by multiplying by the length and by the quantity tV ; and as the formula subsists for the middle rod, it will be sufficient to sum, supposing n to take the successive values 1, 2, . . . m , then to double and subtract the value relative to $n=1$, in order not to reckon the middle bar twice. We thus find the value given in the following section for the total weight of the lower portions of the $2m-1$ rods.

156. Adding to the rods thus calculated the total weight of the flanges (147) and that of the two systems of diagonals (149 and 153), we shall have the total weight of the bow-girder.

$$\text{Weight of the flanges} = \frac{(p+p')\delta t U}{h+h'} \left[2m^3\delta^2 + (4m-1) \frac{h^2+h'^2}{3m} \right];$$

Weight of the diagonals

$$= \frac{p'\delta t}{30m^2(h+h')} \left[30m^3(m-1)\delta^2 + (h^2+h'^2) \left(16m^4 - 60m + 59 - \frac{15}{m} \right) + 8hh'(4m^4 - 5m^2 + 1) \right];$$

$$\text{Weight of the vertical rods} \begin{cases} \text{Upper portion} = \frac{(4m^2-1)(p+p')\delta th^2V}{3m(h+h')}; \\ \text{Lower portion} = \frac{(4m^2-1)(p+p')\delta th'^2V}{3m(h+h')} + \end{cases}$$

$$\frac{p'\delta th'V}{60m^2(h+h')} [h(16m^4 + 15m^3 - 20m^2 - 15m + 4) + h'(16m^4 - 40m^3 + 20m^2 + 10m - 6)].$$

Mean weight of the bow-girder a lineal mètre

$$= \frac{(p+p')t}{12m^2(h+h')} \left\{ 3m^2U^2 + 2(U+V)(4m^2-1)(h^2+h'^2) + \frac{q}{10m^2} [15m^2(m-1)^2 + 2(h^2+h'^2)(16m^5 - 60m^2 + 59m - 15) + 16mh'h'(4m^4 - 5m^2 + 1) + mVh'h'(16m^4 + 15m^3 - 20m^2 - 15m + 4) + 2mVh'^2(8m^4 - 20m^3 + 10m^2 + 5m - 3)] \right\} + \Omega.$$

For the case in which $h=h'$, this formula becomes, representing the total height by H :

Mean weight a mètre of bow-girder with flanges of an equal curve

$$= \frac{(p+p')t}{12m^2} \left\{ \frac{3m^2U^2}{H} + (U+V)(4m^2-1)H + \frac{q}{10m^2} \left[\frac{15m^2(m-1)^2}{H} + H(32m^5 - 20m^3 - 60m^2 + 63m - 15) + \frac{mVH}{4} (32m^4 - 25m^3 - 5m - 2) \right] \right\} + \Omega;$$

or making $2m=N$: Weight a mètre

$$= (p+p')t \left\{ \frac{U^2}{4H} + \frac{(U+V)(N^2-1)H}{3N^2} + \frac{q}{60N^4} \left[15N^2(N-2) \frac{H^2}{H} + 4H(2N^5 - 5N^3 - 30N^2 + 63N - 30) + \frac{NVH}{8} (16N^4 - 25N^3 - 20N - 16) \right] \right\} + \Omega.$$

The important part played by the vertical rods, which serve in several ways, will require a high value of V .

157. *Parabolic Arched Girder, divided into an even number of intervals.*—The particular case in which $h'=0$ gives:

Weight a mètre of arched girder

$$= (p+p')t \left\{ \frac{U^2}{4H} + \frac{(U+V)(4m^2-1)h}{6m^2} + \frac{q}{m^2} \left[\frac{(m-1)^2}{8h} + \frac{h}{60m^2} (16m^5 - 60m^2 + 59m - 15) \right] \right\} + \Omega;$$

or, N being even: Weight a mètre

$$= (p+p')t \left\{ \frac{U^2}{4h} \left(U + \frac{N-2}{N^2} \right) + \frac{2h}{3N^2} \left[(U+V)(N^2-1) + \frac{q}{5N^2} (N^5 - 30N^2 + 59N - 30) \right] \right\} + \Omega.$$

The observations in 144 apply here. No rod will be subject to compression if we have $p > \frac{(m-1)^2}{4m} p'$, and even when this condition is not fulfilled, the compressions may be neglected, for they are always much less than the tensions. The coefficient V is, therefore, really retained to give to the rods a rigidity which may enable us to utilize them in connecting the girders; but its value may be considerably less than in the case in which $h=h'$, of the preceding section.

158. The strains upon the pieces are easily deduced from the general formulæ. We have:

$$\text{Constant maximum strain upon the lower flange} = \frac{m^2 (p + p') \delta^2}{2 h};$$

$$\text{Maximum strain upon the } n\text{th section of the upper flange} = \frac{(p + p') \delta}{2 h} \sqrt{m^4 \delta^2 + (2n - 1)^2 h^2};$$

$$\text{Maximum strain upon the } n\text{th diagonal (full lines)} = \frac{p' \delta}{4 m h} \sqrt{m^4 \delta^2 + (m^2 - n^2)^2 h^2};$$

$$\text{Maximum strain upon the } n\text{th diagonal (dotted lines)} = \frac{p' \delta}{4 m h} \sqrt{m^4 \delta^2 + [m^2 - (n - 1)^2]^2 h^2};$$

$$\text{Maximum strain upon the } n\text{th vertical rod} \begin{cases} \text{tension} + (p + p') \delta; \\ \text{compression (if any)} = \frac{(m - n)(m + n - 2)}{4 m} \frac{p' \delta}{h} - p \delta. \end{cases}$$

159. *Bow Bridges continued.—Examples.*—The great height which bow bridges attain renders the bow subject to compression liable to distortion in the middle of the bearing; but this height will generally enable us to use ties on the upper part without impeding the passage of the trains. The lower and upper ties, with the vertical rods, will constitute a rigid frame, binding the whole together. If the height is very great, simple gussets will be insufficient at the corners of these frames, and recourse should be had to vertical St. Andrew crosses, similar to those shown in Fig. 1770. This is the case in which it is especially necessary to give the vertical rods an excess of section, to prevent their yielding at the points to which the vertical cross-bracing is fixed.

At the end, the decrease of height allows the suppression of the upper ties without compromising the stability. In the intermediate parts, it will be prudent to place vertical rods with broad projecting ribs, firmly fixed to the horizontal portion of the bridge, as in the case of girders loaded on the lower side.

The rigidity of the whole is completed by the lower horizontal cross-bracing, and a cylindrical upper cross-bracing extending over that portion of the bridge where the height is sufficient. In this way distortion, or the strain of torsion, will be better prevented or overcome than in girders loaded on the lower side, and it may be done at a less expense than in a straight tubular bridge, in which the upper tying must extend throughout the length.

The framing, or bow-girder, should terminate at its two extremities in solid wrought-iron plates binding the two flanges together; great strength is here required, but it may be obtained without much expense, because the height is inconsiderable.

160. *Rigidity of the Bows.*—If the form of a bow-girder with a straight lower flange, or stringer, be preferred, we saw (144 and 157) that it is easy, whatever the height may be, to elude completely the compressions upon the diagonals, and almost wholly also upon the vertical rods, which, besides, are always provided with considerable rigidity. It is, therefore, useless in this case to make the bow rigid; perhaps it is wise to allow the flanges a certain flexibility, in order that the spandrels may have to maintain the form of the bow; for if the rigidity of the latter usurped this duty in too marked a manner, there would result moments of rupture in virtue of which the distribution of the pressures would be made in an unequal manner among the several sections.

In a certain degree this will always be the case, and it should be taken into account by slightly increasing the coefficient U . This remark applies also to straight girders which are not strictly articulate or jointed pieces, though calculated as such. It is advantageous to regard the two flanges as solid with each other, and furnishing a moment of resistance in virtue of which the pressure is greater upon certain fibres than upon others. The cross and the vertical bars will benefit by this circumstance, and will bear strains a little less than those given in the calculations.

It is when the moving load is great with respect to the dead weight that it is especially necessary to consider the bow-girder as an articulate system. On the contrary, if we place the resistance to distortion in the rigidity of the bow, we are obliged to increase the permanent load by means of a thick layer of ballast. The bow may then be calculated by the formulæ of the flexion of the curved pieces; the diagonals are, however, retained, but they are reduced to very slender rods; the flanges, on the contrary, are strengthened, and their section should have a considerable height. Under these conditions, the principal part will be played by rigidity; for when several pieces act together, the strain will concentrate itself upon those which are best able to resist it.

161. *Comparison between Straight and Arched Girders.*—When the height allowed is unlimited, a bridge of straight girders loaded on the upper side will have, over bow-girders, the advantage of diminishing the cube of masonry by requiring a lower bed. But if the height is limited, we have only, in making choice of a system, to compare the metallic portions.

If the bridge had to carry only the permanent load p , uniformly distributed throughout the length, the comparison would be exceedingly simple. Indeed, an arched girder may, in this case, be deprived of diagonals, and by giving it the most advantageous height, its weight a lineal metre will be expressed by the following value, supposing $l = 2m\delta$:

$$\frac{P_1}{l} = \frac{p l t}{m} \sqrt{\frac{4m^2 - 1}{3}} \left(\text{for height} = \frac{m l}{2} \sqrt{\frac{3}{4m^2 - 1}} \right);$$

Neglecting all coefficients, a girder of triangles, Fig. 1657, would give for the theoretical minimum expense (α being equal to β),

$$\frac{P_2}{l} = \frac{p l t}{2 m} \sqrt{m \left[m + \frac{2}{3} (4m^2 - 1) \right]} \text{ with height} = \frac{l}{4 m} \sqrt{1 + \frac{2}{3 m} (4m^2 - 1)}.$$

Or for $m = \dots \dots \dots$	1	2	3	4	5	6	7	8
We have $\frac{P_2}{P_1} = \dots \dots$	0.866	1.094	1.298	1.480	1.638	1.790	1.920	2.046

Thus for $m = 8$, the straight girder would weigh more than twice as much as the arched girder; but this supposes that the rise of the latter is not less than 0.43 of the bearing, whilst the height of the former would not exceed 0.148.

The effect of a moving load will be to render necessary the addition of diagonals to this latter girder; but for the straight girder also the strains upon the bars will be greater than with a permanent load. Rigidity requires another increase, but more especially upon the struts of the straight girder. The arched girder will generally have a great advantage in respect to the lattice, even with heights which are not the most economical; but in order that there may be nothing to lose upon the flanges, it must have a rise κl greater than the height $\kappa' l$ which would be given to the straight girder. The weights of the flanges will be equal in the two systems when we have between κ and κ' the following relation, the coefficient U being supposed the same in

both systems: $\kappa' = \frac{2\kappa(N^2 - 1)}{3(N^2 - 1) + 8N^2\kappa^2}$, in the case of N odd; or

$$\kappa' = \frac{2\kappa(N^2 - 1)}{3N^2 + 8(N^2 - 1)\kappa^2}, \text{ if } N \text{ is even.}$$

N has, however, but a small influence; if for the straight girder we take $\kappa' = 0.10$, we shall have $\kappa' =$ about 0.16; for if $\kappa' = \frac{1}{8}$, the rise would be 0.21 of the bearing.

In general, with the rise allowed in practice, we ought not to reckon upon saving in the flanges, but the advantage of the arched form will be essentially in relieving the vertical portion (see 168).

162. *First Example.*—*Arched Girder with Simple Rigid Diagonals*, Figs. 1761 to 1765.—Data: $l = 36^m$, $p = 2000^k$, $p' = 3300^k$, $p + p' = 5300^k$, $q = 0.623$; $\delta = 4^m$, $N = 9$, or $m = 4$, $h = 6^m.50$.

The lower flange supports, under a load, a constant strain of $130\frac{1}{2}$ tons. It is composed of three angle-irons of $\frac{100/100}{12}$ millimètres, a vertical rib of $550/10$, to which the vertical bars are fixed by twelve rivets of $0^m.025$, and two horizontal plates of $600/10$ each.

The upper flange supports strains expressed by $\frac{(p + p')\delta}{2h} \sqrt{m^2(m + 1)^2\delta^2 + 4(n - 1)^2h^2}$, which vary from $130\frac{1}{2}$ tons in the middle ($n = 1$), to 155.6 tons in the extreme section ($n = 5$).

The vertical rods have a maximum tension which varies from 30 to 21.2 tons. The first may, besides, be compressed by a force equal to $\frac{p'\delta}{2(2m + 1)}(m - n)(m + n - 1) - p\delta = 800^k$ only, and for the others the strain is always one of tension. The vertical rods are therefore strengthened only with a view to the stability of the whole flooring. The two girders, or framings, are bound firmly together in two places towards the middle of the bearing by tie-beams so arranged as to form a rectangular figure enclosing the whole bridge.

The strain upon the diagonals (139) varies from 17.2 tons for the first (middle) to 10.8 tons for the last ($n = 4$). The first is divided into two portions to form a cross, each arm of which supports only 8.6 tons. The sections adopted have sufficient rigidity, regard being had to their strain a unit of section, which strain is very small.

Calculation gives:

Flanges {	Angle-irons and vertical ribs, with their joint-plates and solid ends	10500 ^k	} 18800 ^k
	Horizontal plates with their joint-plates	8300	
Vertical rods		2130	} 4200
Diagonals		1800	
Two horizontal pieces of railing and central gusset		270	
Total		23000 ^k	

Say 612 kilogrammes a lineal mètre (of the whole length $37^m.60$).

The formula of 141 becomes, with the data of the present example, and adding a special term for the addition to the vertical rods,

$$\frac{P}{l} = 369U + 22.6V + 38.5 + 7.04\theta + \kappa.$$

The flanges weighing $\frac{18800^k}{37^m.60} = 500^k$ a mètre, we shall have $U = \frac{500}{369} = 1.35$, including the plates at the ends. These latter having an excess of strength, the value of U may be reduced a little.

For the diagonals, $V = \frac{50}{22.6} = 2.21$.

The vertical rods weigh, according to the calculation, about 60 kilogrammes a lineal metre of girder; the theoretical weight being only 38·5, we have to cover 21·5 by means of a term θ requiring $\theta = 3$; in other words, the excess of section given to the rods is equivalent to the addition of a projecting piece weighing $\theta h = 19\cdot5$ a metre (of its own length).

Ω is here only $\frac{270}{36} = 8$ kilogrammes (say 0·013 of the total weight).

163. If double diagonals were adopted, we might leave the vertical rods unchanged, since they are determined by other conditions than the theoretical strain; and the double diagonals, calculated for tension only, would give a weight of 58 kilogrammes a metre. Thus, in this example, the single diagonals, though V is a little greater than 2, give a small advantage, which is due to the fact of their having been chosen short, and exposed to the least strain. The saving is, however, so trifling that it would have been quite as advantageous, and perhaps more so, to adopt the cross. This will be done in the following example.

164. *Second Example.—Arched Girder of Tension-crosses*, Figs. 1770 to 1787.—Data: $l = 66^m$, $p = 2500^k$, $p' = 3000^k$, $p + p' = 5500^k$, $q = 0\cdot545$, $\delta = 6^m$, $N = 11$, or $m = 5$, $h = 11$.

As in the preceding example, we shall adopt a moderate load, for the value $p' = 4000$ corresponds with the purely fortuitous case of two heavily-laden trains crossing the bridge at the same time.

The lower flange bears, under a complete load, a constant tension of 270 tons; the upper, 270 in the middle to 316·5 tons at the end; or more correctly, this last strain will be less, for towards the ends the bow ceases to be parabolic and terminates by tangents, for the purpose of lengthening sufficiently the bearing upon the rollers.

Regarding the diagonals as resisting only by tension, so that one arm only of each cross acts under a given load, the strains will be:

Short diagonals	No. 1 (middle)	2	3	4	5
Long diagonals	Nos. 1 and 2	3	4	5	6
Strain	27·860	26·540	23·764	19·904	15·690

The sections adopted have a form possessing considerable rigidity. If they had been made to resist compression for the half of the load, the maximum strains would have been the half of the above, so that the sections adopted would give at least $V = 2$, which would warrant us in increasing to 50 the ratio of the length to the reduced thickness, a condition which is not far from being fulfilled. The spandrels are thus susceptible of two modes of resistance; the one which will be produced will be an intermediate mode, in virtue of which the strains will be less than those provided for.

The vertical rods bear 33 tons under a full load. They always resist by tension, except the first towards the middle, which may be subject to a strain of compression of 1·345 ton only. Their sections are, however, increased to give rigidity to the rectangular figure formed by the tie-beams already alluded to, to which the vertical cross-bracing is fixed.

Direct calculation gives the following results:—

Flanges	Angle-irons with vertical ribs with their joint-plates and the end plates	27550 ^k	67000 ^k
	Horizontal plates with their joint-plates	37400	
	Gussets between the vertical rib and the horizontal plate, angle-iron on the edge of upper flange	2050	
Vertical rods (including 330 ^k for joint-plates and other accessories required in fixing) ..		8100	
Diagonals (including 1100 ^k for joint-plates, filling-plates at the points of crossing) ..		7250	
Railing		650	
Total		83000 ^k	

Say 1203 kilogrammes a mètre of the total length 69 mètres.

The formula of 145 becomes in the present case $\frac{P}{l} = 754 \cdot 5 U + 52 \cdot 5 V + 97 + \Omega$. The

flanges weigh $\frac{65000^k}{69^m} = 942$ kilogrammes a lineal mètre of girder, which gives $U = 1 \cdot 25$. For the vertical rods we have $V =$ about $2 \cdot 25$. These quantities do not include the accessories independent of h , the details of which are as follows:—

Accessories forming a part of the flanges	2050	3880 ^k ,
" " " vertical rods	330	
" " " crosses	850	
Railing	650	

which gives $\Omega = 57$ kilogrammes a mètre of the total length, or $0 \cdot 0475$ of the total weight.

To discuss the height h , suppose that with the present data we have to adopt $V = 0 \cdot 205 h$ (for a height above 5 mètres), and that the value U is regarded as nearly constant. The weight of the girder (145) may be put in the form $\frac{P}{l} = 7 \cdot 15 \left(\frac{1392}{h} + 1 \cdot 624 h + 0 \cdot 137 h^2 \right) + 57^k$. It becomes then a minimum for $h = 15^m \cdot 50$, which brings it down to 1115 kilogrammes, instead of 1208 kilogrammes, which the same formula gives for the height adopted of 11 mètres.

165. To compare the arched girder with the bow properly so called, having an equal height in the middle, let us take for example the data: $l = 60^m$, $N = 10$, $p + p' = 5500^k$, $q = 0 \cdot 55$, total maximum height = 10^m , $U = 1 \cdot 25$, $V = 2$ for the arched girder.

We must first ascertain what value of V will be required for the bow-girder having flanges of an equal curve. Now the upper portion of the vertical rods has as a constant maximum strain $16\frac{1}{2}$ tons, whilst the lower portion may be subject to strains of compression varying from 30 to $21 \cdot 9$ tons. The vertical rods of the arched girder will have to resist loads less than 33 tons, but in the present case the rigidity to resist compression is necessarily in the lower portion; but it is not this condition even which fixes the limit, the rods must be stronger than theory requires on account of the duty they have to perform as mediums between the girder and the flooring. We shall, therefore, give them a section at least equal to that adopted for the arched girder, which leads to a coefficient V' equal to about 3.

The term Ω has also a more disadvantageous value in the case in which both flanges are curved, on account of the longitudinal girder which will always be required on a level with the flooring, though it is not strictly indispensable. Let us take, for example, $\Omega = 55$ for the arched girder, and $\Omega = 120$ for the girder with both flanges curved.

Then the formulæ of 156 (for $h = h'$) and 157 ($h = 0$) give respectively for the example under consideration:

Weight of the mètre of bow-girder with both flanges curved = 1137 kilogrammes.

Weight of the mètre of arched girder with a straight lower flange = 1092 "

Thus, with an equal total height, the simple arched form, which is the more convenient, is to be preferred. Yet it is possible that the double curve form may become the more advantageous in certain cases in which it may be regarded as warranting a greater total height, on account of the

triple tying on three different levels, provided this additional tying do not consume all the saving effected in the girder itself.

166. The last plan, Fig. 1770, gives us U smaller and Ω greater than the first example. But we may, to make the matter more simple, bring them to about the same values: to do this we may include in U the accessories forming part of the flanges, so that the latter will amount to 67000 kilogrammes (164); consequently, U will be equal to 1.29, instead of 1.25, and Ω to 0.022 of the total weight, instead of 0.0475. Already, in section 102, we have similarly attributed to U the angle-irons upon the edge of the flanges and the plates at the ends of the cross-girders, although strictly speaking these accessories do not depend upon the height, but rather upon the particular form of the flanges.

167. Admitting generally $h = 0.18l$, $U = 1.30$, $V = 2.50$, and $\Omega = 0.025$ of the weight, we may form Table X. of the quantities $\frac{P}{(p+p')l^2}$ for various values of N and q , and for arched girders with crosses. The numbers of this Table, being multiplied by $(p+p')l$, will give the mean weight of the lineal metre. They have been calculated by means of the formulæ in sections 145 and 157, which, with the data admitted, become respectively

$$\frac{P}{(p+p')l^2} = 0.0030135 - \frac{0.0024}{N^2} + \left[0.00185 \frac{N^2 - 1}{N^3} + 0.000032 \left(N + \frac{1}{N} \frac{30(N-1)}{N^2(N+1)} \right) \right] q,$$

for N odd; and

$$\frac{P}{(p+p')l^2} = 0.0030135 - \frac{0.0006}{N^2} + \left[0.00185 \frac{N-2}{N^2} + 0.000032 \left(N - \frac{30(N^2+1) - 59N}{N^4} \right) \right] q,$$

for N even. Ω is included in the numerical quantities, which have been multiplied by 1.025.

168. For girders carrying a whole line of rails, we may allow:—

	Mètres.	Mètres.	Mètres.
For $l = \dots$	20	60	80
	Kilos.	Kilos.	Kilos.
$p + p' = \dots$	6900	6700	7300
And $q = \dots$	0.72	0.60	0.55

Supposing besides, as in 92, $N = 7$ for bridges of 20 mètres, 8 for those of 30 to 60 mètres, 9 for 70 mètres, and 10 for 80 mètres, we may draw up the following Table:—

$l = \dots$	Mètres.	Mètres.	Mètres.	Mètres.	Mètres.	Mètres.	Mètres.
	20	30	40	50	60	70	80
	Kilos.	Kilos.	Kilos.	Kilos.	Kilos.	Kilos.	Kilos.
Weight of the mètre of girder carrying a whole line of rails	460	680	890	1100	1310	1600	1900

These weights differ but little from those of girders of simple triangles (92), or of crosses without vertical rods (105); so that the advantage of the arched form is not in the girder itself, but consists merely in diminishing the length over which the upper tying and cross-bracing extends. Over other systems of girders the advantage in weight will be more sensible; but it may happen that the builder asks a higher price the kilogramme for structures with curved flanges than for those with straight girders. In this case the price must be taken into consideration in comparing the relative merits of the several systems.

As the arched form allows the rigidity of the vertical portion to be relegated to the rank of secondary questions (144 and 157), an arched girder carrying only one rail will weigh but little more than half of the weights given above for girders loaded with a whole line. Therefore, in the case of a small load, the advantage of the arched form becomes more decided.

We will repeat once more a remark already made several times: it is that, in general, in order that a girder may support wholly the load of one line of rails, we must consider the case of two heavy trains crossing at the same time; if, therefore, for this fortuitous case we are willing to raise slightly the value of R , we may reduce the weights given above.

181. *Weight of the Lineal Mètre of Railway Bridges carrying Two Lines of Rails.—Case of Limited Height.*—When the depth between the level of the rails and the lower side of the girders is limited, the system of loading the girders upon the lower side is resorted to, which for long spans is developed into the tubular system.

A.—*Three-girder Bridges loaded on the lower side.*—If the depth allowed, though limited, is yet sufficient to enable us to give to the cross-girders a height of $0^m.70$ or $0^m.80$; these, added to the minor longitudinal girders will make up a weight of about 640 kilogrammes the lineal mètre of flooring under two lines of rails, the distance apart being included between 3 and 5 mètres. In detail:—

With a distance apart of 3 mètres and } Cross-girders = 375^k ; minor longitudinal girders = 265^k .
a height of $0^m.70$, we should have } Total = 640^k .
And with a distance apart of 5 mètres } Cross-girders = 250^k ; minor longitudinal girders = 385^k .
and a height of $0^m.80$, we should have } Total = 635^k .

For spans of 30 mètres and above, a horizontal cross-bracing is added, weighing from 80 to 100 kilogrammes the mètre of flooring; and in that case the total of the pieces and the chief girders will increase to 720 or 740 kilogrammes.

If the height of the girders exceeds 5 mètres, we shall adopt the tubular system by adding tie-beams at the top reckoned at 90 or 100 kilogrammes, Fig. 1719, and an upper cross-bracing reckoned at 70 or 90 kilogrammes. The total will be from 880 to 930, according to the span. The upper tie-beams increase but little with the span; for if, in a large bridge, they are increased in size, they may be placed farther apart.

The outside girders carry only one rail, and should never be subjected to a strain greater than 6 kilogrammes the square millimètre; but the middle girder may support a whole line in the case of two trains crossing the bridge at the same time, an exceptional circumstance when the strain may without injury be raised to $7\frac{1}{2}$, especially as the loads supposed (34) are for very heavy trains. In the ordinary case of the passage of one train, the middle girder will not be subject to a strain of 6 kilogrammes. In virtue of this increase of R , the weight of the girder, or at least the part which is a function of t , will be reduced to $\frac{4}{5}$; or, which amounts to the same thing, t will have the value 0.00104, instead of 0.0013. If the height be not changed, something will yet be gained by the fact that the lightening of the girder diminishes to an equal amount the load which it bears.

Girders loaded on the lower side are badly supported if their height is great without being sufficient to allow an upper tying. The heights between $3^m.50$ and 5 mètres should, therefore, be avoided. For example, if the height theoretically the most favourable were 4 mètres or under, it should be reduced to about $3^m.30$; if it were above 4 mètres, it should be increased to $5^m.30$, in order to adopt the tubular system. However, if the depth allowed will permit, we may sometimes raise the cross-girders as shown in Fig. 1718, in a two-girder bridge, and in that case we may without inconvenience retain the height calculated.

182. Table XII. A gives the weights of three-girder bridges calculated according to the preceding indications. An addition of $\frac{1}{10}$ has been made to include unforeseen necessities. Multiplying the weight of the lineal mètre of total length by 1.045, we obtain the weight a lineal mètre of bearing (37), given in the last column. Multiplying this last by 1.05, or immediately those of the preceding column by 1.0973, we obtain the weight a mètre of clear span between the abutments.

In the case of multiple lattices, we suppose that the outside girders have single vertical rods placed upon the inside of the girder, and that they may be computed by a mean between the weights of 117 and 118, at least when the height does not differ too widely from that of 0.11 t , which was supposed in the sections referred to. The middle girder will have double vertical rods and a flat lattice if there is no upper tying; if the bridge is tubular, it will, on the contrary, have a rigid lattice and no vertical rods.

In arched girders, the upper tying extends only over those portions where the height is sufficient; so that its mean weight is less than in straight bridges. But in long spans this economy diminishes, and is compensated by the necessity of placing struts or St. Andrew crosses forming a vertical cross-bracing. The weights given in the Table include these circumstances.

183. If the depth allowed be very limited, we shall not be able to give the cross-girders the height supposed in 181. If, for example, we are obliged to restrict this height to $0^m.35$, as shown in Fig. 1592, the weight of the lower cross-girders and longitudinal girders will be increased to 960 kilogrammes the mètre of flooring, instead of 640. We must, therefore, increase by 320 kilogrammes the numbers of the fifth column of Table XII. A, by 350 those of the following, and by 370 those of the seventh or last column.

The limit in height may be still less, and may require more expensive arrangements, such as those of Fig. 1591. In these cases we must of necessity adopt the three-girder system; for that of two girders, which we are about to consider, does not allow the height of the cross-girders to be decreased to such an extent.

184. B.—*Two-girder Bridges loaded on the lower side.*—When the cross-girders can be of a good height we may reckon as a mean for their weight, joined to that of the longitudinal girders, upon 750 kilogrammes the mètre of flooring. In detail:—

With a distance apart of 3 mètres and a height of 1 mètre, we have	Cross-girders = 530 ^k ; minor longitudinal girders = 240 ^k . Total = 770 ^k .
With a distance apart of 4 mètres and a height of 1 mètre, we have	Cross-girders = 410 ^k ; minor longitudinal girders = 320 ^k . Total = 730 ^k . Fig. 1600.
With a distance apart of 4 mètres and a height of $0^m.80$, we have	Cross-girders = 425 ^k ; minor longitudinal girders = 320 ^k . Total = 745 ^k . Fig. 1708.
With a distance apart of 5 mètres and a height of 1 mètre, we have	Cross-girders = 340 ^k ; minor longitudinal girders = 360 ^k . Total = 700 ^k .

Above 30 mètres span, a horizontal cross-bracing must be added, estimated at 60 or 80 kilogrammes. Total 810 to 830, according to the span.

When the bridge becomes tubular, 170 kilogrammes must be added for upper tie-beams, and 70 kilogrammes for upper horizontal cross-bracing; in long spans these pieces are strengthened, and, in a case of necessity, vertical cross-bracings would be added; but, at the same time, the distance of the cross-pieces apart may be increased. We shall reckon, for all the pieces, as well as for the principal girders, 1050 to 1100 kilogrammes, according as the span varies from 40 to 80 mètres.

In arched girders the upper tying extends only over a fraction of the length, but this fraction increases with the span, while the vertical cross-bracing acquires at the same time more importance: therefore in long spans the secondary pieces weigh as much as in straight girders.

When there is but one train upon the bridge, the girder subjected to the greatest strain will sup-

port only about $\frac{3}{4}$ of the load of a whole line, and under these circumstances we may subject it to a strain of 6 kilogrammes, since on the exceptional hypothesis of two heavy trains being on the bridge at the same time, the maximum strain will still be less than $7^k \cdot 50$. The weight of girders may, in general, be rapidly calculated by interpolation. For example, for a solid girder of 20 mètres span, we may reckon $p = 1800$ kilogrammes (including 500 kilogrammes for the girder itself); $p' = \frac{3}{4}$ of a line of rails = 3750; total, $p + p' = 5550$ kilogrammes. Now the Table of 129 gives 370 kilogrammes for a girder carrying one rail, and the load of which was valued at 3600 kilogrammes, and 570 kilogrammes as the weight of a girder carrying two rails, and for which we had supposed $p + p' = 7000$. Interpolation will give for the present case

$$370 + 200 \cdot \frac{5550 - 3600}{7000 - 3600} = 485 \text{ kilogrammes.}$$

The height, interpolated between $1^m \cdot 70$ and $2^m \cdot 25$, would be about 2 mètres. In these cases, in which the height thus found would have to be modified considerably to prevent its falling between $3^m \cdot 60$ and $5^m \cdot 60$, for reasons already stated, the weight would be calculated directly by the formulæ, with suitable values of U and V .

Table XII.B gives approximative weights for two-girder bridges constructed according to the hypotheses which have just been made. The multiple lattices are supposed to be with single vertical rods, which allows one of the systems of bars at 45° to be constructed of pieces with projecting ribs.

185. In the case in which it is required to decrease to $0^m \cdot 60$, for example, the height of the cross-girders, in consequence of the limited depth, we shall have to increase by a constant equal to about 300 kilogrammes the numbers of the third column of Table XII.B. The following column, including an addition of $\frac{1}{10}$, will increase by 330 kilogrammes; and the weights of the last column will be augmented by 345 kilogrammes.

186. *Case of Unlimited Height.*—When the height allowed is unlimited, we are none the less free to adopt one of the preceding systems, but we have the advantage of placing the girders entirely below the level of the rails, which will give rise to other systems: these systems we are about to consider. They may be preferred, if they are found to be more economical, and it may be at once remarked that they possess an advantage in requiring a lower bed of masonry. The fact of the bed being far removed from the plane of vibration may appear detrimental to the stability of the structure; but this may be remedied by means of vertical cross-bracing, especially that which is placed above the supports.

187. C.—*Four-girder Bridges under Rails.*—According to Figs. 1612, 1614, supposing a distance of 3 mètres between the cross-girders, we may reckon from 260 to 345 kilogrammes a metre of flooring for the pieces other than the principal girders, and the horizontal cross-bracing, according as the height of the girders varies from $1 \cdot 50$ to 4 mètres; say 300 to 400 kilogrammes, including the horizontal cross-bracing.

The girders carry each one rail, and their weight is found ready calculated, according to their mode of construction, in the Tables of sections 92, 105, 106, 117, 118, 129, 133.

Table XII.C gives the weight a metre of four-girder bridges for spans of 20 to 50 mètres, for this system will never be adopted for very long spans.

188. D.—*Three-girder Bridges under Rails.*—According to Figs. 1605 and 1618, 1619, the pieces other than the principal girders and the horizontal cross-bracing will weigh from 460 to 620 kilogrammes, according as the height of the girders varies from 2 to 5 mètres. As in the preceding case, the resisting breadth of the flooring hardly exceeding 5 mètres, it is necessary to have recourse to horizontal cross-bracing beyond 20 mètres span; reckoning it at 40 to 60 kilogrammes, we shall have a total of 500 to 680 kilogrammes for heights of 2 to 5 mètres.

Beyond 50 mètres span, it is preferable to increase the distance between the outside girders by adopting the second arrangement, Fig. 1619: we may then reckon upon $830 + 70 = 900$ kilogrammes for a span of 50 mètres to 1100 kilogrammes for a span of 80 mètres.

Each girder will be calculated for a permanent load p equal to its own weight a metre, increased by 700 to 900 kilogrammes. As to p' , it may be estimated at $\frac{7}{5}$ of a rail, for an outside girder, if

the distance apart is 5 mètres, and at $\frac{7}{6}$ of a rail if the girders are arranged as in Fig. 1619 (second arrangement). For the middle girder, p' will be, in the same cases, respectively equal to $\frac{6}{5}$ or to

$\frac{5}{3}$ of a rail, both lines being loaded simultaneously by heavy trains. For this exceptional case we may raise R to $7^k \cdot 50$, or reduce t to $0 \cdot 00104$, for then the maximum strain will always be less than 6 kilogrammes a square millimètre in the ordinary case of one line loaded, in which p' would be reduced by one-half.

It is possible to give different heights to the middle and to the outside girders, but the advantage of this complication is too small to render it worthy of adoption.

Table XII.D gives approximative weights for bridges constructed according to this system.

189. E.—*Two-girder Bridges under Rails.*—Fig. 1615 would give 560 kilogrammes a metre, for the pieces other than the principal girders, including 60 kilogrammes for the horizontal cross-bracing, the height of the girders being $2^m \cdot 50$. With a height of 3 mètres, and taking the

arrangement of Fig. 1606, we may reckon 600 kilogrammes: Fig. 1742 would give 660 kilogrammes, the height of the girders being $4^m \cdot 50$.

With the first kind, in which the distance between the girders is 5 mètres, we shall take from 550 to 700 kilogrammes, according as the height varies from 2 to 5 mètres.

Beyond a span of 40 mètres, it is better to widen the flooring by adopting the arrangement shown in Fig. 1580. We may then reckon, for the pieces other than the principal girders, from 800 to 1000 kilogrammes, including the horizontal cross-bracing, according as the height varies from 4 to 9 mètres.

Each girder is calculated for a strain $R = 6$ kilogrammes a square millimètre, taking for p the weight of the girder itself increased by 1000 to 1200 kilogrammes, according to the span, and for p' the load of $1 \cdot 70$ or $1 \cdot 55$ of a rail, according as the distance between the girders is 5 or $6 \cdot 40$ mètres. These values relate to the case of only one line loaded; but in the case of two heavy trains passing each other upon the bridge, R will not exceed 7 kilogrammes.

Table XII. E gives weights for two-girder bridges, a mètre, increased by $\frac{1}{10}$.

In all the systems of girders loaded on the upper side, vertical rods will be quite unnecessary.

190. *Comparison of the several Systems.*—On comparing Tables XII. A, XII. B, XII. C, XII. D, and XII. E, we see immediately the advantage of reducing the number of girders to two, especially in the case of long spans. But when the depth allowed is limited to the absolute minimum, the system of three girders (Table XII. A) becomes the only possible one. When the height is unlimited, the two-girder bridge loaded on the upper side (Table XII. E) is preferable to the two-girder bridge loaded on the lower side (Table XII. B); but in long spans, this latter system will be generally more advantageous than those of four or of three girders (Tables XII. C and XII. D).

As to the mode of constructing girders considered by themselves, the solid form is the most expensive: then come multiple, triangular, and cross lattice-girders, and last, cross-lattice arched girders. However, in two-girder bridges loaded on the lower side (Table XII. B), the arched form offers but a trifling advantage in weight over the straight form with cross-lattice, and it is besides more complicated in construction. Compared with a straight girder with multiple lattice, it has again a certain advantage: for example, for a two-girder bridge of 60 mètres span, it would offer a total saving of about 44 tons; but if there were a difference in price, and the arched-girder bridge were paid for at the rate of $0 \cdot 70$ franc, for example, a kilogramme, whilst the straight-girder bridge cost $0 \cdot 60$ franc, the saving would be reduced to 4000 francs.

To make the comparisons more evident and palpable, we might represent graphically the weights given by the Tables.

191 a. *Observation.*—In using the Tables, care must be taken not to lose sight of the hypotheses on which the calculations are based. Thus, there will be no ground for surprise that the bridge represented by Fig. 1708 weighs 4335 kilogrammes a mètre, whilst Table XII. would give a less weight: this apparent anomaly proceeds from the fact of our having calculated that structure for a heavier load, on the supposition that R should never exceed 6 kilogrammes, even in the exceptional case of both lines loaded simultaneously. So in the two-girder tubular bridge, Fig. 1690, calculated for $p + p' = 7000$, the span being 56 mètres, the weight of a girder reached 1300 kilogrammes a mètre, whilst by interpolating in Table XII. B we should compute it at 1080 kilogrammes only; but this is because, according to the hypotheses of this Table, the load considered for a strain

of 6 kilogrammes is only $\frac{3}{4}$ of a line of rails, and, besides this, the permanent load, reduced to its just value by taking into account the lightening of the girder, is, by 400 or 500 kilogrammes, smaller than the value liberally computed in section 89.

And, indeed, if we multiply 1300 kilogrammes by the ratio of the loads supposed, say about $\frac{5550}{7000}$, we obtain 1030 kilogrammes, which is not quite so much as the Table gives. In the same bridge, calculation had given also a slightly greater weight for the flooring, because the cross-girders had been reduced to a height of $0^m \cdot 70$.

191 b. Bridges of 10 mètres span and less are always of solid girders, this form being simpler and more advantageous for an inconsiderable height. The best arrangements in these small structures are, in general, easily discovered, and ready-made plans exist in abundance. In the case of very limited depth, we may adopt the hollow form of girder, if the bearing does not exceed 5 or 6 mètres. Beyond that, the three-girder system, with minor longitudinal girders of the hollow or of the double T form, will be the best. And when the height permits, we may take the bridge of four girders, one under each rail, with very light tie-beams.

If the depth is unlimited, it is sufficient to reckon from 600 to 1200 kilogrammes (including parapet) as the weight of a flooring under two lines of rails, a mètre of bearing, according as the latter varies from 3 to 10 mètres. In the case of very limited depth, these figures must respectively be increased to 1000 and 2000 kilogrammes, if a general notion, only, of the expense is required.

192. *Weight of Road Bridges.*—When there are inclined struts, as in Figs. 1607 to 1611, and 1625, care must be had to take into account the increase of weight which they occasion when the height increases. For instance, in the last of these three figures, we may suppose that the weight of the pieces other than the principal girders is represented by $720 + 50h$, h being the height of the girders.

For the kinds shown by Figs. 1625 and 1788, 1789, which are applicable to small spans, solid girders from $0 \cdot 70$ to 1 mètre high should be adopted; the joints in the vertical rib should be far apart, indeed there should be only one in spans of 10 mètres; the vertical stays or stiffening rods should consist of single angle-irons, serving to fix the cross-girders and brackets. For other kinds, it will be advantageous to employ multiple lattice-girders, or, better still, cross lattice-girders; these girders should in general be provided with vertical rods for the purpose of affixing the cross-girders and brackets, but often it will be sufficient to give them a small sectional area: it was seen in

108 to 118, that in multiple lattice-girders it is advantageous to use single vertical rods, that is, rods upon one side only of the lattice, in order that one at least of the systems of oblique bars may have projecting ribs.

In three-girder bridges, the middle girder is more heavily loaded than the outside ones, and, when nothing prevents, it will be well to give it greater height; this is easily done in the case of girders loaded on the lower side; when the height is unlimited, as in Fig. 1609 for example, the bed-plate of the middle girder may be placed at a lower level than those of the outside girders. It is in the kind of bridge represented in Fig. 1626 that the difference in the load upon the girders is especially great; when the bridge is tubular, the upper tie-beams may be arched, and the middle girder raised.

1788.
Road Bridge.
 Roadway, 7m; footways, 1m·50.
 Small span. Scale, 0·02.

1789.
Road Bridge.
Roadway, 10^m; footways, 2^m.
Small span. Scale, 0·02.

Table XIII. gives some general values of weights for roads of 6, 10, and 14 mètres broad, and for spans of 10 to 50 mètres.

In long spans a considerable saving may be effected by suppressing the ballasting, which will diminish the permanent load. This may be done without danger, because vibration is much less to be feared than in railway bridges, where the moving load is driven at greater velocities, and the ratio q usually possesses a value near $0\cdot60$; whilst in a road bridge where the ballast would have a mean thickness of $0\text{m}\cdot20$ (35), q would be about $0\cdot40$. In any case, if the ballasting is retained, it is evident that the cross-bracing will be much less important in a road bridge than in a railway bridge.

193. *Bridges of several Bays.*—When a continuous girder rests upon several supports, and carries a load uniformly distributed throughout a bay, but liable to vary from one bay to another, the locus of the moments of rupture, in any bay in which the load is p_n a mètre, will always be a parabola with a vertical axis, having as a parameter $\frac{1}{2}$, and the position of

which will be determined by the condition of passing through the summits of the ordinates which, raised upon the supports limiting the bay under consideration, will represent the moments of rupture in a line with these supports. Thus for the bay A B of Fig. 1790, the length being l_n , the load a metre p_n , the moments of rupture upon the supports A and B

being μ_{n-1} and μ_n , we shall have as the variable moment in the point M, the abscissa of which is x reckoning from A, the expression

$$\mu = -\frac{p_n x^2}{2} + \left(\frac{p_n l_n^2}{2} + \mu_n - \mu_{n-1}\right) \frac{x}{l_n} + \mu_{n-1};$$

and the stress in the same point will be the derivative

$$F = -p_n x + \frac{p_n l_n}{2} + \frac{\mu_n - \mu_{n-1}}{l_n}.$$

194. The moments of rupture upon the supports depend upon the circumstances in which the other bays are placed, and are calculated by Clapeyron's formula, the demonstration of which is found in the works of MM. Bélanger and Bresse, and to which we can merely allude: it is the following relation connecting the moments of rupture μ_{n-1} , μ_n , μ_{n+1} , upon three consecutive supports, Fig. 1790,

$$\mu_{n-1} l_n + 2\mu_n (l_n + l_{n+1}) + \mu_{n+1} l_{n+1} + \frac{1}{4} (p_n l_n^3 + p_{n+1} l_{n+1}^3) = 0.$$

Applying this relation to each group of two consecutive bays, we have $m-1$ equations (m being the number of bays in the bridge) between the $m-1$ moments of rupture upon the piers, those upon the abutments being nul. These equations may be immediately written under a numerical form with the given bearings and loads, and the resolution effected; then the moments upon the supports being all known and represented by ordinates to a given scale, we have only to apply a parabolic model corresponding to each bay, keeping their axes vertical. We thus construct the geometrical locus of the moments of rupture over all the bridge, not only for a particular mode of loading, but for all which are capable of producing a maximum strain upon certain portions of the girder. For a determinate plan, two parabolic models are sufficient, one for the dead weight only, which is supposed to be constant throughout the bridge, at least when the length of the bays do not differ too much; and the other for the maximum total load, including the dead and the rolling weights.

The several loci thus traced cut each other in certain points, and we make use only of the envelope, that is, of the portions of the curves giving the maxima ordinates in absolute value. In calculations for bridges of several bays, the cases in which the load would affect only portions of a bay are not considered.

Clapeyron's formula is established on the hypothesis that the moment of inertia of the girder remains constant throughout the length. This condition is hardly ever fulfilled, because the thickness of the flanges is made to vary for the purpose of economizing material. Yet we generally regard calculations made on the hypothesis of a constant section as applying with sufficient approximation to a case in which the section varies. It is then prudent not to reduce too much the maximum thickness of the flanges, which, in the computation of weight, will amount to forcing a little the coefficient U.

195. In the particular case of two bays each equal to l , and loaded respectively with p_1 and p_2 a mètre, the moment of rupture upon the pier will be $-\frac{(p_1 + p_2) l^2}{16}$.

In the case of three bays, l_1, l_2, l_3 , the respective loads of which are p_1, p_2, p_3 , we have for the moments μ_1 and μ_2 upon the first and second pier

$$\mu_1 = -\frac{2p_1 l_1^3 (l_2 + l_3) + p_2 l_2^3 (l_2 + 2l_3) - p_3 l_2 l_3^3}{16 \left[l_1 (l_2 + l_3) + l_2 \left(\frac{3}{4} l_2 + l_3 \right) \right]}, \text{ and } \mu_2 = -\frac{p_2 l_2^3 + p_3 l_3^3 - 4l_2 \mu_1}{8 (l_2 + l_3)}.$$

In a bridge in which the bays are numerous, the load upon one of them has a considerable effect upon those which are contiguous to it, but very little upon the others. Thus we may, with sufficient approximation, study successively each bay by taking into account the two next and rejecting the others; the calculations will in this way be made similar to those for bridges of two bays.

196. According to the remark made in section 84, the weight of the flanges of a girder is proportional to the mean ordinate G of the locus of the maximum moments of rupture in absolute value, and the vertical portion depends generally upon the mean ordinate G' of the locus of the stress. We will, therefore, give the values of G and G', applicable to bridges of several bays, and by the aid of which the computation of the weight of the girders may be effected without difficulty, as in the case of a single bay.

Let us consider, in the first place, a bridge of unlimited length, consisting of an infinite number of equal bays. Let l be the length of each bay, p the permanent load a mètre, and p' the moving load.

The load p will by itself produce, in a given bay, moments of rupture represented by the parabola $\mu = \frac{-p}{2} \left(\frac{l^2}{6} - lx + x^2 \right)$; upon the supports ($x = 0$ and $x = l$) the moment is $\frac{-p l^2}{12}$, it is

nul at the abscissa $0.211 l$, and takes with the contrary sign the value $\frac{p l^2}{24}$ in the middle of the bearing. This parabola is identical in form with that which we should have for a bridge of a single bay, but it is raised in such a manner that the segment which remains below the axis of the x 's is equivalent to the sum of the two segments situate above this axis, and having the form of triangles, one side of which is curvilinear. This circumstance, due to the continuity of the girder beyond the supports, affects only the flanges, the weight of which is diminished by it, but it has no influence whatever upon the vertical portion.

As to the load p' , if, in the first place, it be applied exclusively to the bay under consideration, A B, Fig. 1791, it will give upon the supports A and B moments of rupture equal to $-0.0528 p' l^2$,

which we carry above the axis of the x 's, and which will determine the position of the parabola of the parameter $\frac{1}{p}$, having for equation $\mu' = \frac{p'x}{2}(l-x) - 0.0528 p' l^2$.

If now we apply the load p' , not upon A B, but only upon the contiguous bay to the left of A, the moment upon A will retain the same value, that in a line with the support B will take the value $+0.0141 p' l^2$, and a right line joining the summits of the ordinates to the supports, and having for equation $\mu'' = 0.0669 p' l x - 0.0528 p' l^2$, will represent the moments of rupture produced in the bay under consideration. If we consider again the case in which the bay A B and the preceding one are simultaneously loaded, to the exclusion of all the others, the moments upon A and B will be respectively $-0.1056 p' l^2$ and $-0.0387 p' l^2$, and the locus of the intermediate moments due to p' will be the parabola $\mu''' = -\frac{p'x^2}{2} + 0.5669 p' l x - 0.1056 p' l^2$. The maximum moments in absolute value will be given by the portions of the curves traced in full lines upon the figure; that is, by μ''' between the limits $x=0$ and $x=0.12l$, by μ' between $x=0.12l$ and $0.235l$, and beyond as far as the middle by μ' . Upon the other half of the bay the same branches of the curves may be symmetrically reproduced.

If we add the moment due to the dead weight p , as it changes its sign at the abscissa $0.211l$, it will be in a point comprised between $x=0.211l$ and $x=0.235l$, values which differ but little, so that the resulting positive moment will begin to exceed the negative, and when μ'' should be abandoned for μ' .

The area comprised between the axis of the x 's and the locus of the absolute maximum moments is equal to $l^3(0.0160p + 0.0296p')$ for the half-bay, and dividing by $\frac{l}{2}$ we obtain the reduced ordinate $G = l^2(0.032p + 0.059p') = 0.032(p + p')l^2(1 + 0.844q)$.

The maximum stress corresponds throughout the bay to μ''' , which gives by differentiation $F''' = \frac{d\mu'''}{dx} = -p'x + 0.5669 p' l$. Adding the stress due to the permanent load p , we find the value of the reduced ordinate of the limiting stress to be

$$G' = l(0.25p + 0.3169p') = 0.25(p + p')l(1 + 0.268q).$$

197. In the ordinary cases in which the mean weight of the lineal metre of girder may be expressed by formulæ of the form $A G + B G' + C$, the values found above will be substituted for G and G' , and for A, B, C, the quantities applicable to the system of girder adopted and determined as in bridges of a single bay.

But for simple approximative computations it may be more convenient to profit by the ready-found results which we have given for bridges of a single bay; and to do this, we must know the span of a single-bay bridge the mean weight of which per lineal metre would be equivalent to that of the bridge of several bays under consideration.

Now, in the case of a single bay of a span l' , the mean ordinate of the limiting moments of rupture is $G_1 = \frac{1}{12}(p + p')l'^2$, and that of the stress $G'_1 = \frac{1}{4}(p + p')l'(1 + \frac{1}{6}q)$. Thus for the bridge of unlimited length considered in the preceding section, we may make, supposing that the term C, which is always small, remains constant,

$$0.032 A l^2 (1 + 0.844q) + 0.25 B l (1 + 0.268q) = \frac{1}{12} A' l'^2 + \frac{1}{4} B' l' \left(1 + \frac{1}{6}q\right),$$

$$\text{or } l'^2 + 3 \left(1 + \frac{1}{6}q\right) \frac{B'}{A'} \cdot l' - 0.384 (1 + 0.844q) \frac{A l^2}{A'} - 3 (1 + 0.268q) \frac{B l}{A'} = 0,$$

an equation whence we may deduce the span l' of the auxiliary bridge.

198. Suppose the case of multiple lattice-girders at 45° , stiffened by special vertical rods. We shall have $A = \frac{2U}{h}$, and $B = B' = 2t$. If we take $h = \frac{l}{10}$ and $U = 1.25$, and retain these values

for the auxiliary bridge, so that we have $A = A'$; and if we take $q = 0.60$, a value which will be generally near enough, we shall obtain $l' = 0.803 l$. Thus, under these conditions, the weight a metre of a bridge of numerous bays will be evidently the same as that of a single bay equal in length to 0.8 of one of the bays of the bridge under consideration, and having girders of the same height.

For example, if the bridge of unlimited length consists of bays of 40 mètres, we shall have $l' = 32$ mètres. Now, by interpolating in the Tables given for the case of one bay, we may estimate at 2300 kilogrammes the weight a metre of a bridge of 32 mètres, composed of two girders of 3^m.85 high and placed beneath the rails, if we suppose the depth allowed unlimited (Table XII. e). As this height of 3.85 differs but little from that of 4 mètres, supposed by the preceding calculation, we may admit that the weight of 2300 kilogrammes a metre of bearing is applicable to the unlimited bridge under consideration.

199. In a bridge of two bays each equal to l , if we go from one abutment taken as the beginning of the x 's, the maximum moment in absolute value will be first given by the hypothesis that the bay under consideration bears alone the full load $p + p'$ a metre, whilst the second is reduced to the permanent load p . This moment is then expressed by the equation

$$\mu = \frac{1}{16} (6p + 7p') lx - \frac{1}{2} (p + p') x^2.$$

From $x = \frac{3}{4} l$, we must, on the contrary, load only the second bay, and we have the equation

$\mu = \frac{1}{16} (-6p + p') lx + \frac{1}{2} p x^2$. And from $x = \frac{7}{8} l$ to $x = l$ we have, both bays being loaded, $\mu = \frac{1}{8} (p + p') (4x - 3l) x$. Squaring the area of the locus of the limiting moments and dividing the result by l , we obtain the reduced ordinate of the moments,

$$G = l^2 (0.0495p + 0.0702p') = 0.0495 (p + p') l^2 (1 + 0.418.g).$$

For the stress, the reduced ordinate will be

$$G' = l (0.2656p + 0.2910p') = 0.2656 (p + p') l (1 + 0.096.g).$$

With the hypotheses of the preceding section, we should find as the bearing of the auxiliary bridge of the same weight a metre $l' = 0.883 l$, a value which should be increased to 0.90 l for example, because in a bridge of two bays we should increase G' if, instead of confining ourselves to hypotheses of complete loads for each bay, we considered besides loads extending over any portion of the girder. This consideration loses its importance as the number of the bays increases, because then the several hypothetical loads becoming more numerous offer more varied circumstances. In certain cases two independent bays of bow-girders may be more advantageous than two continuous bays of straight girders.

200. In a bridge of three equal bays, if l is the length of bay, half the length of the bridge will be $L = \frac{3}{2} l$, and we shall have

$$G = L^2 (0.0201p + 0.0319p') = 0.0201 (p + p') L^2 (1 + 0.589.g) = 0.452 (p + p') l^2 (1 + 0.589.g);$$

$$\text{and } G' = 0.1711 (p + p') L (1 + 0.188.g) = 0.2567 (p + p') l (1 + 0.188.g).$$

With the same data as for the preceding cases, we find $l' = 0.881 l$.

201. In a bridge of three bays, if we suppose the middle one equal to $\frac{5}{4}$ of one of the end ones, a small saving will be effected over the arrangement of three equal bays, for, L still denoting half the length of the bridge ($= 1.625$ times an end bay), we shall have

$$G = L^2 (0.0188p + 0.0308p') \text{ and } G' = 0.1749 (p + p') L (1 + 0.180.g).$$

202. For a bridge of four equal bays, l being the length of one bay, we shall have

$$G = l^2 (0.0415p + 0.0693p') = 0.0415 (p + p') l^2 (1 + 0.67.g);$$

$$\text{and } G' = l (0.256p + 0.31p') = 0.256 (p + p') l (1 + 0.22.g).$$

With the data already adopted (198) for multiple lattice-girders, we should have here $l' = 0.865 l$.

203 a. For bridges of more than four bays, the weight a metre will be the same as for a bridge of a single bay having a bearing between the values of l' calculated for the case of four bays, and for that of an unlimited number of bays. For example, for five bays, with the same hypotheses as before, we might take $l' = 0.85 l$.

203 β. In computations which are required to be as exact as possible, the weight of the girders should be calculated directly by formulæ in which G and G' have the values given above according to the number of bays. In general, girders resting upon several supports will be either of multiple lattice or of crosses or cross-lattice. In the former case, we shall have as the mean weight of the metre of girder without vertical rods,

$$\frac{P}{l} = \frac{2tU}{h} G + (1 + V) t G' + \frac{1}{2} (p + p') t h + \frac{60 h^2}{l} + \alpha.$$

If there are vertical rods placed at a distance δ from each other, a term $\frac{15 h^2}{\delta}$ must be added, supposing the sections of Fig. 1728 to be adopted.

For a girder of crosses or cross-lattice, without vertical rods, we shall have the following approximative formula, more general than those of sections 97 and 99:

$$\frac{P}{l} = \frac{2tU}{h} G + \frac{1}{2} (1 + V) \left(\frac{Nh}{l} + \frac{l}{Nh} \right) tG' + \frac{1}{4} (1 + V) (p + p') th + \Omega,$$

N denoting the number of crosses in a bay l . If there are vertical rods, they must be taken into account by a term $\frac{rNh}{l}$ as in section 100, r being the weight of the rod a mètre.

The continuity of the girders from one bay to another having the effect of lightening the flanges, whilst it tends to increase slightly the vertical portion, a less height should be adopted than in bridges of a single bay. In general the ratio of the height of the girders to the length of

a bay will not exceed $\frac{1}{10}$.

Figs. 1792 to 1801 are of the principal details of the Chelsea Suspension Bridge, Fig. 1571.

The abutments of this bridge consist of a mass of brickwork and concrete, measuring at the base 112 ft. in length by 56 ft. broad, and at the top 100 ft. by 46 ft., and 40 ft. deep.

The face of the abutment adjoining the river is composed of cast-iron piles and plates, somewhat similar to those of the pier, with the exception that the ironwork is not brought above the level of low water.

The portion of the abutment on which the land saddles and cradles bear, for changing the direction of the chains, rests upon timber piles, 14 in. square, driven deep into the bed of the river, and are from 3 ft. 2 in. to 4 ft. from centre to centre: these piles are cut off at the level of low water, 16 ft. below Trinity high-water mark, and the spaces between filled up with hydraulic concrete; the cast-iron and timber piles are tied together with wrought-iron ties 3 in. $\times$ $\frac{3}{4}$ in. On the top is bedded a series of landings forming a table at the level of low water 53 ft. 6 in. $\times$ 27 ft. $\times$ 6 in., upon which a mass of brickwork is erected, up to a mean level of 3 ft. below the level of the roadway; upon this, 12 in. landings are bedded for the reception of the cradles which carry the saddles on rollers: the cradles are bedded in asphalted felt, and firmly secured by wrought-iron holding-down bolts, brought up through the masonry from below. An invert, springing from beneath each saddle, is built in the brickwork below, so as to distribute equally the pressure from the cradles over the whole area of the foundation.

The mooring chains are carried down tunnels to the moorings, the tunnels forming an angle of 155° with a horizontal line. The chains are secured to massive cast-iron mooring plates, resting against three courses of 12 in. landings, respectively 12 ft. $\times$ 8 ft. 9 in., 16 ft. $\times$ 12 ft. 6 in., and 20 ft. $\times$ 16 ft. 3 in. The tunnels are contracted at the bottom by elliptical brick domes, thus afford-

ing a complete bearing for that portion of the landings at the end of the tunnel. These landings rest against a mass of brickwork, with inverts, to distribute the pressure over the whole area of the abutment.

This mass of brickwork rests on a series of timber piles, driven at an angle of 65° with a horizontal line; the tops of the piles coming up above the level of the concrete, and having a good bond with the brickwork, by which means the tendency to slide is greatly diminished, the whole spaces between the masses of brickwork being filled up solid with concrete.

The Pier Foundations, Figs. 1792, 1793.—The construction of the foundations of the piers combines all the advantages of foundations on bearing-piles, made by means of cofferdams, without the expense and obstruction to the waterway which they involve, and which would have rendered their use at Westminster Bridge all but impracticable.

The foundations of the piers consist of timber bearing-piles 14 in. square, driven deep into the bed of the river at intervals of 3 ft. over the whole area of the pier, varying in depth from 40 ft. 6 in. to 25 ft. below the level of low water, according to the resistance offered by the bed of the river.

The face or external surface of the piers consists of a cast-iron casing of piles and plates driven alternately; the main piles are 12 in. in diameter and 27 ft. long, with longitudinal grooves on each side for the reception of the plates. These piles are driven to a uniform depth of 25 ft. below the level of low water, and between them are driven cast-iron plates or sheeting 7 ft. 2 in. wide, so that the pier is entirely cased from the foundations to the top, which is 7 ft. 6 in. above Trinity datum. The space enclosed by this casing is then dredged to the hard gravel above the clay, and filled in solid with concrete up to the level of the top of the timber piles. On this foundation a flooring of stone landings is bedded, and on this the cast-iron plates, frames, &c., forming the base of the towers, are placed.

The portion of the caisson situated above low water is hollow, being so formed to avoid throwing useless weight on the foundation, and is merely lined with brickwork, strengthened by cross-walls and iron ties.

The whole of the ironwork below the water was covered when hot with a protecting coating of tar. The thickness of metal in the caisson is 1 in.

The towers, Figs. 1800, 1801, which support the chains are entirely independent of the ornamental cast-iron casing surrounding them, and consist of a cast-iron columnar framing strongly braced both horizontally and vertically, carried to a height of 57 ft. above high water.

The columns are cast in pairs and have a diameter of 10 in., and thickness of metal of 1 in. They are arranged in clusters of fours, and the whole are connected with six horizontal frames, occurring at intervals. The columns are not vertical, but incline towards each other upwards from either side of the pier, the columnar framing being 13 ft. 6 in. at the base, and 9 ft. 9 in. at the top. In the direction of the piers the columns are 4 ft. 3 in. apart, and rise parallel to each other. There are two towers on each pier, 32 ft. from centre to centre. The pressure from the chains coming directly from their centre, each tower carries therefore one-fourth of the whole weight of the bridge, or about 375 tons, or about 670 tons when the bridge is completely loaded; the sectional area of the columns is 284 sq. in., and there is, therefore, a pressure upon them, when the bridge is loaded, of 2.36 tons per sq. in. of section. The weight of the towers, exclusive of the ornamental cast-iron casing, is 350 tons.

On the towers are fixed massive cast-iron cradles upon which the saddles rest.

BUDDLE. FR., *Baquet à rincer, lavoir*; GER., *Waschtrog*, *Waschwerk*; ITAL., *Lavatoio della miniera*; SPAN., *Mesa de lavar*.

The apparatus shown in Figs. 1802, 1803, was invented by Hundt, a Prussian engineer. Its introduction in the gold mines of Victoria has been attended with success. The arrangement of this buddle possesses the advantage of affording a large working area at the head, and at the same time effects a better separation of the waste than can be produced by round buddles of the ordinary construction. And when the lighter portions of the tailings have become separated from the heavier near the periphery of the circle, the area over which they are distributed gradually diminishes, which, by increasing the rapidity of the flow, enables them to be more readily carried off. In Australia this apparatus is employed for concentrating tailings from which a large proportion of gold has been previously extracted by the usual appliances. A is the spout which conducts the mixture of water and sand to the buddle: B, the outlet for carrying off the earthy impurities or final tailings; C, shaft communicating motion to the buddle arms *d*; *e*, distributing launders; and *g*, pipes attached to them. The pipe *f* supplies clean water to the annular cistern *g*, from whence it passes by the pipes *g*, with rose apertures at the ends, and serves to dilute the mixture of water and tailings discharged by the launders *e*, on the annular incline at the periphery. The whole of this arrangement revolves on the shaft D. The final tailings fall

into the circular pit *i*, previous to being carried off by the channel *B*. To the wooden bars *k* are attached pieces of canvas, which sweep over the surface of the stuff deposited in the buddle, and keep it even and free from ruts. The tailings, entering the receiver *h*, are distributed at the periphery of the buddle through the four launders *c*, which at their extremities are turned at right angles to the direction of their motion when in action; and at the same time clean water is distributed by the apertures pierced in the terminations of the pipes *g'*. The speed given to this arrangement of arms, launders, and pipes, revolving on the shaft *D*, varies in proportion to the state of divisions of the sands to be treated. When these are rather coarse, the machine may make from six to eight revolutions a minute; but when very fine stuff has to be operated upon, the speed is considerably increased. The influx of tailings and water must be regulated in accordance with the speed of the arms and the density of the material operated upon; and although no very definite instructions can be given with regard to this subject, a chart of the apparatus will enable any intelligent workman to make the necessary adjustments. The bed may be from 12 to 18 ft. in diameter, and it may have an inclination of from 6 to 9 in. from the edge to the centre. At the Port Phillip works the tailings cleaned by machines of this description are subsequently roasted, and passed through Chilian mills; but where, as in California, the enriched pyrites have to be transported to considerable distances, it would require to be more than once passed through the machine, or, after being once buddled, the heads might be further enriched, either in the rocker, or by a hand-buddle or shaking-table. A buddle of this kind can be filled in about four hours, and it will be found an excellent apparatus for enriching ores with but little waste. If it be intended to dress sulphides directly from the *riffles*, so as to render them almost entirely free from siliceous matter, the first heads will require to be re-washed once at least, and the second heads twice; but when this is done, it is necessary to be provided with other buddles besides those which first receive the tailings direct from the riffles, and which will be constantly in use for that purpose.

When the tailings to be washed are not conducted directly from the blanket boards, but are taken either from tyes or the heads of other buddles, they are charged with a shovel into a hopper connected with a circular sieve, working in water, which discharges into the spout *A*.

See GOLD AND GOLD MINING.

BUFFER. FR., *Tampon, Appareil de choc*; GER., *Buffer*; ITAL., *Respingente*.

A buffer is a cushion, or apparatus with strong springs, employed to deaden the concussion between a moving body and one, in motion or at rest, on which it strikes, as at the end of a railway carriage. A buffer is sometimes called a *buffing apparatus*, when it is composed of two or more parts or of two or more springy substances, as of steel, india-rubber, gutta-percha.

The central buffing and drawing apparatus, designed by E. D. Chattaway, is shown in Figs. 1804 to 1806.

Fig. 1804 is a side elevation, and Fig. 1805 a plan of the new coupling, working in connection with an ordinary draw-hook; and Fig. 1806 is an end view of the buffer-head. The buffer and draw-hook are constructed in one piece, and the buffer-head *A*, instead of being circular, is made of the peculiar form shown in Fig. 1806. The lower portion only is curvilinear, and the upper part is made narrow, and while presenting a buffing surface in front, it is shaped on its inner side similar to a *draw-hook*, for the purpose of receiving the coupling-link *B*, which works upon it as upon an ordinary draw-hook, and thus forms a complete hook and link connection. The draw-rod *C* is screwed near the end just within the buffer-head. Upon this screwed part is fitted the

adjusting nut and collar D with projection arms E, Fig. 1805, carrying the large coupling-link B. The coupling can thus be drawn hard up or slackened off by means of the pendulous lever F.

The ordinary coupling and buffing arrangements as applied to railway wagons are open to several objections. As there is no means of tightening up the couplings, there is always a considerable amount of play between the adjacent vehicles of a train, frequently as much as 18 in. with wagons. The effect of this is, in the first place, to lengthen the train, thereby causing a greater expenditure of motive power, owing to increased effect of the wind and pressure of the flanges of the wheels against the rails, when the train is running through sharp curves; and, in the second place, to render the couplings liable to break or to become detached from the draw-hooks, in consequence of the train being started and stopped in detail by a series of sudden and violent jerks: a jerking action also causes a severe strain upon the draw-springs and often breaks them; besides, it acts injuriously upon the permanent way, and increases the risk of conveying goods of a fragile nature. As regards corner buffers, they are objectionable from the circumstance of the two buffers being seldom struck at the same instant or with the same degree of force, even on a perfectly straight line; while on curves the buffing action is mainly confined to one side of the train, severely straining the framing of the vehicles, and having a tendency to force the tenons out of the mortises. Besides tending to damage the rolling-stock, this action also tends to injure the permanent way, and to increase the cost of maintenance of both. It is also to be remarked that the ordinary buffers and couplings are always opposed to instead of being in harmony with each other, the couplings being slackened as the buffers are brought into play, and *vice versâ*; and the reaction of the buffers has sometimes fractured the couplings.

A further objection to the ordinary couplings is the difficulty and delay frequently experienced in attaching and detaching wagons, since, unless the couplings be slack, it requires a violent shunting together of the train to allow the coupling-link to be slipped over the draw-hook; and if the draw-hooks be close to each other before the coupling has been lifted up, the train has to be drawn apart to admit of the link being raised, and then shunted together again in order to be attached. Independent of extra expenditure of engine-power and wear and tear of rolling-stock, this shunting is also a source of accident.

The most complete and effective buffing apparatus now in use is that of L. Sterne, shown in Figs. 1807 to 1811.

The buffers or springs, Figs. 1807, 1808, are built up of soft india-rubber rings and circular steel plates; the terminal plates of each of the springs being complete discs, some are formed with a hole through the centre. During the process of vulcanization the buffer-rings become inseparably united with the plates, and each spring thus becomes a perfectly air-tight chamber. When the pressure is brought to bear on the springs, the air within them becomes compressed, and offers a resistance proportionate to the amount of such compression and to the area of the discs upon which the

pressure of the air is exerted. The india-rubber rings not only perform the office of securely retaining the air within them, but they completely resist sudden concussions.

In order to avoid friction upon the rubber, by which it would be quickly destroyed, the circular plates are extended beyond the rings to a distance proportioned to the depth of these rubber rings. The india-rubber, therefore, cannot be injured, or come in contact with the inner surface of the cylindrical cover.

These buffers can be made of any desirable form, and air-tight chambers, constructed in the manner just described, can be built up to any length required in practice. It will be seen that no mechanical fittings are required to make a perfectly air-tight chamber. The union of the rubber to the metal being of a solid and not merely adhesive character, the juncture is impervious.

These buffers are capable of resisting great compressive force, while at the same time they possess great sensitiveness as springs. Unlike a steel spring, which, if made to resist great force, is rigid until a considerable weight is brought to bear upon it, this buffer-spring is sensitive to a very slight pressure, and yet absorbs a power of 15 tons, being 100 per cent. more than the resisting power of any steel springs used for this purpose. In most cases, where the action of buffers is required, the apparatus of Sterne, without alteration of principle, may be applied.

Fig. 1807 shows a cast-iron case, with a solid wrought-iron plunger, four rubber rings, and five steel plates.

Fig. 1808 is of a cast-iron case, containing a cast-iron cylinder-plunger, pneumatic spring power, five rubber rings, and six steel plates.

Fig. 1809 represents a pneumatic rubber draw-spring. It has four rubber rings and three oval steel plates.

Sterne's buffer is in use on many railways. The arrangement, Fig. 1810, is that adapted to the carriages of the Metropolitan Railway.

1811.

Each buffer-rod carries a kind of shoe embracing the ends of a compensating travelling beam, which extends from one spindle to the other. This transmits the pressure fairly to the springs, at the same time enabling the buffer-rods to accommodate themselves freely to the position of the carriages passing round curves. The buffing spring occupies a length of $13\frac{1}{2}$ in. when uncompressed, and is capable of being compressed 9 in. The light spiral springs at the end of the buffer-spindles are merely placed there to prevent chattering. The draw-spring is formed by a pair of pneumatic springs composed of four rings of rubber each, inseparably united to three oval steel plates through which the draw-bar, Figs. 1810, 1811, passes. See LOCOMOTIVES.

BUILDING. FR., *Construction, bâtiment*; GER., *Bauen*; ITAL., *Costruzione*.

See BOND. BRIDGE. FOUNDATIONS. JOINTS. MASONRY. RAILWAY ENGINEERING. ROOFS. SCAFFOLDING.

BULLET-MAKING MACHINE. FR., *Machine à faire des balles*; GER., *Kugel-Giessmaschine*.

In the manufacture of ordinary bullets for small arms the lead is first melted in an ordinary cast-iron vessel, fitted with a spout and movable plug at the bottom. By means of a removable spout, the liquid lead is conveyed to the cylinder A in Fig. 1813, where it remains until it is a solid, but not any longer, as the nearer it is to the fluid state, the easier it is shaped, so as to form a rod. The lead, being pushed up by hydraulic pressure, as in the lead-pipe machine of Cornell, flows out at the orifice in the die B, which may be made with different shaped orifices.

To convert the rod into bullets, it has first to be cut into portions, then each portion has to be compressed in ventilated dies, care being taken to prevent metallic contact, which is done by lubrication.

1812.

Such conditions may be attained by a great variety of mechanical arrangements: Figs. 1811, 1814, illustrate John Anderson's Bullet-making Machine, which was extensively employed at Woolwich.

By referring to Fig. 1812, it may be seen that the rod of lead from the lead-pipe or lead-rod machine, after being coiled upon a portable reel, is wound upon the reels C, C, which are fixed upon the framing of the bullet machine, Fig. 1812.

The lead rod is then conducted by a pair of small rollers D, through the cutting-off lever E, into the clips F, Fig. 1814, in which it is gripped while being sheared off; when the lever is raised up to perform this operation by the cam (G Fig. 1812) the length of lead rod thus cut off is determined by the adjustable stop.

To prevent the lead rod from slipping out of the die, it must be thoroughly clean and free from grease; it is therefore passed through a roll of tow or cotton waste I saturated with turpentine.

After the block of lead of the required length is cut off, the clips E, F, Figs. 1812, 1814, are opened, and the block is allowed to fall by gravitation to the bottom of the clips, and from thence is pushed into the forming-die J, Fig. 1812, by the punch K (the point of which is lubricated at each stroke); the finished bullet is then knocked out by the small punch L, into a shoot, by which it is conveyed to suitable boxes.

In order to ensure a clean and perfectly-formed bullet, it is necessary to ventilate the die; in this case the air escapes through the small punch L, which is bored out for that purpose.

When the portion of lead within the die has been compressed, the superfluous metal is squeezed out at the junction, thus forming a sort of frill, to remove which clips, Figs. 1812, 1814, are employed. These clips are pieces of steel containing a hole the size of the bullet; they rise in front of the die so soon as the punch has retired; at the next instant the bullet is pushed through the hole, thus leaving the frill behind.

When indentures have to be given to bullets, this is accomplished by passing them between a revolving disc and a corresponding fixed segment, the acting surfaces being of the required shape, and so placed with regard to each other that the entrance of the indenting channel shall be wider than the opening at the

point of exit. The revolving surface imparts a circular motion to the bullets, in a manner similar to that of milling coin.

J. D. Custar's Bullet Machine, Fig. 1815, has an arrangement of devices for cutting off the blank from a rod or thick wire, and depositing it in a radial groove *w* in the flat face of a turn-

table which carries it in front of a cylindrical die. A piston or male die fitting the said cylinder forces the blank therein and against a female die. When the male die is retracted, and the female die thrust forward, it forces the blank out of the cylinder and upon the carrier S, which during the operation of the dies remains at rest. The bullet is then carried around the lathe, where it is again seized between the sliding mandrel and centre of the lathe, and trimmed off to the proper shape by a tool which is fed to the work by means of a lever operated by a cam attached to the driving machinery C.

See **FORGING**.

CABLE. FR., *Câble*; GER., *Tau*; ITAL., *Canapo, Cavo*; SPAN., *Cable*.

A cable is a large, strong rope or chain, employed to retain a vessel at anchor, and for other purposes. It is commonly made of hemp or iron, but sometimes of iron or copper wire, as in the case of the cable of a suspension bridge, or of a submarine connection in the electrical telegraph. Practical information, however limited, upon the strength of rope and chain, is of great value and importance to the seaman, since there is scarcely an operation connected with his duties that can be performed without the use of a chain or a rope.

William Macdonald, Superintendent of the Liverpool Chain-testing Works, in 1860, before a committee of the House of Commons, gave the following tabulated statements, which show the total number of fathoms of chain proved by him from 1855 to 1859.

STUD CHAIN.

Date.	Total Number of Fathoms proved.	Number of Fathoms defective.	Number of Fathoms not defective.	Number of Fathoms condemned.	Percentage of defective Chains.

Deductions and rules respecting the strength of materials, based on the experiments of Tredgold, Barlow, Fairbairn, and Hodgkinson, are not reliable, for these and other experimentalists

employed incomplete testing apparatus; and in general they operated upon fragments of materials too small to warrant their conclusions with regard to large and complicated structures. This remark does not apply to David Kirkaldy, who, from his skill and the accuracy and great range of his testing machinery, furnishes results in every respect reliable. We add a tabulated statement respecting the relative strength of welded joints, taken from Kirkaldy's work, 'Results of an Experimental Inquiry into the Tensile Strength and other Properties of various kinds of Wrought Iron and Steel.'

In the experiments made by Kirkaldy to ascertain the strength of welded joints, the pieces were cut through the middle, and then scarfed and welded in the ordinary manner by the same smith who prepared the bolts for his other experiments, and a few were prepared by a chain-maker, for comparison. The results varied greatly,—fourteen, operated on by the smith, show a loss, compared with the original whole bar, from 4·1 to 43·8 per cent., the mean loss being 20·8 per cent.; four by the chain-maker, from 2·6 to 37·4; mean, 15·1 per cent. Of the former, four broke solid, away from the weld; eight, partly through solid portion and partly at the weld; two separated at the weld. Of the latter, two broke solid; one broke partly solid and partly at the weld; and one gave way at the weld. It may be noticed that different sizes and also different qualities were used, but the results were alike uncertain, and are further proof of the correctness of the following observations by James Nasmyth, which appeared in 'The Engineer,' 8th March, 1861, a considerable time after the experiments of Kirkaldy were made:—

"Of all the processes connected with the working of malleable iron there is none that has a more intimate relation to the security of life and property than that of *welding*, or the process by which we are enabled to unite together, in one mass, the several portions of malleable iron, of which the generality of works in that material are formed. Every single link in a chain cable, every wheel-tire in a railway train, directly owes its trustworthiness to the manner in which the process of welding has been performed, in so far as that any imperfection in any one single member of the set of cable links or railway wheel-tires may involve a most fearful loss of life, of which, of late years especially, we have had such distressing and melancholy experience.

"In order to render clear the following remarks as to the cause of, and means that should be employed to prevent, defective welding, it is necessary to explain the nature of the process of welding, which consists in inducing upon malleable iron, by means of a very high heat, a certain degree of adhesiveness, so that any two pieces of malleable iron, when heated to the requisite degree, will, if brought into close contact, adhere or stick together with a greater or less tenacity, according to the amount of force applied to urge them into close contact. . . .

"It is, therefore, to the means of thoroughly expelling this vitrified oxide from between the surfaces of the iron where the welded junction is to take place that we must direct our attention; for so long as any portion of this adhesive viscid substance is permitted to exist and interpose itself between the surfaces we desire to unite, no sound junction can take place, and once it has made a lodgment no after-heating or hammering, be it ever so severe, will cause its thorough expulsion. It is, therefore, to the thorough expulsion of the vitreous oxide in the first stage of the welding that we must direct the most careful attention; and it would, in no small degree, tend to prevent those fearful accidents of which defectively-welded ironwork is the principal cause.

"Since the chief cause of defective welding arises from portions of the vitreous oxide of the iron being shut up between the surfaces at the part presumed to have been welded, and that, besides the impossibility of ascertaining, in the majority of cases, after the process of welding has been gone through, whether or not this vitreous oxide has been thoroughly expelled, and the surfaces at the welding brought into perfect metallic union, and that no after-heating or hammering can dislodge the vitreous oxide when once it has effected a lodgment, our best security is to form the surfaces of the iron at the part where the welding is desired to take place, so that when applied to each other, at the welding heat, *their first contact with each other shall be in the centre of each.*"

Kirkaldy tested two steel bars welded at the makers' works, the result still more unsatisfactory than with iron—one showing a loss of 45·0, the other 59·6 per cent.; whilst other two parted at the weld during the operation of forming the heads, previous to testing. At the commencement of these experiments several attempts were made to form heads on the steel specimens, in the same manner as on the iron, by welding on rings; but as they either failed at the weld, or the steel was found to be burned, that method was abandoned.

With the view of ascertaining the effect of heating iron to the welding point, and then allowing it to cool slowly without being hammered, an experiment was made by Kirkaldy with a bar of Glasgow B. Best, the results of which are stated in his table N, 1095. Although its breaking strain was nearly the same as that borne by another piece, 1094, off the same bar, in the ordinary condition, yet it will be found that the ductility of the iron had been injured by the high temperature and want of hammering; for it was found that instead of 42·2 per cent. it only contracted 27·8, or 34 per cent. less than the latter.

Figs. 1816 to 1829 exhibit mooring and other chains, with the articles required to be appended to such chains, and the proportions of iron chain cables, as supplied to the English Royal Navy.

Fig. 1816 shows the pin and lead pellet, through forelock, and part of the ring or shackle on the anchor-shank. Figs. 1816 to 1821 present two views of each part of a cable where connections are made.

The dimensions given on the links, &c., signify so many diameters of the iron of the common links of the cable, thus forming the scale for all sizes. In the mooring chains and gear, the unit is the thickness of the iron of the link.

Referring to Figs. 1816 to 1821, and large shackle for connecting any length of cable of 12½ fathoms: B, end links, without stay-pins; C, enlarged links, with stay-pins; D, common links, thickness put = 1; E, swivel in the middle of every other length of 12½ fathoms; F, joining shackle for connecting either end of any length with any other length of the same size.

Angle between lower end of cable and a horizontal line	2° 28' 25"·09	2° 57' 59"·37	0° 10' 26"·15	0° 39' 19"·07
Vertical force to lift the anchor	..	2·067 tons	..	0·459 ton
Length of semi-catenary, of which the 100 fathoms is a segment	131·895 faths.	143·88 faths.	102·16 faths.	109·71 faths.
The forces on the bow, and horizontal force on anchor	..	as above	..	as above
Depth of the semi-catenary, of which length 100 fathoms is a segment	11·68 faths.	12·136 faths.	7·0034 faths.	7·055 faths.
Lower part hangs horizontally, hence force to lift anchor	..	0	..	0
Length of semi-catenary at the depth specified in the respective columns, or the greatest length of cable that can be employed, so that no part of it shall lie on the ground	127·98 faths.	137·03 faths.	102·23 faths.	109·29 faths.
Angle between the upper end of this semi-catenary and a vertical line	80° 10' 29"·88	80° 49' 15"·3	82° 9' 56"·94	82° 40' 12"·38
Horizontal pull on ship and anchor	..	39·98 tons	..	40·1688 tons
Vertical force to depress the bow	..	6·46 tons	..	5·167 tons
Lower part hangs horizontally, hence force to lift the anchor	..	0	..	0

it at its lowest point R; the vertical distance between its extremities being DR or $Ay = 11·68$ fathoms, which corresponds with Ay , Fig. 1830, measured on its proper scale. A Q, Figs. 1830, 1831, is a segment of the semi-catenary A R. Hence a diagram being constructed as above, if the point Q, Fig. 1830, should be found to lie *within* the semicircle, the cable forms a segment of a semi-catenary, and its lower part makes an angle with a horizontal line; if the point A O, Fig. 1831, lie in the *circumference* of the semicircle, the cable forms a complete semi-catenary, to the lowest point of which a horizontal line forms a tangent. If the point Q be found to lie *without* the semicircle as q , Fig. 1830, the length A R will form a semi-catenary; and the remaining portion R q , which is beyond the semicircle will rest on the ground, as R g , Fig. 1831.

1831.

If it be required to ascertain what length of chain cable will form a complete semi-catenary, at the proposed depth A x , or 11 fathoms; let the arc x Q, Fig. 1830, be continued until it intersects the semicircle in some point S; join AS, PS, then AS is the length required; which is the greatest length of cable that can be employed with a depth of 11 fathoms, so that no part of it shall rest on the ground, as A n S, Fig. 1831. The angle PAQ, Fig. 1830, or P A x , Fig. 1831, which the upper part of the cable makes with a vertical line, may be found from the following expression: $\cos. PAQ = \frac{(PA)^2 + (AQ)^2 - (PQ)^2}{2 \times PA \times AQ}$. Substituting for PA, 750 fathoms; for PQ, 739 fathoms; and for AQ, 100 fathoms:

$$\cos. PAQ = \frac{(750)^2 + (100)^2 - (739)^2}{2 + 750 \times 100} = 0·17586 \text{ to rad. 1.}$$

And from a table of cosines we have angle PAQ, or P A x , Fig. 1831, = 79° 52' 16"·66.

The angle QPR, Fig. 1830, or L Q x , Fig. 1831, which the lower part of the cable makes with a horizontal line, may be found from the following expression:

$$\sin. QPR = \frac{(PA)^2 - (PQ)^2 - (AQ)^2}{2 \times AQ \times PQ}$$

Substituting, as before, the proper values of P A, P Q, and A Q,

$$\sin. Q P R = \frac{(750)^2 - (739)^2 - (100)^2}{2 \times 100 \times 739} = 0.043159 \text{ to rad. 1.}$$

And from a table of sines we have angle $\frac{Q P R}{\text{or } L Q x} = 2^{\circ} 28' 25'' \cdot 09$.

The greatest length of cable that can be employed with a depth of 11 fathoms so that no part of it may rest on the ground is A S, which is equal to $\sqrt{(A P)^2 - (P S)^2}$. Substituting for A P and P S their values $\left. \begin{array}{l} \text{A S, Fig. 1830} \\ \text{or A n S, Fig. 1831} \end{array} \right\} = \sqrt{(750)^2 - (739)^2} = 127.9 \text{ fathoms.}$

The angle P A S, which this length of cable makes with a vertical line may be found from the expression $\sin. P A S = \frac{P S}{P A}$. Now P S = P Q = 739 fathoms, and P A = 750 fathoms. Hence,

by substitution, $\sin. P A S = \frac{739}{750} = 0.9853$ to radius 1; and from a table of sines we have $\left. \begin{array}{l} \text{angle P A S, Fig. 1830} \\ \text{or angle P A x, Fig. 1831} \end{array} \right\} = 80^{\circ} 10' 29'' \cdot 88$.

The position which a chain cable would assume under any given circumstances may also be obtained experimentally, by the suspension of a small chain of any convenient length.

Let it be required to find by experiment on a chain $\frac{1}{8}$ of an in. in diameter and 25 ft. long, the position which a $1\frac{1}{2}$ -in. chain cable would take, whose length is 100 fathoms, vertical distance between the extremities 11 fathoms, and strain on the upper end $40\frac{1}{2}$ tons:

The weight of 100 fathoms of $1\frac{1}{2}$ -in. chain cable is 108 cwt.

The proportionate strain to be applied to the $\frac{1}{8}$ -in. chain may be found from the following expression:

$$= \frac{\text{Weight of chain the 100 fathoms}}{\text{Weight of cable the 100 fathoms}} \times \frac{\text{length of chain}}{\text{length of cable}} \times \text{strain}$$

$$= (\text{by substitution}) \frac{15 \text{ 0 21}}{108} \times \frac{25}{600} \times 40\frac{1}{2} = 4 \text{ 2 27} \cdot 552.$$

The length of the experimental chain being $\frac{1}{8}$ the length of the cable, the vertical distance between the extremities of the chain should be taken $\frac{1}{8}$ of 11 fathoms, or 2 ft. 9 in.

The curve formed by the cable suspended under these circumstances was similar to that derived

from calculation for a $1\frac{1}{2}$ -in. chain cable of 100 fathoms on a $\frac{1}{24}$ scale. The deflection at the middle of the length from a straight line joining the extremities of the chain measured 5 in. This deflection, multiplied by 24, gives the deflection on the full scale 10 ft., agreeing with the result of calculation.

Let one end of a chain cable be made fast, and a given strain act on the other end; both extremities being in the same horizontal line, to find by construction the depth of the lowest part of the chain; let the size of the cable be $1\frac{1}{2}$ in., length 100 fathoms, strain $40\frac{1}{2}$ tons. Take a vertical line A R, Fig. 1830, equal to one-half the length of the cable, or 50 fathoms; from R draw the line R P at right angles to A R; from A as a centre, with a radius equal to 750 fathoms, or the number of fathoms of a $1\frac{1}{2}$ -in. chain cable due to $40\frac{1}{2}$ tons strain, describe an arc *ab* cutting R P in P; join P A; from P as a centre, with a radius P R describe the arc R y cutting A P in y. A y is the required depth of the lowest part of the chain.

The same may also be found from the expression

$$\text{Depth of lowest point of cable} = T - \sqrt{T^2 - s^2};$$

where T is equal to P A, the tension at A in fathoms of chain, or 750 fathoms; and s is equal to A R the half-length of cable, or 50 fathoms. Hence, by substitution,

$$\begin{aligned} \text{Depth of lowest point of cable} &= 750 - \sqrt{(750)^2 - (50)^2} \\ &= 750 - 748.331 = 1.668 \text{ fath.} \\ &= \frac{6}{10.008} \text{ ft.} \end{aligned}$$

The deflection of a cable from a horizontal line may also be found experimentally, by the suspension of a small chain of any assumed length.

Let the size of the experimental chain be $\frac{1}{16}$ in., length 25 ft., weight the 100 fathoms, 15 cwt. 0 qr. 21 lbs.

The proportionate weight to be attached

$$\begin{aligned} &= \frac{\text{Weight of chain the 100 fathoms}}{\text{Weight of cable the 100 fathoms}} \times \frac{\text{length of chain}}{\text{length of cable}} \times \text{strain} \\ &= (\text{by substitution}) \frac{\text{cwt. qr. lbs.} \quad \text{ft.} \quad \text{tons.} \quad \text{cwt. qrs. lbs.}}{15 \quad 0 \quad 21 \quad 25}{108 \quad 600} \times 40\frac{1}{2} = 4 \quad 2 \quad 27.552. \end{aligned}$$

The length of the chain in this experiment being $\frac{1}{24}$ the length of the chain cable, the curve observed is the curve on a $\frac{1}{24}$ scale, which the cable will form.

The deflection was found to be $4\frac{1}{8}$ in., which being multiplied by 24 gives the deflection, or depth of the lowest point of the cable of 100 fathoms with $40\frac{1}{2}$ tons strain, equal to 9 ft. $10\frac{1}{2}$ in. Let the same be tried with $12\frac{1}{2}$ ft. of $\frac{3}{8}$ -in. chain, weighing 7.96 cwt. to the 100 fathoms.

Proportionate weight to be attached

$$\begin{aligned} &= \frac{\text{Weight of chain the 100 fathoms}}{\text{Weight of cable the 100 fathoms}} \times \frac{\text{length of chain}}{\text{length of cable}} \times \text{strain} \\ &= (\text{by substitution}) \frac{\text{ft.} \quad \text{tons.} \quad \text{cwt. qr. lbs.} \quad \text{oz.}}{7.96 \quad 12\frac{1}{2}} \times 40\frac{1}{2} = 1 \quad 0 \quad 27 \quad 4.7. \end{aligned}$$

The length of chain in this experiment being $\frac{1}{24}$ of the length of cable, the curve observed is that on a $\frac{1}{24}$ scale, which the cable will form. The deflection was found to be $2\frac{5}{8}$ of an in., which multiplied by 48 is 9 ft. 3 in., the depth of the lowest point of the cable.

Let the size of the cable be as before $1\frac{1}{2}$ in., and the strain $40\frac{1}{2}$ tons, but the length $12\frac{1}{2}$ fathoms. Take a vertical line A R, Fig. 1831, equal to one-half the length of the cable, or $6\frac{1}{4}$ fathoms; from R draw the line R P at right angles to A R; from A with the radius 750 fathoms, being the number of fathoms of a $1\frac{1}{2}$ -in. chain cable due to a strain of $40\frac{1}{2}$ tons, describe an arc *ab* cutting R P in P; join P A; from P with the radius P R describe the arc R y cutting A P in y. A y is the required depth of the lowest point of the chain.

The same may also be found from the expression

$$\text{Depth of lowest point of cable} = T - \sqrt{T^2 - s^2};$$

where T is equal to P A, the tension of A in fathoms of chain, or 750 fathoms; and s = A R, the half-length of the cable, or 6.25 fathoms. Hence, by substitution,

$$\begin{aligned} \text{Depth of lowest point of cable} &= 750 - \sqrt{(750)^2 - (6.25)^2} \\ &= 750 - 749.974 = 0.026 \text{ fath.} \\ &= \frac{6}{0.156} \text{ ft.} \\ &= \frac{12}{1.872} \text{ in.} \\ &= 1\frac{1}{4} \text{ in. nearly.} \end{aligned}$$

The deflection may also be found by experiment. Suppose a length of 25 ft. of $\frac{1}{16}$ chain, weighing 15 cwt. 0 qr. 21 lbs. to the 100 fathoms, be taken for the experiment.

Then the proportionate weight to be attached is

$$= \frac{\text{Weight of chain the 100 fathoms}}{\text{Weight of cable the 100 fathoms}} \times \frac{\text{length of chain}}{\text{length of cable}} \times \text{strain}$$

$$= (\text{by substitution}) \frac{15 \text{ cwt. } 0 \text{ qr. } 21 \text{ lbs.}}{108} \times \frac{27 \text{ ft.}}{75} \times 40\frac{1}{2} = 1 \text{ } 17 \text{ } 3 \text{ } 24\frac{1}{2}.$$

The length of the chain in this experiment being $\frac{1}{3}$ the length of the chain cable, the curve observed is that which the cable will form on a scale of $\frac{1}{3}$.

The deflection was found to be $\frac{1}{3}$ of an in., which, multiplied by 3, is equal to $2\frac{1}{3}$ in. On the addition of $\frac{1}{4}$ cwt. to the above weight, the deflection was $\frac{5}{8}$ of an in., which, multiplied by 3 = $1\frac{1}{2}$, agreeing with the calculation. As the nip on the roller where the weight was attached was considerable, it is probable that the chain was not sufficiently free.

The experiment was also tried with a $\frac{3}{8}$ -in. chain, weighing 7.96 cwt. the 100 fathoms, and $12\frac{1}{2}$ ft. long.

The proportionate weight to be attached

$$= \frac{\text{Weight of chain the 100 fathoms}}{\text{Weight of cable the 100 fathoms}} \times \frac{\text{length of chain}}{\text{length of cable}} \times \text{strain}$$

$$= (\text{by substitution}) \frac{7.96 \text{ cwt.}}{108} \times \frac{12\frac{1}{2} \text{ ft.}}{75} \times 40\frac{1}{2} = 0.49766 = 9 \text{ } 3 \text{ } 22.32$$

The length of the chain in this experiment being $\frac{1}{3}$ of the length of the cable, the curve observed is that, on a scale of $\frac{1}{3}$, which the cable will form.

The deflection was found to be $\frac{5}{16}$, which, multiplied by 6, is equal to $3\frac{3}{8}$ = $1\frac{1}{2}$ in., which agrees with the calculation.

The weight attached was $1\frac{1}{2}$ lb. more than should have been employed.

Where the result of the experiment does not exactly agree with that of calculation, it is owing to an imperfection in the experiment. See ANCHOR, FOUNDED, CASTING, AND FORGING. MATERIALS OF CONSTRUCTION, *Strength of. ROPE-MAKING MACHINERY.*

CAGE, SAFETY. FR., *Cuffat des mines de houille*; GER., *Kübel, Fahrstuhl*; ITAL., *Gabbia di sicurezza*.

The safety-cage of J. P. Harper with conducting ropes of iron wire is represented and the mechanical arrangements illustrated in Figs. 1832 to 1835. Fig. 1832 is of this cage in working order; Fig. 1833, sectional elevation of compressors when not in action; Fig. 1834, sectional elevation of the compressors when first brought into action; and Fig. 1835, elevation of compressors when in extreme action, showing the conducting iron-wire rope in a compressed state.

Harper's safety-cage differs both in principle and detail from any that have preceded it, and certainly stands alone in this respect, that it is specially designed, constructed, and adapted for the ordinary wire-rope conductors.

Safety-cages have hitherto been brought out more particularly for adaptation to the wooden guides, but, as these are becoming superseded by the iron-wire ones on account of their durability and cheapness—if safety-cages are to be universally adopted, they must be made applicable to wire-rope conductors.

Safety-cages can be used to greater advantage in connection with the iron-wire than with the wooden guides, for, with the wooden ones, sharp-pointed or toothed instruments are usually brought to clutch or dig into the conductor; and if it so happens that the length of guide-rods on which the apparatus is brought to play be rotten, unsound, infirmly fixed, or in any way defective, the safety apparatus is of no avail; indeed sometimes, be the rods ever so sound and in good repair, we hear of accidents occurring, owing to the guide-rods being split and ripped down by the apparatus brought to bear on them.

Accidents of this description are less liable to occur with the iron-wire guides. It has been found that it would not do to employ an instrument with a sharp point, a toothed or uneven surface, to bear on the conductors, for, as the circumference of a wire rope is uneven, they would cut and injure the more prominent parts.

This safety-cage acts effectually without damaging or depreciating in the least the wire conductors, of whatever description they may be. The apparatus is extremely simple, substantial, inexpensive in its construction, is not easily deranged, and can be applied to cages and hoists, of whatever description or size, whether conducted at the ends, corners, or sides, and carrying any weight. The principle by which the apparatus, on the severance of the winding-rope from the cage, is brought to bear on the conductors is by compression; and its operation is (of its own accord) to bring the cage to an immediate stand by means of catches or compressors, which fasten on, encircle, and compress *not only the sides but the whole circumference* of the conductor. When the winding-rope is readjusted by the tension of the rope, the compressors at the same instant release their grasp of the conductors, and the whole is again in working order.

The general features of the cage will be readily seen on examining Fig. 1832. The catches, or more properly the compressors, are of peculiar shape: Figs. 1833 to 1835 show their positions when out of play and held from the guides by the tension of the rope, the position they assume when first brought into play, and the iron-wire guide in extreme compression. This will, of course, vary in proportion to the weight on the cage at the time they are brought into requisition.

Fig. 1832 is a design for double cages in a 13-ft. shaft, fitted with wire-rope conductors, each cage having two, three, or four guides as may be required, and single or double tiered to carry either two or four wagons.

The cage, Fig. 1832, though conducted by four guides, the apparatus is brought to bear on two only, that is, across the corners. The compressors, A, Fig. 1835, made of malleable iron and case-hardened, are of peculiar construction, made in a fork-like shape, and of any proportionate elevational depth: see Fig. 1834. They work on each side of the conductors on axles B attached to the cage, and when not in play are held by the tension of the winding-rope at an acute angle; and, when brought into play, slide into each other, and encircle the conductor, assuming a nearly horizontal position, and forming, both in plan and elevation, a circular hole the full depth of the compressors, but less in diameter than the conductor, so that as the angle is made to increase in proportion to the weight on the cage, so will the compression also increase on the conductors.

The compressors A are constructed with lever ends, and when the cage hangs freely on the winding-rope they are held away from the conductors by side rods D, attached on each side of the cage to main vertical and shouldered rods E working through guide-boxes F, in which are inserted spiral springs (merely to give impetus to the compressors) bearing on the inside shoulders of the main vertical rods E, which are connected on each side of the cage by a cross-bar G, working over the top or cover of the cage H, and attached to the winding-rope. To prevent the compressors A wrenching apart, they are connected by a front tie-plate C. K represents ordinary cast-iron guide-boxes through which the conductors slide.

It will be seen that when the cage hangs freely on the rope the shoulders on the main vertical rods E are brought up by means of the cross-bar G to the under-sides of the guide-boxes F, and the compressors, now being held away from the conductors, are allowed to pass freely between the forks of the catches; but immediately on the rope becoming disconnected from the cross-bar G the concealed spiral springs, hitherto held in subjection, are released, give impetus to and assist in bringing the compressors A into instantaneous play, which, then sliding into one another, so close round and compress the conductor into a circular hole, less in diameter than the conductor itself, through which it is impossible for it to pass; hence the cage is brought to an immediate stand.

In the arrangements by which the compressors are connected to the winding-rope, it will be perceived that both sets must work simultaneously on the guides, and are such as cannot be easily deranged.

CAISSON, *FR.*, *Caisson*; *GER.*, *Versenkasten*; *ITAL.*, *Cassone a cilindro*; *SPAN.*, *Cajon*.

Floating bodies, constructed of sheet iron, designed to open or close the entrances of a docks or basins, are termed caissons.

The engravings, Figs. 1836, 1837, represent one of the caissons for closing dock or basin entrances at Haulbowline Navy Yard, Cork, constructed by A. Clarke. It is one of the class termed sliding caissons, and is drawn into a recess formed for its reception at right angles to the entrance of the dock or basin, when the entrance is opened to allow ships to pass in or out. Such caissons are also used as roadways for the traffic, usually very heavy, passing across the entrance of the dock or basin.

The object sought is to preserve the roadway or deck of the caisson level with the wharf on one side of the entrance and with the cover of the recess on the other side when the caisson is in its place and being used as a roadway; likewise to keep the sides of the entrance level and free from obstruction when the caisson is drawn into its recess, and the operation of taking ships into

or out of the dock or basin is in progress. These objects have hitherto been accomplished by making the deck of the caisson capable of being lowered, when it is necessary to draw the caisson into and under the cover of the recess, or by lowering the caisson bodily by sinking it to a sufficient depth to admit of its passing below the cover.

In the present instance a third method has been adopted, that of raising and lowering a part of the cover of the recess sufficiently to allow the caisson to pass down a series of slopes at the bottom of the recess and entrance; these slopes being so adjusted that when the caisson is drawn completely into its recess it has become lowered to a very small extent, and at the same time so thrown out of the level as to fit under the cover, which for this purpose is formed with a slight inclination towards the entrance. The part of the cover which was raised to allow the caisson to pass is then lowered, and the wharf is clear for docking operations.

The flotation of the caisson is so adjusted that the portion of its weight borne by the masonry of the entrance is small, being only sufficient to keep the caisson steady when moving. The power, therefore, required to force it up the slopes on which it slides is but trifling, and means are provided by which it can be made to float completely if necessary.

The machinery for lifting the cover of the recess, and that for moving the caisson, will be worked by a small steam-engine. A pair of endless chains on either side of the upper part of the recess supply the moving power for the caisson.

Referring to the drawing, A is the caisson in its place across the entrance, B is the recess into which it is drawn, C is the cover of the recess, and D the portion of the cover which is raised, as

shown by the dotted line, to allow the caisson to pass into the recess; EEE are the slopes on which the caisson slides, and the dotted line F shows the position of the caisson when drawn into the recess, after which the cover D is lowered into its former position. GG are the endless chains which are attached to the swivelling cross-head H connected to the caisson. I, I, I, are rubbing-pieces; K is a trap for mud; and L the skids on which the caisson slides, which are so formed as to clear the sliding ways E of any mud which may have accumulated.

The caisson can be used as an ordinary floating caisson when disconnected from the cross-head H; and by temporarily placing one of these caissons on either side of the basin entrance, and pumping the water out from between them, access to the caisson recess can be obtained for cleaning and repairs.

Many chest-like vessels, in both civil and military engineering, are termed *caissons*. In military engineering a chest that contains ammunition, and also the wagon or tumbril which conveys military stores, is called a caisson. A chest filled with explosive materials to be laid in the way of an enemy, as under some work at the possession of which he is aiming, and to be fired when the enemy is exposed to its effect; a wooden box or frame of strong timbers, used for laying the foundations of a *bridge* in situations where the coffer-dam cannot be employed; and other structures, receive the appellation caisson.

See BRIDGE. DOCKS. FORTIFICATION. LOCKS. ORDNANCE.

CALENDER. FR., *Calandre*; GER., *Calender*; ITAL., *Sopressa*; SPAN., *Calandria*.

Calender, Five-roller, by Thomson Brothers and Co., of Dundee.—The arrangement of this calender is illustrated in Fig. 1838. It may be modified to finish either linen or cotton goods. This machine may be employed to effect:—*Plain calendering*, by passing the cloth through the rollers; *Chesting*, or rolling cloth on the top roller under heavy pressure, either without or after passing it through the other rollers; and *Mangling*, or rolling the cloth on the second roller from the top; to effect this object, the end of the piece being sewed to the body of the cloth, the calender is kept revolving under heavy pressure backwards and forwards. A drag or slip is made between the centre driving-roller and the lower cast-iron roller when the machine is employed for *Glazing*; the centre driving-roller may be heated either by steam or by hot bolts, the latter being necessary for high glaze. The top and bottom rollers A E, Fig. 1838, are of cast iron, 20 in. in diameter, with wrought-iron journals to sustain the pressure to which they may be subjected. The centre roller C, 11 in. diameter, is made hollow, and fitted at the ends with stuffing-boxes for the admission of steam. The two paper rollers, B D, 24 in. diameter with 54 in. width of paper, have wrought-iron journals and end-plates. The two upper rollers have small pivots set into the ends of the journals for the purpose of suspending them by rods from top-blocks while the cloth is being drawn off by the *stripping* motion, after the operation of chesting or mangling. The machine, Fig. 1838, is driven by a shaft connected by a wheel and pinion to the centre roller. This shaft carries two pulleys I I, for open and for cross belts, each pulley being 34 in. diameter, and the belts 8 in. broad;

a double friction clutch is placed between the pulleys, for the purposes of starting, reversing, or stopping the machine—the handle *h* being retained in a central position by a spring catch. The calender does not require to be attached to side walls; a foundation capable to carry its weight is sufficient. The crane motion for lifting the levers and top rollers is fixed to the frame, and the top rollers are held in position, when suspended, by a friction strap which also serves to lower the rollers. The blocks for the journals of the rollers are not attached to the framing, the brasses

being set forward by side screws when they wear in the blocks, thus keeping the rollers in the centre; the upper part of the block being made hollow, so that the journal may be lubricated. Pressure is applied by weights suspended by the chain at *Z*, which is coiled on the screw pulley, and is equal to about 22 tons, which includes the weight of the rollers. By reversing the chain on the screw pulley, the weights, when a light pressure is required, may be made to counterbalance the weight of the levers and top rollers.

Calender with Five Rollers; designed and constructed by A. More.—Fig. 1839 is an end view; Fig. 1840, a side elevation. The same letters of reference denote the same parts in each view. *A, A, A*, three cylinders or rollers made of paper, the construction of which will be noticed afterwards. *BB*, two cast-iron cylinders, made hollow to allow of the introduction of hot bolts within them; or of steam when it is required. *CC*, the two side frames into which are fitted the several brass bushes for the cylinders to turn upon. *DD*, top guides into which the cross-head *G* and elevating screws *HH* work. *EE*, top-pressure levers connected by a strong rod of iron with the under-pressure lever *F*. This system of levers is connected with the cross-head *G* by two strong links of iron. The elevating screws *HH* pass through the cross-head, and rest upon a strong cast-iron block, into which is fitted the brass bush of the top paper roller. By means of the screws, the cross-head and levers can be raised or depressed as required, and when the calender is working warm and requires to be stopped, the elevating screws are screwed up for the purpose of lifting the paper rollers off the hot cylinders, to prevent their being injured by the heat.

The construction of the paper rollers or cylinders is as follows:—Upon each end of a journal

of malleable iron, of sufficient strength to withstand the necessary pressure without yielding, is fastened a strong plate of cast iron, of the same diameter as the roller to be made; the plate is secured in its proper place by a ring of iron, cut in two, and let into a groove or cheek turned in the journal. When the roller is finished, the annular pieces are kept in their groove by a hot hoop put upon the outside of them and allowed to cool. A plate is fitted on the other end, of exactly the same size, and in the same manner. In building the rollers, one of the plates is taken off the journal, but the other is allowed to remain in its place. The paper sheets of which the rollers are

1839.

1840.

to be made have each a circular hole cut in the centre of it, of exactly the same diameter as the journal. The sheets are then put upon the journal, and pressed hard against the fixed plate. When the journal is filled with paper, it is put into a strong hydraulic press and pressed together, always adding more paper to make up the deficiency caused by compression, until the mass will press no harder. The half rings are then put in their place, to prevent the plate from being pressed back by the elasticity of the paper. The roller is now to be dried sufficiently in a stove, the heat of which causes the paper to contract so as to be quite loose. The roller is then again taken to the press, and the unfixed plate being removed, more paper is added, and the whole again compressed until the roller is hard enough for the purpose to which it is to be applied. It is next turned truly in a lathe till it acquires a very smooth surface. The woodcut, Fig. 1841, shows the manner in which the calender is geared to make it a glazing calender. In this cut, *a* marks the top cylinder of the calender, upon which is keyed a spur-wheel *b*; and *c* is the under cylinder, upon which is also keyed a spur-wheel *d*. The intermediate or carrier wheel *ee*, when drawn into gear, reduces the speed of the under cylinder *c* one-fourth. Now, the cylinder *a* being the one that gives motion to all the rollers, and revolving always at the same speed, the cloth, in its passage through all the rollers below the cylinder *a*, is carried through at a speed one-fourth less than if it passed only below the cylinder *a*; consequently, when it comes into contact with *a*, it is rubbed and thereby *glazed*, in consequence of the cylinder *a* moving one-fourth quicker than the cloth, as above stated. The woodcut, Fig. 1842, shows the manner in which the rollers are lifted clear of each other when the machine is stopped. In this, *ee* are two rods of iron attached to the block or seat of the top roller; *bfg*, three bridges of malleable iron, capable of sliding upon the rods *ee*, but held fast upon the rods when once they are adjusted to their proper places by pinching-screws. The bridge *b* is placed $\frac{1}{2}$ in. clear of the bearing of the cylinder *a*, when all the rollers are resting upon each other; the bridge *f* is placed 1 in. below the bearing of the paper roller *h*; and the bridge *g* is placed $1\frac{1}{2}$ in. below the bearing of the cylinder *c*. When the pressure-screws of the calender are lifted, the blocks of the top roller being attached to them, the rods *ee* are lifted also, and along with them the different rollers, as the bridges successively come into contact with their respective bearings.

1841.

1842.

The manner of passing the cloth through the calender varies very much according to the amount of finish required upon it. The various methods are accomplished by different arrangements of the gearing, so that a calender calculated to do all the different kinds of finishing becomes a very complicated machine, on account of the quantity of gearing required. For common finishing

the method of passing the cloth through the calender is as follows:—The cloth is passed alternately over and under a series of rails placed in front of the machine, so as to remove any creases that may be in it, and is then introduced between the lower roller A and cylinder B; returns between the lower cylinder B and the centre roller A; passes again between the central A and the upper B, and again returns between the top pair A B, where it is wound off on a small roller (hid in the drawings by the framing of the machine), pressing against the surface of the top roller A. When this small roller is filled with cloth it is removed, and its place supplied by another, to be in succession filled as the motion of the machine progresses.

Water-Mangle, with Two Copper and Three Wooden Rollers; designed and constructed by A. More.
—This machine, Figs. 1843, 1844, differs nothing in principle and little in general construction

from the five-rollered calender above described, except in this, that it is intended for wet goods. It is drawn on a scale slightly less, but the views given and the lettering of the parts correspond to those of the preceding figures. A, A, A, three wooden rollers, and B B the two copper rollers of the mangle. These last consist of a copper cover upon a cast-iron body, through which passes a wrought-iron journal, differing from those of the wooden rollers in being round, whereas these are square between the bearings. The smaller of the two copper rollers, namely, the third in order, is in this arrangement the driver, the mangle being driven like the calender, by a system of reversing gear not shown in the drawings.

The pressure in the mangle is brought on by a system of levers, which differs slightly from that described. In this indeed there are strictly two distinct pressures: that brought on the axis of the middle roller by the lever E, which is connected by a link with the weighted lever F; and that transmitted through the whole system of rollers by the single-weighted lever D. The weight of this last is regulated by means of a set-screw which turns in a nut in the jaws of the lever D, and bears upon the set-block which rests upon the journal of the top roller. This pressure is thus transmitted downwards from the top roller throughout the whole set, and at the middle roller B is added to the pressure obtained by the lever E. By this arrangement the pressure between the three under rollers is greater by the pressure of E than it is between the upper pair; but for very high pressure the lever D may be locked by set-pins, and the set-screws turned down by the hand-wheel G, until the requisite degree of pressure is obtained.

The manner of passing the cloth through this machine is the same as that already described in the calender, with this single exception, that before the cloth enters between the lower roller A and the small cylinder B, jets of water from a pipe, perforated with small holes, extending the whole width of the machine, are allowed to play upon the cloth, so as to impart to it sufficient moisture for causing it to receive the requisite degree of smoothness preparatory to the starching process, and at the same time allow the cylinder B to free it from any impurities that may be remaining in it, by forcing them back with the expressed water.

Calender.—Description.—A, two cast-iron frames; B C D, three cylinders, Figs. 1845, 1846; E F G, three cog-wheels; H I, two force-screws; K L, two fly-wheels with handles. The cylinder B, which is in cast iron and hollow, is heated by another iron cylinder heated red hot. The material of the cylinder C is pasteboard; its axle is of wrought iron. These three cylinders must be perfectly round and parallel.

The wheel F forms the communication between E and G, which rest upon the cylinders B and D. The relation of F to the circumference of the cylinders is such that when the machine is set

to work these cylinders slide, causing friction, and thus give a gloss to the cloth. The friction is variable according to the nature of the cloth or tissue.

1845.

1846.

In order to set the machine in motion, the fly-wheels K and L being turned in order to press the screws H and I against the pillows of the first cylinder B, the cloth is placed between the rollers in the direction indicated by the arrows.

CALIPERS. FR., *Compas*, *Compas d'épaisseur*; GER., *Taster*; ITAL., *Compasso da grossezza*; SPAN., *Compas curro*.

See COMPASSES.

CALKING. FR., *Calfater*; GER., *Kalfatern*; ITAL., *Calfatare*; SPAN., *Calafateo*.

The process of copying or transferring a drawing by covering the obverse side of a design with black lead, or red chalk, and tracing lines through on a waxed plate, or wall, by pressing lightly over each stroke of the design with a point, which leaves an impression of the colour on the plate, paper or wall, is termed calking, which is often spelled *calquing*.

CALKING IRON. FR., *Calfat*; GER., *Das Kalfateisen*; SPAN., *Hierro de Calafateador ó Estopero*.

An instrument, like a chisel, used in calking ships, boilers, caissons, and so on. These little implements are of various forms, fashioned to suit different sorts of work: one form is shown in Fig. 1847; *a* the joint of the plates, *b* the tool driven by a hand-hammer. See HAND-TOOLS.

CALORIMETER. FR., *Calorimètre*; GER., *Wärmemesser*; ITAL., *Calorimetro*; SPAN., *Calorimetro*.

The apparatus invented by Lavoisier and Laplace for measuring the amount of heat contained in certain bodies is often designated as a calorimeter; this apparatus Laplace operates by the melting of ice around the body to be tested. See PYROMETER.

CAM. FR., *Came*, ou *camme*; GER., *Zahn-Daumen*; ITAL., *Palmola*, *Dente*; SPAN., *Escéntrico*.

A projecting part of a wheel or other moving piece, so shaped as to give an alternating or variable motion of any desired velocity, extent or direction, to another piece pressing against it, by sliding or rolling contact. Cams are much used in machines that involve complicated and irregular movements, as in the sewing and pin-making machines.

The cam-wheel A, Fig. 1848, revolving on its axis C, raises and lets fall the beam D; the heart-cam B, revolving on its axis E, gives an irregular motion to the rod S; and the cam G, revolving on its axis F, moves H, and may be made to operate an alarm bell. The cam and the toggle-joint should be considered two of the *mechanical powers*; then we should have, 1, the lever; 2, inclined plane; 3, wheel and axle; 4, screw; 5, pulley; 6, wedge; 7, cam; 8, toggle-joint. When valves are employed instead of slides, for altering the flow of steam to the steam-cylinder, it is usual to move them by cams. In the rough sketch, Fig. 1849, P is a pipe connected with the boiler, Q a port to the cylinder, and V a valve, which is here represented single, but it is usually of the double-beat kind, shown in Fig. 1850. The valve V, Fig. 1849, closes the passage from P to Q, the valve-rod R V, passing through a stuffing-box in the cover of the valve-box, terminates in a roller R, which bears upon a cam S, fixed on a shaft T, caused to rotate by the engine. This cam is a disc, partly circular, with part of it, S, projecting to a greater distance from the centre. As long as the roller R bears upon the circular portion, the valve V remains down upon its seat; but as the projecting part of the cam is brought by the revolution of the shaft under the roller, the valve-rod is pushed up, and the valve lifted to allow the passage of the steam. When it is desirable that the valve should be kept open during a greater or less portion of the revolution of T, the cam is sometimes made with steps of various extent, on any of which the roller may be made to bear at pleasure, as shown in plan and section, Fig. 1851. To prevent the valve being

1847.

damaged from repeated blows against its seat, a *dash-pot* is employed, which is a small cylinder, partly filled with fluid, and having a loosely-fitting piston to ease the blow of the falling weight. The stationary under-part of the dash-pot is usually filled with water, and the plunger rises and falls with the valve-stem. See DASH-POT. In Fig. 1852 is represented the gearing for operating the steam and exhaust valves of the Ridgwood pumping engines, belonging to the Brooklyn Water Works, New York.

piston, and is for the purpose of closing the steam and exhaust valves; two levers *c*, with the rollers on the upper ends, transmit the motion from the inclines through the rod *d*, arms *e* and *f*, rod *g*, and arm *h*, to the exhaust-valve rock-shaft; the exhaust-valve being closed when the lever *c* has made half its movement, or on reaching its vertical position. The steam-valves are closed by the same cam-yoke *a*, through the rod *i*, lever *J*, arm *K*, rods *l*, *l*, and rock-arm or cam *m*, communicating motion to the closing-arm *A* of the steam-valve. The closing-arm *A* is in the form of a segment; the face being made of two curves, the difference in their radii being equal to the lift of the steam-valve: this segment or cam is adjustable by hand, that is, the closing-face can be brought sooner or later under the toe of the lever *B* or upper steam-valve, performing the closing or "cut off" at the point required. The water-cylinder *C* is used exclusively for opening the steam and exhaust valves, and is furnished with a piston, admission and exhaust ports, valves, &c., like any steam-cylinder. The piston-rod is attached to a cross-head, and connected to the levers *c*, by the rod *D*. The admission and exhaust valve are operated from the double-curved arm or cam *E*, on the rock-shaft *E*. The slot in the arm *E* is composed of two curves joined together in the vertical centre by an inclined slot; the difference in the radii of the curves being equal to the movement of the valve, and the length of the incline determines the time of action. On the end of the lever *G* is a roller revolving freely on a journal, and fitting the slot on the arm *E*, the vibrating motion of the arm raising or depressing the roller from one curve to the other, imparting a like motion to the other end of the lever *G*, and through the rod *H* and right-angled arm *I* to the valve-rod *K*. It will be observed that this valve motion is intermittent. There is another valve in the water-cylinder chest which we call the supply-valve; as it opens and closes the communication between the water-chest and the rising main, and is operated from the roll-lever *c*, through the connecting-rod *L* and lever *M*, attached to the valve-rod; this motion to the supply-valve is also intermittent, and made by the slot in the rod *L* and lever *M*. The ends of the lower levers *B*, *B'*, of the steam-valves are connected to weighted plungers *N*, *N'*, working in small open cylinders, or dash-pots *R*, *R'*, one for each valve; the gravitation of the weighted plungers opens the steam-valves through the rods *O* and lever *P*, attached to the valve-stems, and the time taken to open the valve wide being regulated by the velocity of the water forced out of the dash-pots, a small cock being fitted to each for this special adjustment. This completes the description of the various parts of the gearing and their separate duties; we shall now show the combined action of the whole in relation to the steam-piston.

The steam-piston having reached midway on its downward stroke, of course the frame or yoke *a* is also at mid-position in the same direction, and the upper steam-valve open—its weighted plunger unlatched and at the bottom of the cylinder; the lower exhaust-valve is also open, leaving free communication between the under-side of the steam-piston and the condenser. These are positions of the parts as illustrated in Fig. 1852. Now, as the cut off usually takes place at or about half-stroke in this engine, it will be seen, by reference to the figure, that the closing part on the periphery of the arm *A* is just entering under the toe or cam *Q* of the lower lever or upper steam-valve; and very little more movement of the arm *A* will close the valve—that is, the lower will be lifted by the action of the arm, transferring its motion through the rod *O* and lever *P* to the valve-stem, forcing it downward and closing the valve, at the same time the lower lever *B* on its lift is carried with its weighted plunger to the top of its dash-pot *R*. The latch-bolt *s*, shown in the figure as withdrawn, enters a socket in the plunger by the action of a spring on its back, and holds the plunger there until it is time to open the upper steam-valve again on its next downward stroke; the closing-arm *A* moves on without producing any further motion to the lower lever *B*, its toe simply resting on the curve of the arm as it passes under it. The steam-valve being now closed, the balance of the down-stroke is made by the exhaust steam; the frame or yoke *a* is descending, and the water-cylinder piston *C* is at full stroke towards the steam-cylinder; the admission-valve *K* of the former has just accomplished its half-movement, that is, it is square over its cylinder ports. When the frame or yoke *a* has descended so that the lower end of the upper incline *b* comes in contact with the roller *t*, on the lever *c*, the water-cylinder valve *K* has completed its movement, opening the back port to the exhaust passage, and removing the water on the back of the piston, and leaving the front port open ready for the admission of pressure on the front side of the piston. The motion of this admission-valve ceases now, or at least until the frame *a* has arrived at the same position on the up-stroke, when a similar but a reverse motion takes place. This cessation of motion to the admission-valve is accomplished by the rock-arm *E* having moved its curved slot or cam over the roller, the movements to the valve attachments being produced while the inclined part of the slot is passing under the roller of the lever *G*. The frame or yoke *a* is still descending under the operation of the expanding steam; the upper incline *b* has forced the lever *c* over its vertical position or half-movement, closing gradually the lower exhaust-valve through the various connections, rock-arms, and toes. The duty of the upper incline *b* ends here for the down-stroke; at the same instant the admission-valve covering the supply port between the water-cylinder chest and rising main is opened by the action of the rod *L* and lever *M*, and water under pressure admitted to enter the already open port of the water-cylinder, carrying the water-piston to the end of its stroke, and with the lever *c*, through the connecting-rod *D*, which movement opens the upper exhaust-valve, and permits the steam that has just expended its power on the down-stroke to escape to the condenser; by this same movement the short arm *V* comes in contact with the end of the slot in the latch-bolt of the lower steam-valve, withdrawing it, and allowing the lower steam-valve to be opened by the gravitation of the weighted plunger *N*, through similar rods, levers, and so on, as described for the upper steam-valve. The engine is now reversed and commencing its upward stroke; but the direction reversed, the lower incline *b*, on the frame *a*, performing a similar duty on the upper stroke as the upper one did on the down-stroke, and so on continually. In such movements cams perform important operations. See BANK-NOTE PRINTING MACHINE. BATTERY. BRICK-MAKING MACHINES. MECHANICAL MOVEMENTS. PIN-MAKING MACHINES. PRESS. SEWING MACHINES.

CAMERA LUCIDA.

The camera lucida is a little bit of peculiarly-shaped glass, placed on a prop, and it enables any person, although that person be ignorant of the rules of perspective and but little accustomed to make drawings, to take with a pencil or pen on paper the lines and shades of any machine or other object with ease and accuracy.

This useful little instrument, conveniently mounted for use by Elliott Brothers, 449, Strand, is shown in Figs. 1853, 1854; the small four-sided glass prism is set at K.

Fig. 1856 is an enlarged section of this prism at right angles to the edges. A is a right angle, and B an angle of 135° . The angle at the eye and the one opposite are equal; each of those angles must therefore be equal to $67\frac{1}{2}^\circ$:

$$135 = 90 + \frac{90}{2}, \text{ and } 67\frac{1}{2} = 45 + \frac{45}{2}.$$

The bit of glass, or glass prism, which is not much larger than a thumbnail of ordinary size, is held in a brass frame K, Fig. 1855, which is attached to an upright rod, having at its lower end a screw clamp, to fix it to the edge of a drawing-board or table, Figs. 1853, 1854. The prism K is fixed at the height of about 10 or 12 in. from the table, and has its upper face, A, Fig. 1856, that is K, 1855, nearly horizontal. Rays coming from an object, R S, Fig. 1856, and falling nearly perpendicular on the first surface, enter the glass prism, and undergo total reflection from the contiguous surface, then they fall at the same angle on the next surface, and are totally reflected again; lastly, they emerge nearly perpendicular to the horizontal surface, as represented in Fig. 1856. The eye receives the emergent rays, and perceives the image $r s$, with all the shades,

lines, and colours of R S, on a sheet of paper upon a drawing-board or table to which the instrument is made fast. If the lines of the image are traced with a pencil, a very correct design

is obtained; but there is some difficulty in seeing both the image and the point of the pencil, for the rays from the object give an image which is farther from the eye than the pencil. This difficulty is readily surmounted by a little practice, and by placing between the eye and the prism a lens, which gives to the rays from the pencil and those from the object the same divergence. In this case, however, it is necessary to place the eye very near the edge of the prism, so that the aperture of the pupil is divided into two parts, one of which sees the image, and the other the pencil. The arrangement of the horizontal face, Fig. 1855, effects this object to the greatest nicety. Amici's camera lucida, represented in Fig. 1857, is preferable to that of Wollaston, Fig. 1856, inasmuch as it allows the eye to change its condition to a considerable extent, without ceasing to see the image and the pencil at the same time. It consists of a triangular glass prism, BDr , right angled at B , having one of its perpendicular faces BD turned towards the object PQ that has to be drawn at pq ; the other side of the prism Br is placed at right angles to an inclined plate of glass, nm . The rays PQA , proceeding from the object, and, entering the prism, are totally reflected from the base at C , and emerge in the direction st . They are then partially reflected from the glass plate mn at t , and form a vertical image of the object PQ , which is seen by the eye in the direction tpq . The eye, at the same time, sees through the glass mn , the point of a pencil applied to the paper, and the outline of the object may be traced: when straight lines have to be traced, a ruler can be applied.

CANAL. FR., *Canal*; GER., *Kanal*; ITAL., *Canale*; SPAN., *Acequia*, *Canal*.

1. Canals differ in this regard from rivers, that they have a regular bed, having throughout the same inclination and the same profile; and they carry down the same volume of water throughout their length. In case one of these conditions is not fulfilled, where, for instance, after a certain slope, another is assumed, there will result two canals, the one succeeding the other.

If from the point o , Fig. 1858, at the bottom of the canal, a horizontal line op is drawn, its corresponding vertical qp will be the slope of the canal for the length oq . It is called the *absolute slope*, if o and q are the extremities of the bed of the canal; and the *relative slope*, or the slope per foot, if oq is 1 ft. long. Calling the slope p , if L is taken for any length of a canal, D being the difference of level between the ex-

tremities of this portion, we have $p = \frac{D}{L}$; or, if e represents the angle of inclination $p = \sin. e$.

The section of a canal, or any water-course, is the area of the section made by a plane perpendicular to the axis of the current; in a rectangular canal, if l = breadth and h = depth, s , or area of section, is $s = lh$; if it is trapezoidal, l = breadth at bottom, and n the slope of the sides, or the ratio of the base to the height, then $s = (l + nh)h$ or $s = (l + \cos. f. h)h$, where f is the inclination of the sides to the horizon.

That part of the contour of the fluid section in contact with the bed or bottom, as well as sides or berms, is called the *wetted perimeter* of the section. Designating it by c for rectangular canals, we have $c = l + 2h$; for trapezoidal, $c = l + 2h\sqrt{n^2 + 1} = l + \frac{2h}{\sin. f}$.

Dubuat gives the name of *mean radius* of the section, for the ratio of the area to that of the *wetted perimeter*, or $\frac{s}{c}$.

Let us now examine the nature of the motion of water in canals, that is to say, the nature and expression of the forces which produce it; thus establish the formulæ of this motion, with their various applications; and, finally, ascertain the quantity of water which canals can receive at their heads or inlets.

2. *Nature of Motion in Canals.*—Gravity is the sole force that acts upon a mass of water left to itself, in a bed of any form; it produces all the motion which takes place.

Whenever its action upon each fluid particle (whether it be that which it exerts directly downwards, or that indirectly produced by the lateral pressure of the adjoining particles) is destroyed, so that the fluid mass is brought to a state of rest, its surface will be horizontal. Reciprocally, when the surface of a fluid is horizontal, exception being made for any impulse before impressed upon it, all action of gravity will be destroyed, and no motion can take place. But as soon as this surface is inclined, motion takes place, and continues, even if the bottom of the bed is horizontal, and even if it should have a counter-slope for some distance. Whence the principle, admitted in hydraulics, that the motion of particles in a water-course is due wholly to the slope at the surface; this slope it is which is the immediate cause of motion, and enables gravity to act.

3. Let us examine the mode of action of this force, and what is its measure in the different cases that may occur, which are represented in Fig. 1858.

Suppose, then, a canal, in which the surface of water is parallel to the bottom of the bed, and consider the very small section A . The fluid particles which are on the bottom $a'b'$, will descend by the direct action of gravity, as down an inclined plane. Those which are above, up to the surface ab , forming, as it were, threads laid upon the first, will descend in the same manner. The effective portion of gravity, that which is not destroyed by the resistance of the bed, and which causes the motion, will be represented by the height ac , and this height will be $g \sin. i$; i being the inclination of the surface ab to the horizontal bc . The indirect action of gravity, or the lateral pressure experienced by each particle, being the same in all directions, by reason of the parallelism of ab and $a'b'$, will not occasion any motion.

Let us admit, now, a current with a surface more inclined than its bed, and represent a small

section of it by B. Take, then, into consideration, any particle, m , traversing the section in the direction mn . This particle, or rather the linear system of particles $m n$, will experience: 1st. The direct action of gravity, which we represent by the height m of the inclined plane mn , or by its equal cd , md being taken equal to nb . 2nd. The indirect action due to the inequalities of pressure upon the two extremes of the system m and n ; at the upper extremity m , conformably to the rules of hydrostatics, the pressure is represented by the height of the fluid column ma ; at the lower extremity it is represented by nb ; the resultant of these two pressures, that which produces motion, will equal then $ma - nb = ad$: as for the pressures which each particle of the system experiences at its sides, perpendicular to mn , they will be equal to each other, and reciprocally destroy each other, and have no effect. Thus the system $m n$ will be urged downwards by the two forces ad and cd , or by their sum ac , which is $g \sin. i$, i being the inclination of the surface.

When the bed is horizontal, as in the section C, the direct action of gravity upon the particles in contact with the bottom will, it is true, be entirely destroyed by the resistance of the bottom; but the indirect action, or the inequalities of pressure, will amount to $ad' - bb' = ac = g \sin. i$. For all other particles m , the moving force will be as above, $mf + (ma - nb) = cd + da = ac = g \sin. i$.

Finally, if the bottom has a counter-slope, as in D, the particles upon it will be urged back or up stream, by its relative gravity, $ka' = cd$; but, on the other hand, they will be urged downward by the difference of the pressing columns ad' and bb' , or by ad . Hence it follows that they will be impelled in this last direction by $ad - cd = ac = g \sin. i$.

4. It follows, from these different facts, that, in a water-course of any form, each particle, in traversing a section having an inclination of surface equal to i , receives from gravity an impulse represented by $g \sin. i$; that is to say, that if the impulse continues during one second, it will produce a velocity equal to $g \sin. i$; this, then, is the expression of the accelerating force, and is dependent solely upon the inclination of the surface.

This slope, so to speak, may vary at every step, or it may be constant for a long space, in which case a longitudinal section of the surface of the current forms a right line. This is frequently the case in canals, properly so called, of a constant slope and profile; the surface lines and the bottom lines can neither converge nor diverge, and must be parallel; the surface will then have the same inclination as the bottom, and the $\sin. i$ will be $= \sin. e$, or $= p$ (2), and the accelerating force will be $= g p$.

5. From what has been said, water running in a canal is constantly subject to the action of an accelerating force; so that, if it encounter no other opposing force, it will descend with an accelerated motion, and its velocity would never be uniform. Nevertheless, it often attains this uniformity in a very short space of time, after which the acceleration is inappreciable. Experience proves this to be a fact; it is to be seen in most canals, even those of great slope. Thus Bossut, causing water to run in a wooden canal 656 ft. long, with a slope of 1 in 10, and having divided the canal into spaces of 108 ft. each, has found that each division, excepting the first, has been traversed in the same time. There must then be, after a certain period of time, a retarding force, which destroys at each instant the effect of the accelerating force, and which is equal to it. Thus, water will move along with a velocity acquired in the first moments of its running; a phenomenon similar to that produced in nearly all motion; in that of machines, for example.

But in canals there can be no retarding force but that which comes from the resistance of the bed. This resistance cannot be called in question; from experiments made with a tube 2.06 ft. long, there was a discharge of 5.22 cubic ft. in 100"; and when its length was doubled to 4.12 ft., dimensions in other respects the same, it took 117" to discharge the same volume. Thus the velocity in the tube was diminished in the ratio of 117 to 100; and it can only be that the canal, by reason of its increased length, offered a greater resistance to the velocity; it therefore resisted motion.

6. Let us examine the nature of this resistance.

When water passes over the surface of a body, there being no repulsion or negative affinity between the two substances, it wets this surface; that is to say, a thin lamina of fluid is applied to it, penetrating its pores, and it is retained there, both by this engagement of its particles, and by the mutual attraction of the particles for each other.

It is over such a revetment or watery covering, fixed against the sides of the canal, that the water which it conducts must pass. The thin sheet of this mass, immediately in contact with this covering, by sliding along and rubbing against it, mingles its particles with those of the covering—it adheres, and its velocity is retarded. In consequence of the mutual adhesion of the particles, this stoppage, gradually diminishing, is communicated from one to another of the adjacent layers, till it is felt by the most distant fillets. The mass, in consequence, receives a mean velocity less than would take place without the action of the sides and the viscosity of the fluid.

The cause of this diminution of velocity has often been attributed to the friction of the water against the sides of its bed. Such a friction, if it occurs at all, is of a nature entirely different from that of solid bodies against each other; it depends neither upon the pressure nor the nature of the rubbing-surfaces. Dubuat is convinced, by direct experiments, that the resistance of water is independent of its pressure. He has never yet found any variation in the friction of water upon glass, lead, pewter, iron, woods, and different kinds of earth.

This last fact might be accounted for by observing that in all cases the friction can only take place upon the aqueous layer which covers the sides of the bed. But a friction independent of pressure? It would seem quite natural to admit that the resistance could proceed from no other source but the adhesion of the particles of water in motion, both among themselves and with those of the fluid-covering of the sides of the bed.

This adhesion has been measured by weights. Dubuat found that, to detach tin plates from tranquil water with which they had been brought in contact, there was needed, beside their own weight, an effort of 0.96 lb. avoirdupois to 1.03 lb. the square foot of surface.

Venturi, by means of a remarkable experiment, affords a direct evidence of the effect of adhesion,

which enables the particles of water in motion to catch up and carry in their train those which are contiguous to them in a fluid mass at rest. To a reservoir A, Fig. 1859, kept constantly full, was fastened a box filled with water, in which was placed a trough CD, open at its ends, and its bottom resting on the edge D. A small tube was placed in the reservoir, with its end at O. As soon as this was opened, the jet which issued, passing through the water which had found its way into the trough, drew with it the part adjacent; this was replaced by that immediately next it, which in its turn was replaced by the water in the box; so that, in a short time, the water fell from the level of gD to gh .

7. Since the resistance is from the action of the sides of the bed, the greater the extent of these sides, that is to say, the greater the *wetted perimeter* for any unit of length, the greater the amount of resistance.

But this resistance of the perimeter will be shared among all the particles of the section, since their motion is connected by a mutual adhesion; thus, the greater the number of particles, or the greater the section, the less will the velocity of each, and consequently their mean velocity, be changed. The effect of resistance will be in the inverse ratio of the section.

On the other hand, the resistance will increase with the velocity. The greater this is, the greater will be the number of particles drawn at the same time from their adhesion to the sides; and, further, it must draw them more promptly, and consequently expend more force; so that the resistance will be in the double ratio of the velocity. The viscosity of the fluid occasions still another resistance, which becomes more sensible, compared to the first, as the velocity is smaller. Dubuat has observed this important fact, and Coulomb, through a series of experiments, found that it is simply proportional to the velocity. Thus the expression of ratio between the resistance and velocity involves two terms; in one, the velocity is as the second power; in the other, as the first; this last, which is but a small fraction of the velocity, will disappear in great velocities; it is always inferior to the other, when the velocity exceeds 0.23 ft., but below this it preponderates. In short, the resistance experienced by water from its motion in a canal, is proportional to the wetted perimeter, to the square of the velocity, plus a fraction of velocity, and is in the inverse ratio of its section. Experience proves that this is very near the truth.

With the symbols already adopted, in calling bv the fraction of the velocity in question, and a' a constant multiplier, the expression of resistance will be $a' \frac{c}{s} (v^2 + bv)$.

8. After what has just been said upon the resistance of the bed and its effects, the different fillets of a fluid in motion in a canal will have a velocity the greater as they are removed from the sides of the bed; thus they will have different velocities. Nevertheless, in estimating the discharge of a canal, we may admit that the whole mass of water in motion is endowed with a mean velocity; which will be such as, being multiplied by the section of the canal, will give the volume of water passed in one second. So that if Q represents this volume, s being the section and v the mean velocity, we have $Q = sv$.

9. From what has been stated above, it follows that the greatest velocity of a current will be at its surface—in its middle, if the transverse profile is regular—if it is not, then in portions very nearly corresponding with the greatest depths; it is there that is generally found the *thread of water*, or fillet of the greatest velocity.

This velocity of the surface, being that most easily determined by experiment, the knowledge of its ratio with the mean velocity is a subject of great interest in practice; it will enable us to determine this last velocity so as easily to calculate the discharge. The investigation of this ratio has been the object of many hydraulic observers, as we shall see in the article on Rivers; we confine ourselves here to what concerns canals.

Dubuat has made precise experiments upon this subject. They are in number thirty-eight. They were made with two wooden canals 141 ft. in length; the one of a rectangular form 1.6 ft. wide—the section of the other a trapezium whose small base was $\frac{1}{2}$ ft., with its sides inclined $36^\circ 20'$ to the horizon (making $n = 1.36$); the depth of water varied from 0.17 ft. to 0.895 ft., and the velocity from 0.524 ft. to 4.26 ft. Dubuat concludes, from these experiments, that the ratio of velocity at the surface, to that of the bottom, is greater according as the velocity is less, and that this ratio is entirely independent of the depth; that to the same velocity of surface corresponds the same velocity of bottom. He has observed also that the mean velocity is a mean proportional between that of the surface and that of the bottom. Calling u the velocity of the bottom, V that of the surface, and v the mean velocity, he gives the results of his observations by the formula

$$u = (\sqrt{V} - .298868)^2 \text{ and } v = \frac{V+u}{2} = (\sqrt{V} - .149434)^2 + .022332.$$

Prony, after discussing the experiments of Dubuat, has thought this the more convenient formula, $v = \frac{V + 7.78188}{V + 10.34508}$.

Here is a small Table of some values of v corresponding to values of V , as given by this formula. Prony, taking a mean term, has thought that, in practice, we may take $v = 0.8V$; that is to say, in order to have the mean velocity of a current of water, we may diminish that of the surface one-fifth.

10. *Formula of Motion.*—We have two kinds of motion to consider. Most frequently, the surface of a current in a long and regular canal

V.	V.	v.
mètres.	feet.	
0.25	.8202	0.77 V
0.50	1.6404	0.79 V
1.	3.2809	0.81 V
1.50	4.9213	0.83 V
2.	6.5618	0.85 V

assumes a constant slope, which is the same as that of the bottom of the bed, and this surface becomes parallel to this bed. Then all transverse sections are equal; the mean velocity is the same in each, and the motion is uniform.

But it often happens that the surface varies from point to point, and is not the same with that of the bottom; so that, at different points of the canal, the sections, and consequently their velocities, are no longer equal. Still, the quantity of water admitted in the canal remaining the same, upon each isolated point, the section of the fluid mass will be constantly the same, and the velocity then will always have an equal value: all, then, is constant, and the motion, without being uniform, will be permanent.

11. *Uniform Motion.*—We have already remarked that, when the water in a canal becomes uniform, the retarding force equals the accelerating force; and that the expression for this last, in such kind of motion, is gp ; so that we have $gp = a' \frac{c}{s} (v^2 + bv)$; or, making $\frac{a'}{g} = a$, we have

$$p = a \frac{c}{s} (v^2 + bv).$$

If, at a portion of the canal where the motion is uniform, we take two points upon the surface of the fluid, whose distance apart we represent by L' , and difference of level or absolute slope by D , we have $p = \frac{D}{L'}$, and $D = a \frac{c L'}{s} (v^2 + bv)$. If we take the canal throughout its entire length, which we called L , and H being the difference between the head and foot of the same; from this difference H , we must take a height due to the velocity v of uniform motion, and it will be presently shown (27) that $H - \frac{v^2}{2g} = a \frac{c L}{s} (v^2 + bv)$.

12. It remains to determine the two constant coefficients a and b .

Prony, in combining the results of thirty experiments made by Dubuat, has undertaken and executed this determination. Some years afterwards, Eytelwein following the steps of Prony, but extending his observations upon ninety-one canals or rivers, in which the velocity varied from 0.407 ft. to 7.94 ft., and the fluid section from .151 sq. ft. to 28.030 sq. ft., found $a' = .0035855$, or $a = .000111415$, and $b = .217785$, the English foot being the unit.

Thus, putting for g its value = 32.18 ft., the fundamental equation for the motion of water in canals will be $p = .000111415 \frac{c}{s} v^2 + .0000242647 \frac{c v}{s}$; or, observing that $v = \frac{Q}{s}$ (8), Q being the discharge, $p s^3 = .000111415 c Q^2 + .0000242647 c Q s$. Of the four quantities, Q , p , s , and c , or, remembering that $s = (l + n h)$, h and $c = l + 2 h (\sqrt{n^2 + 1})$ (1), of the four quantities, Q , p , h , and l , three being given, this equation enables us to ascertain the fourth. As for n , the slope to be given to the banks, it will be indicated by the nature of the soil in which the canal is dug.

13. It is seldom that the velocity is found among the list of problems to be resolved; still, for any case where its direct expression is required, the first of the two equations above gives

$$v = -0.1088946 + \sqrt{8975.414 \frac{p s}{c} + .01185803};$$

or, more simply, and with sufficient accuracy, $v = \sqrt{8975.414 \frac{p s}{c}} - 0.1088946$.

14. Consequently, we have from $Q = s v$,

$$Q = s \left(-0.1088946 + \sqrt{8975.414 \frac{p s}{c} + .01185803} \right), \text{ or}$$

$$Q = s \left(\sqrt{8975.414 \frac{p s}{c}} - .1088946 \right).$$

15. In great velocities, those of 3.2809 ft., for instance, or any above this, where the resistance is simply proportional to their square, we have

$$v = 94.738 \sqrt{\frac{p s}{c}}, \text{ and } Q = 94.738 s \sqrt{\frac{p s}{c}}.$$

Let there be, for example, a canal, whose section is a trapezium 13.124 ft. wide at top, 3.2809 ft. at bottom, and 4.92 ft. deep; with a slope of 0.001. Required, the quantity of water which it will convey.

We have $p = 0.001$; $l = 3.2809$ ft.; $h = 4.9214$ ft. With regard to n , or ratio of base to height of banks, the height is that of the trapezium, and the base is one-half the difference between the two bases; so that $n = \frac{13.124 \text{ ft.} - 3.2809 \text{ ft.}}{2 \times 4.9214} = 1$. From this, $s = (l + n h) h = (3.2809 + 4.9214) 4.9214 = 40.366$ sq. ft.; and $c = l + 2 h \sqrt{n^2 + 1} = 17.2$ ft. Consequently, Q , the quantity sought, is

$$Q = 40.366 \left(\sqrt{8975.414 \frac{40.366 \times .001}{17.2}} + .01185805 - .108895 \right) = 180.87 \text{ cub. ft.}$$

If we neglect the term .01185805 under the radical, we have for $Q = 180.843$, which only differs from the above by .027.

The formula above for great velocities would give

$$Q = 94.738 \times 40.366 \sqrt{\frac{.001 \times 40.366}{17.2}} = 180.65 \text{ cub. ft.}$$

16. The slope is directly given by the fundamental equation which we have already established (12).

The Canal de l'Oureq furnishes both an example of the mode of its determination, and some remarks worthy of attention.

There were 106.61 cub. ft. of water a second to be disposed of; the projected navigation required there a depth of 4.9214 ft.; and in order that the water should always be at hand for the service of the fountains in Paris, it was necessary that it should have at least a velocity of 1.1483 ft.; the soil was such as to admit of a slope of $1\frac{1}{2}$ base to 1 of height.

We have, then, $Q = 106.61$ cub. ft.; $v = 1.1483$ ft.; $h = 4.9214$ ft.; and $n = 1.50$. Moreover, from the given terms of the problem, s is known, for $s = \frac{Q}{v} = \frac{106.61 \text{ cub. ft.}}{1.1483 \text{ ft.}} = 92.843 \text{ sq. ft.}$

l will also be known, since from the expression $s = (l + n h) h$, we deduce

$$l = \frac{s - n h^2}{h} = \frac{92.843 - 1.50 \times 4.9214^2}{4.9214} = 11.483 \text{ ft.};$$

consequently, we have $c = l + 2 h \sqrt{n^2 + 1} = 29.227$ ft.; whence the general equation,

$$p = .0001114155 \frac{v^2 c}{s} + .000024265 \frac{v c}{s};$$

substituting the numerical quantities, gives $p = 0.00005502$: such is the slope indicated by the formulæ.

Girard, the engineer who planned the canal, arrived at very nearly the same result. But he has observed, with reason, that aquatic plants, growing always upon the bottom and berms of the canal, augment very much the wetted perimeter, and consequently the resistance; he remembered that Dubuat, having measured the velocity of water in the canal (du Jard) before and after the cutting of the reeds with which it was stocked, has found a result much less before the clearing. Consequently, he has nearly doubled the slope given by calculation, and has carried it up to 0.0001056; the length of the canal being 314966 ft., this gives 33.260 ft. of absolute inclination.

17. If the dimensions l and h were the one unknown, and the other one of the given quantities of the problem to be solved, we take the values of c and s as functions of these two dimensions, and substitute them in the fundamental equation (12); l would then be deduced by the resolution of an equation of the third degree, and h by that of an equation of the fifth degree.

Let us determine, for example, the width to be given at the bottom of a canal, appointed to conduct 123.60 cub. ft. of water, with a depth of 4.9213 ft., the slope being 0.0001, and the soil of such a character as to require for slope the base to be twice the height. Thus, $Q = 123.60$ cub. ft.; $p = 0.0001$; $h = 4.2649$ ft.; and $n = 2$.

We substitute these two last quantities in the expressions of s and c (1), which in their turn are substituted in the general equation. This will involve, then, only the unknown term l ; and, making all reductions, and arranging according to the powers of l , we have

$$l^3 + 23.943 l^2 - 46.578 l - 3832 = 0.$$

Substituting for l , we find, on trial, $l = 11.188$ ft.

18. Most generally l and h are not given terms of the problem; we have only Q and p , or the volume of water which the canal ought to conduct, and the slope which it should have, leaving the engineer to determine the width and depth. To obtain these two unknown quantities, there is but one equation; the problem, therefore, is indeterminate. The engineer then supplies the gap, in giving such a figure as he deems best adapted to the profile of the projected canal; this figure, indicating the relation between the two dimensions, furnishes the equation which was hitherto needed.

In the choice of this figure, regard must be had to the object most important to be fulfilled, and that that is adopted which fulfils it with least expense of construction and of maintenance. When it is desired to convey the greatest possible quantity of water to the point where the canal empties, according to the formula of discharge (14 and 15), the volume of water brought down is so much the greater, as the section of the fluid mass is greater, and as the wetted perimeter is smaller; consequently, we must take a figure which, with the same perimeter, presents the greatest surface.

19. Geometry informs us that the circle has this property. The semicircle, and therefore a semi-circular canal, has the same property, the ratio between the semicircle and semicircumference being the same as that between the circle and entire circumference.

Then follow the regular demi-polygons, and with the less advantage, as the number of their sides is less; and so among the most practicable forms we have the regular demi-hexagon, the demi-pentagon, and finally the half-square.

But these figures are not admissible for canals in earth excavations; their berms, not having sufficient slope, would cave in.

In order that they should be sustained without revetment, they should have a slope of from 1.50 to 2 of base to height, as there is more or less consistency in the soil; in the regular semi-hexagon, where the slope is larger than the other named polygons, it is only 0.58. A slope of 1 is only adopted in excavations of small importance or for temporary use; but for canals, the slope of 2 to 1 is usually adopted, and sometimes 2½; such was the slope adopted at the canal of Languedoc.

20. As the usual profiles of canals are trapezoidal, the question of figure of greatest discharge is reduced to taking, among all the trapeziums with sides of a determinate slope, that which yields the greatest section for the same wetted perimeter.

Since the section s , or $(l + n\hbar)\hbar$, should be a *maximum*, its differential will be zero, and we have $\hbar dl + l d\hbar + 2n\hbar d\hbar = 0$.

Since the perimeter remains constant, the expression $c = l + 2\hbar\sqrt{n^2 + 1}$ (1) being differentiated, gives us $0 = dl + 2d\hbar\sqrt{n^2 + 1}$. The value of dl , derived from this equation and substituted in the preceding, gives $l = 2\hbar(\sqrt{n^2 + 1} - n)$.

With this value of l , we have $s = \hbar^2(2\sqrt{n^2 + 1} - n) = n'\hbar^2$, by making $2\sqrt{n^2 + 1} - n = n'$; and $c = 2\hbar(2\sqrt{n^2 + 1} - n) = 2n'\hbar$.

Putting these equivalents of s and c in the fundamental equation of motion (12), it becomes

$$\frac{p n'^2 \hbar^5}{2} = 0.0001114155 Q^2 + 0.0000242651 Q n' \hbar^2.$$

This and the preceding equation give for l and $\hbar$ the *maximum* sought.

Let us take, for example, $Q = 70.6632$ cub. ft., $p = .0012$, $n = 1.75$. The second of the above equations is reduced to $\hbar^5 - 1.2522 \hbar^2 - 178.04 = 0$.

Making, by a first approximation,

$$\begin{array}{llllll} \hbar = 2.82 \text{ ft.}, & \text{we have} & \dots & \dots & \dots & -9.6593 = 0. \\ \hbar = 2.85 \text{ ft.} & \dots & \dots & \dots & \dots & -0.1821 = 0. \\ \hbar = 2.850567 \text{ ft.} & \dots & \dots & \dots & \dots & +0.0002 = 0. \end{array}$$

So that the true value of $\hbar$ will be 2.850567 ft. This will give for l , which is $2\hbar(\sqrt{n^2 + 1} - n)$, = 1.5107 ft.

These dimensions are those of the stream. But the depth of the excavation should be greater.

It would be well to increase it to $\dots \dots \dots 3.937$ ft.

The breadth at bottom remains the same $\dots \dots \dots 1.5105$ ft.

The breadth at level of earth will be $\dots \dots \dots 15.29$ ft.

There will then be, a running foot of cut, an excavation of $\dots \dots \dots 33.1$ cub. ft.

In homogenous earth, so long as the depth of excavation does not exceed $6\frac{1}{2}$ ft., and the upper width $16\frac{1}{2}$ ft., the expense of digging will be proportional to the volume of excavation, and the figure of least section will therefore be the most economical.

21. As for those canals where there is no fear of caving in, such as those excavated in rock, or protected with masonry, which are more particularly termed *Aqueducts*, as well as those in wood and mill courses, they most always have a rectangular form. Still, as we have seen, the regular demi-hexagon of the same section will conduct more water; but simplicity, facility, and economy of construction have prevailed. We must remember that the dimensions of the rectangle should have a width nearly double the depth of the fluid mass it is destined to carry, and consequently it

should be $\sqrt{\frac{2Q}{v}}$.

22. *Permanent Motion.*—We have seen (10) that permanent motion differs essentially from uniform in this, that the mean velocity in each section, remaining constant, is not the same as in the adjacent sections; consequently, the sections of water are no longer equal to each other, their depth is not the same, the surface of the fluid is not parallel to that of the bed of the stream, and its inclination varies from one point to another. We have examples of such motion in canals too short for the velocity to acquire a uniformity, at the head and foot of long canals, and in those whose bottom is horizontal.

23. Let there be a current endowed with permanent motion, and let us regard that part of it comprised between A and M, Fig. 1860. Through these two points of the surface, and through N infinitely near to M, imagine transverse sections A O, M P, and N p, made perpendicular to the axis of the current. From the points A and M we draw the horizontal lines A E and M t; E M will be the fall of the surface from A to M, which we designate by p' ; t N, or the elementary increment of the slope, will be $d p'$ or $M N \sin. i$, i being always the angle t M N of inclination of the surface to the horizon. Let us consider upon the section A O, taken up stream for the point of departure, the particle having the mean velocity of the section, whatever else may be its position, and let $m m'$ be the path which it describes as far as M P. Call z the length of this path, t the time employed in traversing it, and v the velocity of the particle on arriving at m . We have then $m' n' = dz$; dt will be the time in passing dz , and $d v$ the increment of velocity during this passage (which will be $-d v$ when motion is retarded).

The forces which act upon the particle m while traversing $m m' n'$ are: 1st, on one side, gravity, which tends to accelerate its motion, and whose whole action, according to what we have said in (3), is $g \sin. i$; 2nd, on the other side, the resistance of the bed, which tends to retard its motion, and whose expression is (7) $a' \frac{c}{s} (v^2 + b v)$.

These two forces acting opposite to each other, their resultant, or the effective accelerating force, will be equal to their difference. But in all variable motion, the accelerating force is also expressed by the increment of the velocity, divided by that of the time, or by $\frac{d v}{d t}$; we have then

$$\frac{d v}{d t} = g \sin. i - a' \frac{c}{s} (v^2 + b v).$$

Multiplying all the terms by dz (remarking that $\frac{dz}{dt} = v$, the space, divided by the time, equaling the velocity; remarking, further, that $dz \sin i = dp'$, since for dz or $m'n'$ we may take MN , which will not differ from it save in extreme cases, but by an infinitely small quantity of the second order, and that $MN \sin i = tN = p'$), we have $v dv = g dp' - a' \frac{c}{s} (v^2 + bv) dz$.

Such is the equation established by Poncelet.

Integrating, determining the constant for the section A, when $p' = 0$, $z = 0$, and $v = v_0$, we have

$$\frac{v^2}{2} - \frac{v_0^2}{2} = g p' - \int a' \frac{c}{s} (v^2 + bv) dz.$$

But (8) $v = \frac{Q}{s}$; and if we designate by s_n the area of the section at the final point M, and by s_0

that at the initial point A, which let us divide by g , and remembering that $\frac{a'}{g} = a = 0.000024265$ (12), and that $b = 0.000111415$, we have finally

$$p' = \frac{Q^2}{2g} \left(\frac{1}{s_n^2} - \frac{1}{s_0^2} \right) + \int \left(0.000111415 \frac{c Q^2}{s^3} + 0.000024265 \frac{c Q}{s^2} \right) dz;$$

a formula which gives directly the slope of the surface from A to M.

In the application, the quantity under the sign $\int$ may be integrated by approximation. For this purpose, divide the arc A M or z into portions, A B, B C, C D, and so on, whose lengths are such that the divisions of the arc may be taken, without sensible error, for right lines. Designate these lengths by $z_1, z_2, z_3, \dots, z'_n$, and the areas of the sections at A, B, C, $\dots$, M, by $s_0, s_1, s_2, s_3, \dots, s_n$, and by $c_0, c_1, c_2, \dots, c_n$, their respective wetted perimeters. We measure or take immediately these lengths, sections and perimeters upon the given stream, and all will be known in the integral, which will become

$$0.000111415 \left(\frac{z'_1 c_1}{s_1^2} + \frac{z'_2 c_2}{s_2^2} + \dots + \frac{z'_n c_n}{s_n^2} \right) Q^2 + 0.000024265 \left(\frac{z'_1 c_1}{s_1^2} + \frac{z'_2 c_2}{s_2^2} + \dots + \frac{z'_n c_n}{s_n^2} \right) Q.$$

Let us represent by M the multiplicator of Q^2 , and by N that of Q ; let us make also $\frac{1}{2g} \left(\frac{1}{s_n^2} - \frac{1}{s_0^2} \right) = D$, the equation will then be $p' = (D + M) Q^2 + N Q$.

$$24. \text{ From this we deduce } Q = -\frac{N}{2(D+M)} + \sqrt{\frac{p'}{D+M} + \left(\frac{N}{2(D+M)} \right)^2}.$$

In our article on Rivers we shall have occasion to apply this formula, with its details, to streams whose form and delivery were otherwise known, and we shall see that its deductions are not far from the truth.

In canals where the slope of the bed and the profiles are constant, the calculations are much simplified; the depth of water at any one station will be sufficient to know its section and wetted perimeter; moreover, the depths, with the inclination of the bed, will give that of the surface.

As an example, let us determine the volume of water which a rectangular mill-course, 8.202 ft. wide, with a horizontal bed, will conduct to a mill. At four points, distant 328.1 ft. apart, we

No.	z .	h	c	s	$\frac{z'c}{s^2}$	$\frac{z'c}{s^3}$
	feet.	feet.	feet.	sq. ft.		
0	0	5.052	18.306	41.44	0	0
1	328.09	4.901	18.004	40.20	3.655	.0909
2	328.09	4.845	17.892	39.74	3.717	.0935
3	328.09	4.573	17.348	37.51	4.045	.1078
	P	.479			11.417	.2922

take four depths, noted in column h of Table. Since the canal is rectangular, and $l = 8.202$ ft., then $s = 8.202 h$ ft., and $c = 8.202 + 2h$ ft. We calculate these values for the different stations, and then, through these, those of $\frac{z'c}{s^2}$ and $\frac{z'c}{s^3}$. All are in the above Table.

The canal being horizontal, $p' = 5.052 - 4.573 = .479$ ft. We have

$$D = \frac{1}{64.364} \left(\frac{1}{37.51} - \frac{1}{41.44^2} \right) = \dots \dots \dots 0.000001995$$

$$M = \text{sum of } \frac{z'c}{s^3} \times 0.000111415 = \dots \dots \dots 0.00003255$$

$$N = \text{sum of } \frac{z'c}{s^2} \times 0.000024265 = \dots \dots \dots 0.0002770$$

$$\frac{N}{2(D+M)} = 4.0092, \frac{p'}{D+M} = 13866, \left(\frac{N}{2(D+M)} \right)^2 = 16.0742 \text{ ft.}$$

So that $Q = -4.0092 + \sqrt{13866 + 16.0742} = 113.81$ cub. ft.

With the formula for uniform motion in taking a mean height between the extreme heights, and for a slope per foot, .479 divided by 984.27 ft., the sum of the z ; we have

$$Q = -4.299 + \sqrt{15072 + 18.478} = 118.54 \text{ cub. ft.}$$

25. The equation (23) which gives the slope of the surface of the current knowing some of the sections, will further, by the taking of one depth only, enable us to trace in its progress the curve described by a fluid point of the surface of a water-course in a canal, whose slope, profile and discharge are otherwise known.

For the place, when the depth of water is given by the aid of the profile, it will be easy to establish its section and wetted perimeter; let us designate them by s_0 and c_0 . Take a second station, at a distance z' from the first, so small, that in this distance there shall be but little variation in s_0 and c_0 , and so that they may be regarded as constant in the expression of the resistance of the bed, and we have $p' = \frac{Q^2}{2g} \left(\frac{1}{s_1^5} - \frac{1}{s_0^5} \right) + a c_0 \left(\frac{Q^2}{s_0^3} - \frac{Q}{s_0^2} \right) z'$.

We may neglect the first part of the second member at the first trial, which amounts to supposing a uniform motion throughout the whole length z' , and we shall have the first approximate value of p' . This will enable us, knowing the slope of the bed, to assign very nearly the depth of the stream at the second station, and consequently gives us s_1 . All will then be known in the above equation, and we have a second and more approximate value of p' than the first. If it is thought best, we are able from this to calculate a third, which shall be still more exact. In the same manner, we may determine the depth at the third and fourth stations, and so arrive at all the ordinates of the curve required to be constructed.

26. But this method involves much uncertainty, and many suppositions, and often leaves us much embarrassed. We can avoid, in part, these inconveniences, and go directly to the solution of the problem, by introducing the slope of the bed in the problem, according to the method of Bélanger.

For this purpose let us take in hand the first differential equation of (23); and we remark that the angle i , or iMN , or MNs , Fig. 1860, is composed of two other angles: first, MNr , which measures the inclination of the surface upon Nr , parallel to the bottom of the bed Pp ; designate this by j : second, the angle rNs , which this bottom makes with the horizon, and which we have already called e ; so that $i = j + e$, and consequently, $\sin. i = \sin. j \cos. e + \sin. e \cos. j$. But $\sin. e = p(1)$, $\cos. e = \sqrt{1 - p^2}$, and $\cos. j = 1$, considering the smallness of the angle j ; thus $\sin. i = \sin. j \sqrt{1 - p^2} + p$, and the equation becomes

$$\frac{dv}{dt} = g \sin. j \sqrt{1 - p^2} + gp - a' \frac{c}{s} (v^2 + bv). \quad [A]$$

The term $\frac{dv}{dt}$ may take a finite form, which will depend upon the figure of the bed. When the canal is of small extent, we usually consider the slope as uniform, with a mean width l . From this supposition results $s = lh$ and $c = l + 2h$; so that $v = \frac{Q}{s} = \frac{Q}{lh}$, and $dv = -\frac{Q l dh}{l^2 h^2}$; moreover (23), $v = \frac{dz}{dt}$ or $dt = \frac{dz}{v} = \frac{lh dz}{Q}$; then $\frac{dv}{dt} = \frac{Q^2 l dh}{l^3 h^3 dz} = \frac{Q^2 l}{l^3 h^3} \sin. j$, since $\frac{dh}{dz} = \frac{Mr}{MN} = -\tan. i$ or $-\sin. j$.

Substituting this value in the equation [A], neglecting p^2 , which will always be small compared to 1, substituting for g , a' and b their numerical values (12), and evolving $\sin. j$, we have

$$\sin. j = \frac{P l^3 h^3 - \{0.000114155(l + 2h)Q^2 + 0.000242651(l + 2h)lhQ\}}{.031073 l Q^2 - l^3 h^3}$$

We have taken for the curve of a fluid thread of the surface of the stream, a polygon, each of whose sides has a finite length $MN = z'$, and whose inclination relative to the bed is j : the difference Mr between the depths of the two extremities of a side will be its slope compared to this bottom; designating it by p'' , we have $\sin. j = -\frac{p''}{z'}$, and consequently,

$$p'' = \frac{P l^3 h^3 - \{0.000114155(l + 2h)Q^2 + 0.000242651(l + 2h)lhQ\}}{l^3 h^3 - .031073 l Q^2}$$

The series of values of p'' will enable us to trace the polygon, or required curve.

Instead of comparing the slopes to the bed, we might compare them with the horizon, and thus have their value p' , in observing that $p' = p'' + p$.

Inlets.—Canals, with the exception of those for navigation, at their points of departure receive their water from reservoirs or retaining basins placed at their heads, and which most frequently are portions of the river whose level has been raised for this purpose by dams.

The head of the canal, at the point for receiving water, is either entirely open, or furnished with gates. Let us examine these two cases.

27. *Canals of Open Entrance.*—Water, on its entrance into an open canal, forms a fall, its level being lowered for a certain distance; then it is elevated a little by slight undulations, beyond which the surface takes and maintains a form very nearly plane and parallel with the bed, its slope and profile being always considered as constant. The velocity is accelerated from the top to the foot of the fall; it then diminishes during the elevation of its surface, and, soon after, its motion continues in a manner sensibly uniform. Dubuat, who has made a particular study of the circumstances of motion at the entrance of canals, and throughout their course, has found such an order of things established, that when the motion has become regular and uniform, the velocity of the surface is very nearly that due to the entire height of the fall, and that the head due to the mean

velocity is equal to the difference between the height of the reservoir and that of the uniform section. So that if H represent the height of water in the reservoir above the sill of entry into the canal, h the height of the uniform section, that is to say, the constant depth of the current after it has attained a uniform motion, and v the velocity of this motion, we have $H - h = 0.015536 v^2$; or rather, $0.015536 \frac{v^2}{m^2}$, m being the coefficient of contraction which the fluid mass experiences at its entrance into the canal, a contraction which occasions a greater fall.

Dubuat, from several experiments made with wooden canals (9), with heights of reservoir H from .394 ft. to 2.887 ft., has found that m varies from 0.73 to 0.91; but he remarks that, in great canals, where the height due to the velocity is small compared to the depth, the contraction will be less, and he thinks there would be no sensible error in taking $m = 0.97$. Eytelwein assumes 0.95 for large canals, and 0.86 for the narrow, such as is adopted for most mill-courses. He, as well as Dubuat, supposes, for these coefficients, that the bottom of the canal is at the same level with the bottom of the reservoir, and that it is but a prolongation of it. If this were not the case, there would be a contraction at the bottom, and the value of m would be a very little smaller.

28. The fall which takes place at the entrance of a canal, by diminishing the depth h , lessens the discharge Q , of which this depth is an element. So that, in order that the canal should receive all the water which it can afterwards convey, we must prevent the fall.

Theoretically, to accomplish this end we must enlarge the upper part of the canal for a length somewhat beyond $0.015536 \frac{v^2}{p}$ ft., so that the mean widths of the new profile should increase as they approach the reservoir, with an inverse ratio to the velocity of the stream at each of these widths, beginning with 0, its value in the reservoir, till, by the uniform acceleration of its descent, it reaches v ft. at the foot of the enlarged part. According to this law, the width at the reservoir should be infinite, since the velocity is zero. Such a case would be impracticable, and any approach to it would involve much labour and expense.

Consequently, the engineer who, without involving himself in unnecessary expense, desires to obtain for the canal all the water that can reasonably be expected, will be content to widen the approach, and in doing this must be governed by local circumstances. For instance, if the head is to be laid in masonry, he will give to the approach the form of the contracted vein; that is to say, taking the width of the canal as a unit, we shall have for length of the enlarged part 0.7, and 1.4 for width at the mouth, as comprising the full sweep to be given to the angles. But it is not worth while to exaggerate the advantages from these widenings, as the discharge by them will hardly be increased by more than some hundredths.

29. Dubuat also concludes, from his observations, that the velocity and section are uniformly established at a certain distance from the reservoir, just as if uniformity commenced at the origin of the canal. In this case we may suppose the fall to be made suddenly on its entrance to the canal, and thence the fluid surface maintains a uniform slope. Its value is obtained (1 and 11) by dividing the difference of level of the two points by their distance apart; one may be taken at the origin of the canal, and according to our supposition its level will be less than that of the reservoir, by a quantity equal to the height of the fall $H - h$. Consequently, if D is the difference of level between the reservoir and any point of the surface at the distance L from the reservoir, but where the motion has acquired its uniformity, p being always the effective slope, we have

$$p = \frac{D - (H - h)}{L} = \frac{D - 0.015536 v^2}{L}.$$

30. With these given quantities we can resolve the various questions pertaining to a canal from a reservoir, supposing always that the motion becomes uniform, which will not be the case unless the canal has a certain length, or should it have no inclination, or approach 90° , and so on.

Let us resume the equation, $H - h = 0.015536 \frac{v^2}{m^2}$, and in place of v substitute its value, given

$$\text{in (13), and we have } H - h = \frac{0.015536}{m^2} \left(\sqrt{8975.414 \frac{p^s}{c}} - .108895 \right)^2.$$

$$\text{Moreover, we have } Q = s \left(\sqrt{8975.414 \frac{p^s}{c}} - .108895 \right).$$

By means of these two equations, in giving to s and c their expression, as functions of the dimensions of the canal, and substituting the preceding value of p , when p is not directly given we can determine either the discharge, or the slope, or one of the dimensions; the other quantities being known. We give an example.

Suppose we purchase the site where it is intended to locate the entrance to the canal, with the condition that it shall be rectangular in form, open to the height of the dam, with a width of 13.124 ft., and whose sill is to be 6.562 ft. below the ordinary low-water line. We wish to conduct this water to a mill distant 869.438 ft., so that the surface of the stream, on its arrival there, shall not be over 1.4436 ft. below the low-water mark of the reservoir above. What will be the quantity of water conducted to the mill?

The cutting being made in the dam, the rectangular canal 13.124 ft. by 6.562 ft. deep is fitted in; the clause of the grant forbids any attempt to enlarge the approach; and every alteration within the appointed limits would diminish the discharge.

Since the canal is rectangular, and 13.124 ft. wide, we have $s = 13.124 h$ ft., and $c = 13.124 h + 2h$; moreover, $p = \frac{1.4436 - (H - h)}{869.4384} = \frac{h - 5.1184}{869.4384}$ ft., H being 6.562 ft. Although the canal is large,

so that the coefficient of contraction would probably be above 0.95, yet, to be prudent, we will take a mean between those indicated by Eytelwein, and call it $m = 0.905$. With these values the first of the two equations above will be

$$6.562 - h = \frac{0.015536}{.905^2} \left(\sqrt{8975.414 \frac{13.124 h (h - 5.1184)}{869.4384 (13.124 + 2h)}} - .108895 \right)^2.$$

Reducing $6.562 - h = .018969 \left(\sqrt{135.47 h \frac{(h - 5.1184)}{(13.124 + 2h)}} - .108895 \right)^2$ gives us the value of h .

To obtain it, put successively for this unknown quantity in the second member, several numbers; first, 6.234 gives $h = 5.889$ ft.; which in its turn gives 6.114. In this manner we obtain successively 5.968, 6.053, 6.001, 6.040, 6.014, 6.034, 6.020, 6.027, 6.0237 ft. Thus the true value of h falls between these two last numbers; let us take the smallest, $h = 6.0237$ ft. Then

$$p = \frac{6.0237 - 5.1184}{869.4384} = 0.001041 \text{ ft.}$$

All the quantities required to ascertain the discharge being known, we introduce them into the second equation, and so obtain $Q = 417.795$ cub. ft. Such is the volume of water per second which the canal will lead to the mill.

When the velocity of the current is required to be 3.28 ft. or more, we substitute the expression for velocity given in (15), and the two equations to be used will be

$$H - h = \frac{139.44}{m^2} \cdot \frac{p s}{c} \text{ and } Q = 94.738 s \sqrt{\frac{p s}{c}};$$

or, supposing a mean width l , and taking always $m = .905$,

$$H - h = 170 \frac{p l h}{l + 2h} \text{ and } Q = 94.738 l h \sqrt{\frac{p l h}{l + 2h}}.$$

The slope p will be given either directly, or by the expression $p = \frac{D - (H - h)}{L}$.

In the above example, the values of H , l and p , put in the first of these equations, which is of the second degree, will give readily $h = 6.027$ ft.; also, $p = .001045$ and $Q = 418.86$ cub. ft.; results nearly identical with the preceding.

31. Among the questions relating to the admission of water in canals, there is one of too much interest to millwrights for us to pass it by without a notice in this work.

The force of a current to move machinery depends not only upon the quantity of water which it conveys, but also upon the height from which it falls; so that this force will be measured by the product of the quantity with the height of the fall of water. The greater the slope given to the canal, the greater will be the amount of water brought, and this is one of the factors of the product; but, at the same time, the fall (the other factor) is diminished, and it will be found that the product having been at first augmented with the slope, will after that be diminished, and then continue to decrease. There is then a *maximum* of power, which it is essential to determine and put in use. Without employing analytical formulae, this determination can be arrived at in a simple manner, as will be seen in the following example.

Let us resume that given in the last number, and let us suppose the height of fall there to be 14.764 ft. The water taken by the canal has arrived at the mill with a loss of level of 1.447 ft.; consequently, the effective fall will only be 13.317 ft. In multiplying this by the quantity of water brought down, 418.86 cub. ft., we have for the product 5577.9 cub. ft.; the corresponding slope was 0.001045. Let us increase this slope successively to 0.0015, .002, .0025, and .003; the respective products of the quantity by the fall will be 1859.42, 1931.12, 1939.94, and 1907.45 cub. ft. The slope of .003 has already occasioned a diminution; in trying that of .0026, the product will be 1938.18 cub. ft.; whence we conclude that the *maximum* of effect lies between the slopes of 0.0025 and .0026. Finally, as the variations of the product are very small between 0.002 and 0.003, we adopt, between these limits, those best suited to the locality and nature of the machinery used; there may be some for which a great fall will be preferred.

I will remark that the given solutions of all the problems in question can be regarded only as simple approximations; for in order that they should be exact, the bases on which they rest, that is to say, the conclusions which Dubuat has drawn from experiments, should be explicitly confirmed by observations made upon great canals; and it would, moreover, be necessary to be quite sure that the water, before it reaches the extremity of the canal, has attained a uniform motion, and we have but limited means of coming to a positive assurance.

If water which is in the reservoir of a river to which a canal has been adapted, should arrive there directly, with an acquired velocity, the height of fall which takes place at the entrance will be less than that indicated (27) by a quantity equal to the height due to this velocity.

Canals with Gates.—When a canal receives its water through openings of a system of gates, established at its head, which is generally the case with mill-courses, either the upper edge of the orifice will be completely and permanently covered by the water already passed into the canal, or it will not.

32. If the head above the centre of the orifice is great, so as to exceed two or three times the height of the orifice, its upper edge will not be covered by the water below, and the discharge will be the same as if there had been no canal. Experiments with orifices in thin sides and furnished with additional canals, leave no doubt upon this subject; they justify an assertion, long since made by Bossut, the exactness of which has been questioned.

Bossut fitted to an orifice .0886 ft. high and .4429 ft. wide, made at the bottom of a reservoir, a horizontal canal of the same width, and 111.55 ft. in length; he produced in it currents under

heads of 12·468 ft., 7·802 ft., and 3·937 ft., and he received at the extremity of the canal the same quantity of water that issued from the orifice when the canal was taken away.

The cause of this equality is apparent. When the water is urged by a great head, and consequently issues with great velocity, the contraction it experiences on all sides renders the section smaller immediately beyond the interior plane of the orifice, so that, on issuing, it touches neither the sides nor the bottom of the canal; it acts as if it were projected in air, and the discharge continues the same that it would if this were really the case. Beyond the contracted section the vein dilates, it is true; it joins the sides of the canal; it meets with resistance, and runs less swift; but then it is too far from the orifice to react against what issues from it, so as to reduce its discharge. This will always be given by the formula $m'l'h'\sqrt{2gH}$, l' and h' being the width and depth of the orifice; m will have the same value as for orifices in thin partitions.

Generally, we take 0·70 for the coefficient of ordinary gates of flumes. See Poncelet and Lesbros' experiments.

Without adopting another coefficient for each particular case, the volume of water which enters a canal furnished with large gates, and under a great head, may be had approximately by the formula $0\cdot70\ l'h'\sqrt{2gH}$.

33. When the water, impelled beyond the gates by a great head, falls into the canal, it meets a resistance which diminishes gradually its first velocity, and so increases the section of its current. If the width of the canal is constant and equal to the opening of the gate, it will be the depth which receives the gradual increase; so that the surface of the fluid below the orifice, or rather below the point of greatest contraction, up to that where the increase of depth ceases, will present a counter-slope. Frequently masses of water will be detached from the summit, and will, rolling back, return towards the orifice; usually they will be retained, being as it were repelled by the velocity of the stream; though sometimes they will return even to the gate, and re-cover the orifice, though but for a moment. Even in this case the discharge will be the same as if there were no canal, and it will be calculated by the formula of the preceding number.

34. These phenomena do not occur when the head is small. Water, on issuing from the gates, is in contact with the sides of the canal; it experiences a retarding force, which is communicated to the fluid at the instant of its passage through the orifice; the discharge, and therefore its coefficient, is lessened; but we have no further guide for its determination. There may be some cases where, with a very small head, the gate is without sensible influence; thus Eytelwein has found the same discharge, whether the gate was wholly raised, or slightly dipped on the down-stream side.

But in case it is immersed any considerable depth, and the fluid vein at its issue is entirely covered over with still water, the height due to the velocity of issue will be the difference between the elevation (above any given point) of the surface above the gate and of that below the gate. For the elevation below the gate we take the height or depth of water in the canal, when its motion has become regular; as that immediately at the gate would be found too small. Consequently, if h is the height in the canal, H' the height up stream above the sill of the inlet, the discharge of the orifice of the gate, and consequently that of the canal, will be expressed by $m'l'h'\sqrt{2g(H'-h)}$. But the dis-

charge of the canal, the motion having become uniform, is also (14) $s\left(\sqrt{8975\cdot414\frac{ps}{c}} - \cdot108895\right)$.

We have then $m'l'h'\sqrt{2g(H'-h)} = s\left(\sqrt{8975\cdot414\frac{ps}{c}} - \cdot108895\right)$, an equation which enables

us to solve the various questions relative to canals furnished with gates at their heads.

Suppose, for instance, we would determine the quantity h' ; we must raise the gate, at the entrance of a long rectangular canal of 4·265 ft. width and ·001 slope, in order that the water may have a depth of 2·625 ft.; the width of the gate is 3·609 ft., and the height of the reservoir 3·937 ft. We take $m = 0\cdot70$ (32). We have then $l' = 3\cdot069$ ft.; $H' = 3\cdot937$; $h = 2\cdot625$; $l = 4\cdot265$; $p = 0\cdot001$; $s = 4\cdot265 \times 2\cdot625 = 11\cdot195$ sq. ft.; $c = 4\cdot265 + 2 \times 2\cdot625 = 9\cdot515$ ft. These numerical quantities, substituted in the equation above, give us $23\cdot209 h' = 35\cdot180$; whence $h' = 1\cdot514$ ft.

The Suez Canal.—The plans and sections of the Suez Canal given in Figs. 1861 to 1867, are, with some trifling additions, the same as those compiled by Sir W. T. Denison from 'Compagnie Universelle du Canal Maritime de Suez: Carte générale de l'Isthme, etc., 1866,' and the plans of Port Said and of the Port of Suez, from 'Percement de l'Isthme de Suez: Actes constitutifs de la Compagnie Universelle du Canal Maritime de Suez, avec cartes et plans,' documents publiés par F. de Lesseps, the engineer of this great work. Our additions are taken from 'Histoire de l'Isthme de Suez,' par Olivier Ritt, 1869. Sir W. T. Denison's paper "On the Suez Canal" was read in the Institution of Civil Engineers, 16th April, 1867, and afterwards published in pamphlet form, edited by James Forrest, the secretary of the Institution. The thick black line in the plan, Fig. 1861, indicates the course, and Fig. 1862 is a vertical longitudinal section, of the canal; the horizontal lines in Figs. 1861, 1862, are to a scale of ·09 in. to a mile, and the ordinates, Fig. 1862, ·01 in. to a foot. Fig. 1864 is a cross-section at Port Said, and Fig. 1863 a cross or lateral of the canal at Suez; the scale of these sections is ·008 in. to a foot. Fig. 1865 is a plan of Port Said and the harbour on the Mediterranean; Fig. 1866 is a plan of the port of Suez, on the Red Sea: the plans of these places are given to a scale of 1000 yds. to an inch. The motions and actions of the water of the canal may be calculated, by the rules just established, from the levels, inclinations, and dimensions registered on Figs. 1867, 1863, and 1864.

Col. Denison, in his notes, as the work was being completed, observed:—The scheme of the Suez Canal may be said to comprise two distinct undertakings. The first, and principal, is the con-

1861.

struction and maintenance of a broad and deep salt-water channel on one level between Port Saïd on the Mediterranean, and Suez on the Red Sea. The second, preliminary in point of time, and indeed essential to the construction, as well as to the beneficial use of the canal, is the maintenance of a supply of fresh water sufficient for the wants of the population congregated along the line of canal, and specially at its two extremities.

The arrangements for the second of these undertakings have been completed. A canal, commencing at a place called Zagazig, to which water is brought from the Nile by one of the many branches from the main stream, has been carried to Suez, passing within about a mile or two of Ismaïlia, the central point of the main canal, and the head-quarters of the establishment of the Company. It is navigable for the whole distance, the fall from Zagazig to Suez being overcome by locks. From the point where the canal turns southward to Suez, a branch is carried first to Ismaïlia, where it provides a supply for the inhabitants, and for some hydraulic machinery, by which water is forced into a double line of 9-in. pipes, through which fresh water is carried along the side of the canal, supplying the various establishments along the line of about 50 miles in length, and a population at Port Saïd already numbering upwards of 10,000; and secondly, for a distance

of about a mile to the east of Ismaïlia, within which distance it is made to drop by two detached locks to the level of the Mediterranean. At the Suez extremity the fresh-water canal terminates in a lock, by which vessels drop into the creek which brings goods and passengers from the anchorage to the town.

In the immediate vicinity of the anchorage a dry dock, capable of taking in the largest steamer, is constructed.

The salt-water canal commences to the south-east of outer port, the ground being dredged out to the necessary depth, and to a width sufficient to give ample space for the exit and entrance of vessels. The canal sweeps away in a curved line towards the north, passing to the eastward of the fresh-water canal through the lowest portion of the land, which is, in point of fact, very little above the level of the Red Sea. Figs. 1861, 1862.

At a distance of $11\frac{1}{4}$ miles from the sea, the line crosses a spur from some hills to the westward, at a place called Chalouf: the cutting here consisted partly of a bed of hard conglomerate, 8 or 10 ft. in thickness, below which were strata of sand and clay. The surface of the soil at this cutting was about 12 ft. above the salt-water level, so that the total depth of excavation is 40 ft. The slope of the side was 2 to 1, and there was left a bench of about 12 ft. in width, 3 ft. above the surface of the water; while another bench, 12 ft. below the water, and 9 ft. wide, formed a base for the stonework employed to face the upper part of the slopes. The stone was procured in part from the excavation itself, and in part from quarries on the west shore of the Red Sea, a few miles south of Suez. The work here was carried on with a good deal of method. Inclined planes were cut in each bank, up which the wagons filled with spoil were hauled by steam-engines, and then drawn to spoil-banks at convenient distances. Pumps discharged the drainage water into a portion of an old salt-water canal, said to have been excavated by one of the Pharaohs.

Soon after leaving this cutting the canal had to pass through the Bitter Lakes, the surface of the water, or soil, in which is nearly on a level with the Red Sea. Here the cutting did not exceed the ordinary section of the canal.

The distance between Suez and Ismaïlia is about 50 miles.

A little east of Ismaïlia the branch from the fresh-water canal comes to an end, and passenger boats drop by two single detached locks to the level of the Mediterranean, into a salt-water canal about the same size as the other. For some distance this was only a branch, but at about 2 miles from Ismaïlia the branch enters the line of the main canal, which turns sharp to the left or northwards, and passes through a heavy sand-bank from 40 ft. to 60 ft. above the level of the surface water in the canal.

The works here were well executed: the contractor cut down the face of the excavation, and loaded the spoil into wagons; trains of these wagons were constantly in motion, being drawn by locomotives obliquely up the slope of the hill, and thence to spoil-banks at some distance on the west side of the canal. Some dredging machines were also employed to deepen the channel; the

soil thus raised was discharged into wagons and hauled up the bank. The amount of work done here was very great, as the sand-bank or ridge extended about 5 miles.

To the north of the sand-bank the canal entered the beds of some lakes—the soil of which was but a few inches above the Mediterranean. Here, in places, the soil had evidently a disposition to slide into the canal; as the trifling load of an embankment, sufficiently high to cover the fresh-water pipes, had forced the bank out, in spite of some piles and sheeting, which had been driven and fixed to support it. This sort of work extended the greater part of the remainder of the distance to Port Said, about 10 miles from which the canal entered Lake Menzaleh, a shallow sheet of salt water, through which the line was marked by slight embankments, distant apart the full width of the canal. At several points between the deep-sand cutting and the shore of Lake Menzaleh, the canal was opened to its full width. Dredging machines were employed both to widen and deepen it, and a great amount of activity and much skill were developed at this place.

The dredging machines were well put together. They were worked by powerful engines, and a variety of expedients had to be devised for the purpose of adapting them to the work they had to perform in lifting the spoil from a great depth, and discharging it at a point above the engine.

The main work at Port Said, Fig. 1865, was the jetty, or breakwater, which protects the port against the action of the north-westerly or prevailing winds. This jetty is formed of blocks of concrete, rectangular in form, and weighing 20 tons. Experience has shown that a block of this size (10 cubic metres) and of this weight is sufficiently massive to withstand the action of the heaviest sea. The concrete is composed of sea-sand, dredged from the harbour, and of good hydraulic lime procured from Marseilles, the proportion of lime to sand being about 350 lbs. of the former to a cubic metre of the latter, or about 1 to 13. Sea-water is used to mix the ingredients, which are well worked and amalgamated in mills, ten of which were driven by one steam-engine. The mixture was poured into cases, or frames, of wood, where it was allowed to remain four days; the cases were then removed, and the blocks subjected to the influence of an Egyptian sun for two months, by which time they became solid enough to withstand the action of the sea. Each mill turned out three blocks a day.

The contractor engaged to furnish the blocks, and to deposit them at appointed spots, for 400 francs a block.

The mass will, of course, stand at a much steeper slope than it would were the blocks of smaller dimensions, and there will be a large space between the blocks, which will eventually be filled with sand drifted in by the sea.

The Suez Canal was officially opened on the 17th of November, 1869. At that time fifty ships had passed from the Mediterranean to the Red Sea, or *vice versa*. From the 1st to the 17th of February, 1870, nineteen vessels, or a little over a vessel a day, went through from one sea to the other. The successful completion of this great work places its engineer, M. de Lesseps, high among the engineers of our time. In France he holds a position similar to that held in America by W. J. McAlpine, or to the one that John Scott Russell should hold in England. See BARRAGE. CONCRETE MACHINE. DREDGING MACHINES. LOCKS AND LOCK-GATES. RIVERS.

CANDLES. FR., *Chandelles, Bougies*; GER., *Kerze*; ITAL., *Candele*; SPAN., *Velas*.

In its natural state, fat of animals is always associated with cellular tissue and other foreign matters, which must be separated before it can be used as candle stock.

In the process called *dry melting*, much practised by small manufacturers, the rough suet is cut into coarse pieces and exposed to the action of a moderate heat. By the more recent processes, the fat is not exposed to heat till it has been subjected to certain mechanical and chemical appliances, for the purpose of destroying the tissues. The first-named method possesses this decided advantage, namely, that the residue or cracklings can be profitably used as food for hogs, fowls, and so on. There is, moreover, an economy in fuel, while the simplicity of the process commends itself to the notice of inexperienced manufacturers. Disadvantages, on the other hand, arise: an obnoxious smell emanates from the heating of rough tallow which has been collected and suffered to remain till it has become rancid, and the cellular tissues, blood, or other portions, advanced towards putrefaction. Fat from animals recently slaughtered does not, however, yield any very unpleasant effluvia. Another and more important disadvantage, in an economical point of view, is found in the smaller amount of fat obtained, as portions always remain with the cracklings when heated in this manner. The first care of the chandler should be to impress on the mind of his tallow merchant the importance of a more careful treatment of the rough suet than is generally observed by the butcher. The fat ought to be freed from the membranous and muscular parts, then cut into thin slices and hung up in a cool place, *not heaped up while yet warm*. By operating thus, the disagreeable odour existing before melting, and increased during the process to an unbearable degree, can, at least, be delayed for several days.

First, the fat is chopped, for which purpose cutting machines are often used similar to the *straw-cutting table*; sometimes a thin, sharp-edged mince-hatchet is employed, about 2½ ft. in length. This is held with both hands, and the fat, spread out on a beech block, is chopped into small pieces in all directions. A third instrument is a kind of stamp trough with muller, having a sharp blade in the form of an S, a contrivance frequently adopted for cutting beets. A more desirable and valuable instrument, however, is the ordinary rotary sausage-cutter. The fat is then placed in melting caldrons (hemispherical in form, and in this country made of cast iron), which are heated by open fire. These caldrons are covered with movable tin-plate hoods, so adjusted that, by means of pulleys, ropes, and counter-weights, they can be easily raised or lowered, whilst at the same time they serve to carry off the offensive vapours arising from the heated fat. Water is sometimes mixed with the fat in the caldrons, and this addition is specially beneficial when the fat has been long kept during the summer months, and thereby lost its natural moisture by evaporation. By gradually raising the temperature in the pan, the fat runs from the cells, and the whole is kept boiling from 1 to 1½ hour. The mixture of water with the fat-bubbles imparts to the liquid a milky appearance, but as soon as the water is volatilized the fat becomes clear. During the whole operation of melting and boiling, the ingredients must be constantly and thoroughly stirred in order to keep the fat and cracklings in incessant agitation, otherwise pieces of unmelted suet, coming in contact with the sides or bottom, would become scorched and acquire a brownish tint, of which the whole melting would necessarily partake. Scorched tallow is not very readily whitened. For separating the melted fat from the cracklings, it is ladled off from the caldron into a fine willow basket, or a copper box perforated at the bottom with innumerable small holes, set over large copper coolers, and allowed to remain undisturbed till all foreign matters have settled down. Before it congeals, it should be transferred into small wooden pails.

This operation is continued so long as the cracklings yield any fat; and during the process the heat must be maintained at a moderate temperature, to avoid scorching the materials. When the cracklings begin to harden they acquire a darkish tint, and hence are said to be *browning*. They are then pressed, and the fat thus obtained possesses somewhat of the brown colour of the cracklings, but not so much as to render it unfit for use as soap stock; it may, consequently, be mixed with that which has spontaneously separated while heating.

New Methods of Rendering.—The complaints of parties residing in the neighbourhood of candle and soap works, in consequence of the offensive effluvia disseminated by these establishments, have led to the invention of new apparatus, as well as to the introduction of new processes of rendering, until an entire reformation has resulted in the melting process, which we propose briefly to describe, long experience having demonstrated their utility.

No doubt the apparatus invented by d'Arcet, of Paris, in 1834, and introduced by the board of health of that city, has been tested in other places, where it did not interfere too much with the workmen's freedom of action, and the ready supervision of the melting process. As it is, moreover, applicable and may prove serviceable in other branches of manufacture, we here offer a few remarks relative to this invention.

One essential and valuable feature in his invention is his suggestion for conducting the rising vapours, consisting chiefly of hydrogen and carbon, through channels under the grate of the rendering pan, and using them as fuel. The pan is also covered with a strong iron plate, the front third of which can be lifted by means of a knuckle whenever it is necessary for stirring, filling, or emptying the kettle. D'Arcet was likewise the first who employed certain chemicals for the purpose of neutralizing or destroying the noisome effluvia arising from the pans. His propositions are found to be, as yet, the most valuable in use. In the process recommended by him, 50 parts,

by weight, of diluted acid (oil of vitriol) are first put into the kettle, then 1000 parts, in weight, of chopped fat are gradually added in four equal portions; and lastly, 150 parts of water, to which 5 parts, in weight, of sulphuric acid of 66° B. have been previously added. The whole is next heated. Under the influence of the acid, which partly destroys, partly solves the membranes, the rendering of even greater amounts of fat is effected in 1½ to 2½ hours; two hours, however, are seldom required. The inventor's proposition of using acids was made when pans were heated by the direct action of the fire; but now, for various substantial reasons, steam is more generally employed. This, however, does not prevent the gases arising from the pans being thrown into the furnace and thereby aiding combustion. It is obvious, moreover, that in the boiler of d'Arcet, stirring, as well as filling or emptying the contents of the pan, cannot be accomplished so readily as in an open pan; nor can these processes be performed without opening the covers, when the noisome vapours escape into the room, to the annoyance of the operators. To obviate this, a contrivance similar to that used by distillers in the mashing process could be introduced with decided advantage of comfort, as well as of certainty, for keeping up the necessary motion, to prevent adhesions to the sides or bottom of the vessel, and consequent incidental scorching.

The same may be said in regard to the pan for boiling fats lately patented in this country by W. H. Pinner, who yet claims the conducting of the noxious vapours into the fire as a *novelty*.

Wilson's Process has first been described by Morfit in his 'Treatise on the Manufacture of Soap and Candles.' The chief feature of this process is to steam the rough suet for ten or fifteen hours in a perfectly tight tank, under a pressure of 50 lbs. to the square inch, or more when lard is being rendered. A higher pressure, according to Morfit, is not profitable, for, though expediting the process, it produces an inferior quality of fat. No chemicals are used. The apparatus consists of an upright cylindrical vessel, made of strong boiler-plates, tightly riveted together. Its diameter is about two and a half times less than its height, and its capacity amounts to 1200 to 1500 gallons. It has a false bottom or diaphragm, below this a pipe enters, which is connected with an ordinary steam-boiler. There is a man-hole at the top, through which the vessel is filled with the rough suet or lard to within about 2½ ft. of the top. By a safety-valve, the pressure can be regulated. There are also some try-cocks, by which the state of the contents can be examined; if the quantity of condensed steam in the tank be too great, it will be indicated by the ejection of the fatty contents at the top one. There is, moreover, a regulating cock at the bottom for drawing off the condensed steam, as well as cocks in the side of the digester, by which the fatty materials can be drawn off. Through a hole made in the diaphragm, which can be shut and opened at will, the residual matters can be let out.

Fouche's Process is one of the most perfect. Fig. 1868 represents a vertical, and Fig. 1869 a horizontal section of the apparatus, as used by the inventor, after the line 1—2 in Fig. 1868. Fig. 1870 is a transverse section after the line 3—4 in the same figure. The vessel has a copper dome B, fastened by rivets. In this dome is a hole C for introducing fat, having a cover, which may be lifted by a chain going over a pulley, and the margin of the cover may be fastened to the vessel by clamps. This cover has a hole for observing the inside, which can be shut by a valve fastened to the lever D. E is a cap on the dome with the eduction-pipe for vapours, and PP is a safety-valve, with a counter-weight R. There is, moreover, an outer valve for the passage of air, either when filling or emptying the vessel, as well as a box for a thermometer. The vapours escaping through P

(which may be opened by the faucet O), pass into U for the purpose of being condensed there, or, when not condensed, for escaping through X. F is a worm, which fastened to the stays G, Fig. 1869, lies on the bottom of the vessel. Through L L steam is introduced from a boiler, and through M passes back into the same boiler. H H is a small pipe entering into the vessel A, through which steam also passes into the vessel, mainly for the purpose of keeping the melted fat in agitation. J is a tube, having a sieve at its upper end, and a movable crank below, by which it is fastened to the faucet Y. If the vessel is being emptied, the tube J is gradually let down until its upper part, with the sieve, reaches the bottom. The fat is then passed through J and Y, and through a fine sieve outside the vessel, which acts as a filter. In this, 1000 lbs. are first introduced with 80 lbs. of water; $2\frac{1}{2}$ lbs. of sulphuric acid of 66° , previously mixed with 16 lbs. of water, are then added. Steam is next turned on, which, as described, passes from the generator through the worm, and must have a tension of three atmospheres, or a temperature of 255° F. In the vessel, however, a tension of $1\frac{1}{2}$ atmosphere is sufficient, and when this is reached, the safety-valve is no longer charged with weights. The vapours formed in the vessel are conducted through X into the hearth of the steam-boiler furnace, so that all the noxious odours (which, however, by the action of the sulphuric acid, are diminished, but not destroyed) are thus conveyed from the working-rooms.

Evard's Process.—In its features, the apparatus used by this inventor very much resembles that of Wilson. The process, however, is based on the application of caustic lye, in the proportion of 25 gallons (each containing $\frac{1}{10}$ to $\frac{1}{4}$ lb. of solid caustic soda) to every 250 to 350 lbs. of rough tallow. It is the object of the application of the lye, as in d'Arcet's process, to dissolve the membranous parts, so that no preliminary mincing be necessary. For boiling the fat, steam is employed. As the alkaline lye is heavier than water, it will also, after the boiling is completed, more easily subside. It is then drawn off, and the fat left in the tank is again boiled with successive portions of fresh water, for the better separation of which, this compound is left for twenty-four hours in a warm liquid state before being drawn off into the coolers.

Stein's Process.—A mixture of slacked lime and small pieces of fresh-burnt charcoal is prepared, and spread upon a coarse cloth stretched over a hoop, of 2 in. in depth, and the circumference corresponding with the size of the pan. During the process of rendering, it is securely adjusted by suitable catches above the pan. The rising vapours from the latter, in necessarily passing this chemico-mechanical arrangement, are said to be entirely absorbed, so that thus all cause of complaint against tallow factories as health-destroying nuisances would be effectually removed.

Clarifying Tallow.—By mere melting and straining we do not obtain a fat entirely free from admixture of fine, undissolved substances. For separating these substances, therefore, it must be clarified. This is done by remelting it in water, either on free fire or by steam. Generally, no more water than 5 per cent. is taken, and stirred well with the fat till the mixture becomes emulsive. The whole is then allowed to rest, without further heating, till the water has separated, when the fat may be drawn off, or dipped off. Sometimes, in order to conceal the yellowish tint, a very little blue colour is added to the clear fat, consisting of indigo rubbed finely with some oil, of which a few drops are sufficient even for large quantities. The process of clarifying is occasionally repeated.

At the line of demarcation between the water and fat, a grey slimy substance is often perceptible, and the liquid itself is turbid. Instead of pure water, some tallow-melters take brine or solutions of alum, saltpetre, chloride of ammonium, or other salts. According to Dr. Orazio Lugo, these agents have no chemical action upon the fats, but simply induce a more rapid settling of the impurities and water, principally when strong agitation is used.

Hardening of Tallow by Capaccioni's Process.—In 1000 parts of melted tallow, 7 parts of sugar of lead, previously dissolved in water, are stirred, during which process the mass must be constantly agitated. After a few minutes the heat is diminished, and 15 parts of powdered incense, with 1 part of turpentine added, under constant stirring of the mixture. It is then left warm for several hours, or until the insoluble substances of the incense settle to the bottom. The hardening is produced by the sugar of lead, yielding a material similar to the stearic acid, while the incense is improving its odour; it is also said that by this treatment the guttering or running of the candles is entirely prevented.

Cassgrand's Process for Bleaching Wax.—By this process, the bleaching of the wax by the sun and air is not prevented, but much time saved. The inventor first melts the wax with steam, which together pass through long pipes, so that a large surface becomes exposed to the steam. After traversing the pipes, it is received into a pan with a double bottom, heated by steam; it is therein treated by water, left quiet for some time until its impurities are settled. It is then forced anew through the pipe together with the steam, washed a second time, and, if necessary, this process is repeated a third time. Probably water is absorbed by the wax, thus rendering it more easily bleached. The following is the arrangement of a bleachery:—

Stakes or posts are driven into the ground, and 2 ft. from the ground bag-clothes are stretched over them, or table-like frames are made from strips, and cloth stretched over the frames in the same manner as a sacking-bottom is stretched over a bedstead, care being taken to fasten the ends of the cords to the posts sufficiently firm as to prevent them loosening by the wind. This done, the wax ribbons are spread upon the cloth in a thin layer. It is important that the place selected for this arrangement be so that the sun's rays may have full play upon the exposed wax, but at the same time protected from the prevalent winds. The ribboned wax is daily turned over, in order that fresh portions of it may be affected by the sun; and should it not be sufficiently moistened by the dew or rain, soft water is poured over it. When it is not gradually becoming whiter, but still continues yellow upon the fracture, it is remelted, ribboned, and again bleached. The continuance of the bleaching process necessarily varies, depending, as it does, upon the weather; often one exposure to the sun and air suffices to bleach it, and no remelting is requisite. Four weeks are generally sufficient. The bleached wax is finally fused into cakes or square blocks,

previously moistening the moulds. As fast as the wax congeals, the cakes are thrown into a tub of clean, cold water, and then taken out and spread upon a pack-thread sieve for draining. Eventually, they are dried and packed in boxes for the market, the loss being from 2 to 8 per cent.

Wicks.—In the present day we designate the wicks as twisted and plaited; the former, loosely twisted, and the fibre presents the appearance of a spiral similar to the separate strands of a rope; the latter, now generally adopted for most kinds of candles, is made by interlacing and crossing the strands of the wicks in the same manner as plaiting straw of bonnets. Common wicks are simply an aggregation of several loosely-twisted threads forming one general cord of many fibres. This is effected by the ball winding machine, an apparatus of a very simple construction.

For cutting wicks, Sykes's Apparatus is in very general use, especially for tallow-candle wicks, which must be soaked with tallow at one end.

Fig. 1871 represents a vertical, and Fig. 1872 a horizontal view of it. *cc* are spools on which the wicks are wound. *b* is a roller with grooves cut around it, by means of which the wicks are conveyed into the clamp *d*, represented in Fig. 1873 on a larger scale, and as seen from the side.

It consists of two wooden frames, which are made tapering from the middle towards the end. On each side there is a feather of steel attached, for the purpose of holding the frames, with a space between them, which may be diminished by sliding the feathered clamps *ee* towards the middle, or increased by drawing them towards the end. Immediately behind the clamp there is a cutting apparatus, consisting of an immovable *f'* and a movable blade *f*, with a handle. *g* is a small vessel filled with liquid fat (which may be kept from solidifying by steam), and a board *i* lying on the lathe *h*.

The use of the apparatus is as follows:—The ends of the wicks, wound upon the spools *ccc*, are passed through the frame *d*, properly tightened by the clamps *ee*, so that all the wicks are kept firm. The knife *f* of the cutting apparatus is then lifted out of the way; the frame, with the wicks enclosed, is drawn backwards to the vessel *g*, and the ends of the wicks dipped in the melted fat; this done, the fat-soaked ends are drawn farther back and placed under the weight *I*, which holds them firmly while the clamps are loosened on the frame, and this returned to its first-described position and again tightened. The knife is next used, cutting all the wicks off at a stroke, then elevated, and the process repeated till a sufficient number of wicks are cut.

The thickness of the wicks, we may here remark, varies according to the diameter of the candles and the material of which they are made. The number of the cotton threads requisite to form a wick also varies according to their firmness. Scarcely two chandlers, however, observe the same rules in these respects. The yarn is composed of a slack-twisted cotton thread; No. 16 generally for plaited, and smaller, such as 8–12, for common wicks.

Bolley has published the appended index relative to the thickness of wicks. The yarn employed is No. 16.

For tallow candles, 8 per lb., the wick contains 42 threads.

"	7	"	45	"
"	6	"	50	"
"	5	"	55	"
"	4	"	60	"

These wicks, composed of ten, twelve, or even sixteen cords, are very loosely twisted, and form a kind of hollow tube.

For stearic candles, three-corded plaited wicks are generally used, smaller in size and of finer yarn. As, for instance—

Stearic candles, 4 per lb., the wicks consist of 108 threads.

"	5	"	96	"
"	6	"	87	"
"	8	"	63	"

Preparing Wicks.—This is done by the so-called *wick-mordants*, by means of which they are less combustible, especially those for stearic acid, and composite candles prepared. For this purpose, compounds composed of solutions of ammoniac salts, of bismuth, of borates, or boracic acid, are used. Some of the receipts given in the journals and books devoted to technology are good as far as the *quality* of the substances is concerned, but not as regards the *quantity*. The recommended solutions are generally too strong. This may be said most assuredly of the following (Smitt's) preparations for wax-candle wicks. He recommends 2 oz. of borax, 1 oz. of chloride of calcium, 1 oz. of nitrate of potash, 1 oz. of chloride of ammonium, to be dissolved in $\frac{3}{4}$ gallon of water, and afterwards dried.

A simple and cheap mordant for wicks consists in a sal-ammoniac solution of 2° to 3° B. This concentration is strong enough, and if a weaker one be used, a spark will remain on the wick after the candle has been blown out, and burning down to the fat, make relighting more difficult. Before moulding is performed, the wicks, having been saturated, are thoroughly dried in a tin box, surrounded by a jacket, in which steam is introduced. Instead of the sal-ammoniac, phosphate of ammonia is used in some factories. A very good mordant is also a solution of $2\frac{1}{10}$ oz. boracic acid in 10 lbs. of water, with $\frac{1}{4}$ of an ounce of strong alcohol, and a few drops of sulphuric acid. Some mordants, we are aware, have become unpopular. The fault is in the nature of the crude cotton, which does not always readily become moistened; consequently, from not having completely imbibed the mordant, portions of the thread remain unsaturated, and are not equally combustible with the others. An admixture of alcohol will possibly remedy this defect, inasmuch as cotton is easier moistened in diluted spirit than in pure water.

Dips.—These candles are made by stringing a certain number of wicks upon a rod, and dipping them in melted tallow repeatedly. Though made in large quantities, they are only manufactured in comparatively small establishments. The process is very simple; it is as follows:—The clarified and remelted tallow is poured into a tightly-joined walnut or cherry trough, 3 ft. long by 2 ft. wide, and 10 to 12 in. wide at the top, gradually diminishing to 3 or 4 in. at the bottom. A handle is fixed on each end for its easy removal, and when not in use it is closed with a cover. The operator commences by stringing sixteen to eighteen wicks at equal intervals on a thin wooden rod, about $2\frac{1}{2}$ ft. long, and sharpened at the ends. He then takes ten or twelve such rods and dips the wicks rapidly into the fluid suet in a vertical direction. This suet should be very liquid, in order that the wicks be soaked as uniformly as possible, after which the several rods are rested on the ledges of the trough, when, if any of the wicks be matted together, they are separated, and the rods so placed on a frame, having several cross-pieces, that the uncongealed tallow from the wicks may drop down, and while this is going on, which continues till the tallow is cooled and solidified, the operator is engaged in preparing another batch of rods. The fat in the trough, meanwhile, is so far cooled that in immersing the first dip again a thicker layer will adhere to the wicks. It is considered, we may observe, that when the suet solidifies at the sides of the vessel, the temperature is the most convenient for the object in view. It is, moreover, sometimes necessary to stir the ingredients to produce a uniform admixture, and in such cases much care should be taken so that no settlings be mingled with the mass, whilst by the addition of hot tallow any desired temperature may be obtained. The tallow on the wicks between each dipping becomes so gradually hardened, that at the third or fourth immersion new layers necessarily solidify; as a natural consequence of the method of dipping, the lower ends of the wicks become thicker than the upper, to remedy which the lower ends are again put into the melted fat for a few minutes, when the heat, as a matter of course, diminishes their dimensions. The process of dipping is continued until the candles acquire the requisite thickness. The conical spire at the upper end is formed by immersing deeper at the last dip, and if, eventually, the candles are too thick at the lower end, they are held over a slightly-heated folded copper sheet, so that the fat may melt, but not be wasted.

For the purpose of saving time, many mechanical arrangements have been devised and completed, one of the most useful and used of which, involving the least outlay and requiring only one operator, is the EDINBURGH CANDLE-WHEEL, Fig. 1874.

The following is a description of it:—A strong vertical post A is mounted on pivots, resting on a block T, and attached at the top in a beam PP, so that it can revolve freely on its centre. In the upright post A, six mortises are cut at short distances from each other, and crossing one another at an angle of 60° . Each of these six mortises receives a bar D, which swings freely on a pin C, run through the centre of the bar E and post A. At the extremity of each bar is suspended a frame E, containing six rods, on each of which are hung eighteen wicks, making in all 1296 wicks on the wheel. As the bars B are all of the same length, and loaded with nearly the same weight, it is obvious that they will all naturally assume a horizontal position. In order, however, to prevent any oscillation of the machine when turning round, the levers are kept in a horizontal position by means of small chains RR, one end being fixed to the top of the upright shaft, and the other in a small block of wood M, which exactly fills the notch F. Notwithstanding its appearance, the machine is very easily turned round, and, when in motion, each

port, as it successively passes over the tallow-kettle H, in its water-bath, mounted on a furnace K, is gently pressed downwards by the handle S. By these means the wicks are regularly immersed in the tallow, and the square piece M (when the handle S is pressed down) is thrown out of the notch by the small lever O, inserted in the bar B. In order that, when the operator raises the port, the piece M may return to its proper position, a cord is attached to it, passing over the pulleys V V, and regulated by the weights W W. In the bars D several holes are bored, by means of which they may be heightened and lowered at will.

It may be readily perceived, therefore, with what expedition the whole operation is performed (and that too by one operator), the ports being not unnecessarily removed after each dip, and the process of congealing being much accelerated, as the candles are kept in constant motion through the air. In moderately cool weather not more than two hours are necessary for a single person to finish one wheel of candles of a common size, and that if six wheels are completed in one day, 7776 candles will be manufactured in that space of time by one workman.

Moulds.—For moulding, besides the common metal moulds (a mixture of tin and lead), moulds of glass are sometimes used. The former are slightly tapering tubes, varying in length and dimensions according to the size of the candle to be manufactured, and, when required, are arranged in regularly perforated wooden frames or stands, with the smaller end downwards, forming the upper or pointed part of the candle. At this smaller end, the wick, previously saturated in melted fat, is inserted, filling the aperture, and, passing up the centre, is fastened perpendicularly at the opposite, that is, the upper end of the tube, to which is attached a movable cover. The melted fat is then poured in, generally with a small can, but a tinned iron syphon is better. It is requisite that the tallow should *completely* fill the mould, that it should remain uncracked on cooling, and should be easily removable from the moulds. This can, however, only be obtained when the fat at the sides cools more quickly than that in the interior, and when the whole candle is rapidly cooled. A cool season is, for this reason, far better; but a certain condition of the tallow, namely, that which it possesses at a temperature very near its melting-point, is absolutely necessary. According to Knapp, candle-makers recognize the proper consistence of the tallow for moulding by the appearance of a scum upon the surface, which forms in hot weather between 111° and 119° F., in mild weather at 108°, and in cold about 104°. The tallow is usually melted by itself, sometimes, however, over a solution of alum. The candles are most easily removed from the mould the day after casting, to be cut and trimmed at the base.

Moulding.—Moulding by hand is a very tedious operation, and only practised in the smaller factories; in more extensive establishments, where economy of time and labour is a consideration, machinery is employed.

Kendall's Moulding Apparatus.—Fig. 1875 represents a vertical transverse section through one of the mould-frames, exhibiting the candles drawn from the moulds. Fig. 1876 represents a top view of a row of moulds, showing the clamp in place ready to centre the wicks. The moulds are mounted upon cars, for being carried from place to place as required, each capable of conveying several dozens, which are heated to about the temperature of the melted fat by running the car into an oven. The moulds thus heated are carried by cars to a caldron containing the melted fat, with which they are filled. The car is then attached to one of the empty trucks and allowed to remain till the candles are cooled, when it is moved to an apparatus, by means of which the candles are drawn and the moulds re-wicked, and again ready to be heated and filled.

To facilitate the transference of the moulds to different parts of the room, the cars on which they are mounted are carried about on trucks fitted with rails at right angles to the track on which they run; so that the car with the moulds can be carried forward or back by the truck, and run to the right or left on its own wheels upon lateral tracks at will.

In Fig. 1875, *m m* represent moulds mounted on two horizontal boards *a* and *b* (in which round holes are cut) and tightly screwed at the upper end, around which a thin wooden frame is attached, three-fourths of which is firmly fastened, whilst the other one-fourth forms a slide. The lower end of the moulds rests on pieces of vulcanized india-rubber *o*, let into the cross-bar *e*; each piece of india-rubber being pierced with a hole somewhat smaller than the wick, and as the wick is passed through this hole, the latter compresses it so tightly as to prevent the fat from leaking out. In like manner, the leakage is prevented between the bottom or tip *n* by the pressure of the mould upon the india-rubber. The spools K hold the wicks firmly and

centrically secured by clamps, as seen in Fig. 1876. On the ledge *c*, moreover, of the bottom *a* there are four pins *i*, which tighten the clamps *j*, Fig. 1876, by means of small holes *g h*. On one side *F* of the clamp there are also toothed jaws, in which the wicks fit exactly, that is, they are thus kept vertical and in the centre of the moulds.

The construction of the clamp, Fig. 1876, is such that the arm working upon a joint at *g*, and

being brought against the arm F, falls into a groove made in its length, so as to press and kink the wicks in said groove, and fasten them firmly there by means of the spring catch K. The object of this is, that in raising the candles from the moulds by this clamp they shall not slip nor move. As the candles are lifted out of the moulds (as in Fig. 1875), the wicks are drawn after them from the spools K, and are then clamped in position in the manner described. The wicks are next cut off above the lower clamp, the candles with the clamps removed, when, by sliding off the spring catch K, the spring S, between the jaws *t t*, causes the arm *j F* to separate and release the wicks.

Composite Candles.—Cérophane.—The mode for manufacturing this block is the following:—Melt together, over a water-bath, 100 parts of stearic acid, and 10 to 11 parts of bleached beeswax; but, to ensure success, the mixture must remain over the bath from 20 to 30 minutes, and without being stirred or agitated. At the end of that time, the fire is to be extinguished, and the fluid allowed to cool until a slight pellicle is formed on the surface, when it is cast direct into the moulds, previously heated to the same temperature, but with the precaution of avoiding stirring the mixture, as a disregard of it would cause opaqueness of the mixture, instead of transparency.

Transparent Bastard Bougie, by Debitte, of Paris.—For 100 lbs. of stock take 90 lbs. of spermaceti, 5 lbs. purified suet of mutton, and 5 lbs. wax; melt each separately over a water-bath, and to the whole, when mixed together, add 2 oz. of alum and 2 oz. of bitartrate of potassa in fine powder, and while stirring constantly, raise the heat to 176° F., then withdraw the fire and allow the mixture to cool to the temperature of 140° F. When the impurities subside, the clear liquid must be drawn off into clean pans. For quality and good appearance, candles made of this cooled block are more than proportional to its cost. Morfit recommends to substitute plaited wicks for the foregoing mixture to the wicks generally used for composite candles, and to prepare them by previously soaking in a solution of 4 oz. borax, 1 oz. chlorate of potassa, 1 oz. nitrate of potassa, and 1 oz. sal-ammoniac, in 3 quarts of water. After being thoroughly dried, they are ready for moulding.

Diaphane.—It is, like the block for cérophane, an invention of Boilot, and made by melting together, in a steam-jacket, from 2½ to 17½ lbs. of vegetable wax, 1½ to 10½ of pressed mutton tallow, and 22 to 46 lbs. of stearic acid. Both the latter and the vegetable wax are the hardening ingredients. By changing the proportions between the above limits, a more or less consistent mixture may be formed. As concerns the moulding, it is performed in the same manner as for stearic-acid candles.

Parlour Bougies, similar to Judd's "Patent Candles."—Although not bougies, a name which, properly speaking, is only applicable to candles of wax alone, the similarity of these candles to those of wax has induced the aforementioned title for them. According to Morfit, their mode of manufacture is as follows:—Melt slowly, over a moderate fire, in a well-tinned copper kettle, 70 lbs. of pure spermaceti, and to it add piecemeal, and during constant stirring, 30 lbs. of best white wax. By increasing the proportion of wax to 50 lbs., the resulting product is much more diaphanous; however, the bougies moulded of this mixture are not as durable as candles made exclusively of wax. They are tinted in different colours. For red, carmine or Brazil-wood, together with alum, are used. Yellow is given with gamboge, blue with indigo, and green with a mixture of yellow

and blue. Sometimes the bougies are perfumed with essences, so that in burning they may diffuse an agreeable aroma.

A still more transparent and elegant bougie is made by adding only $6\frac{1}{2}$ lbs. of wax to 100 lbs. of pure, dry sperm, and the candles made of the block formed in these proportions resemble very much the "patent candles" of Judd.

Composite Candles.—The block for these candles is made by adding a portion of hot-pressed cocoa-stearine to stearic acid of tallow. It is an excellent and economical mixture, in which the red, carbonaceous flame of the latter ingredient is improved in illuminating power by the white and more hydrogenated flame of the stearine.

"*Belmont Sperm.*"—It consists merely of a mixed stock of hot-pressed stearic acid, from palm and cocoa-butters. Palmitic acid coloured by gamboge is called *Belmont wax*.

Harrison Gambo's Machine for manufacturing Candles, Figs. 1877, 1878.—B, Fig. 1878, is the receiving-chamber, surrounded by a steam-jacket BB, Fig. 1877, m MB', Fig. 1878. The tallow is forced from this receiving-chamber into supply-cylinders L', Fig. 1877, M Q S, Fig. 1878, where it is acted upon by a plunger N, which forces the tallow into the space in front of a tubular plunger. This tubular plunger contains the candle-presser and the wick-tube *a*. The tallow is pressed into the mould R, then ejected from the mould, and the wick-tube drawn back; the wick being held by a clamp *d*, is severed by the drawn shears W. The levers *pp* and the reacting springs repeat the motion. Upon leaving the mould R the candle enters a mould Y, which is surrounded by ice or cold water. From mould Y the candle is forced on to arms h^1, h^2 , which are operated by levers *h*, and conveyed to an endless carrier *g*. The reels T T are used in combination with the dog U for the purpose of limiting the let-off motion of the wick. P² is a fixed support; E bevel gear; and C C' feed-screw.

The engine used by the ancients, Fig. 1880, termed a *Catapult*, possesses several mechanical properties which deserve particular attention.

This engine, says Ramellus, writing in 1620, which we have borrowed from the ancients, is of great service in defending a town from assault. Its use is to throw large quantities of stones, iron, balls filled with fire, and other noxious substances upon the enemy. The following is its mode of construction.

Upon a base or platform A B, Fig. 1880, are placed, in a vertical position, seven stout supports C D E F G H I; these supports are joined together and strengthened by horizontal pieces firmly fitted to them in the middle. The arrangement of the several smaller parts, such as wheels, screws, bolts, and so on, will be better understood from the figure. To the tops of the four supports F G H I are affixed, in the manner shown in the figure, three pieces K L M, connected at one extremity by a cross-bar and terminated at the other extremity by a kind of trough or spoon, of a sufficient capacity to contain a considerable quantity of stones or other matter which it is required to throw upon the enemy; the opposite end of each of these pieces is weighted to counterbalance the load of missiles. The pieces themselves being suspended by means of several double cords, great force may be communicated to them by twisting the cords; the force thus obtained is considerably increased by the pressure of the part N O, which is affixed to the three front supports C D E in the same manner as the pieces we have been considering. The part N O is also connected with the lever P by means of a cord attached to its lower extremity. This lever P is designed to throw balls or pots filled with fire, or other similar missiles.

The mode of preparing the engine for action may be thus described:—A rope is attached by a hook to a ring on the middle receptacle, the other end of which rope is passed round a drum S; this drum is made to revolve by means of the perpetual screw T. The three receptacles are in this way brought down, and the lever P is raised; the operation, by tightening the twisted cords, increasing the recoil. They are then fixed in this position by a bolt Z. The receptacles are now filled with missiles, and the engine is ready for action. When the bolt Z is withdrawn, each of the pieces acted upon by the twisted cords, being liberated, recoils with great force. The ends of the levers carrying the missiles are brought violently against the ropes Q and 12, and the force of the concussion hurls the charge to a great distance.

The engine is removed from place to place by means of perpetual screws and toothed wheels fixed to the spindles of the screws and working into cavities in the two wheels 5 and 6, upon which the engine rests. Two men are thus sufficient to move and guide it. The five feet upon which the engine rests when stationary are firmly fixed into the ground with iron cramps; during its removal from one place to another these are turned up.

The cords should be made of the same material and in the same manner as the counter-bass strings of a violoncello. See ANGULAR MOTION. INERTIA. PENDULUM. PROJECTILES. REACTION. VELOCITY.

CEMENT. FR., *Ciment*; GER., *Cement*; ITAL., *Cimento*; SPAN., *Cimento*.

As the many varieties of cement which have during the last seventy years been more or less used for building purposes are now nearly superseded by the more valuable and better understood Portland and Roman cements, it is deemed unnecessary to describe them, more especially as they are now becoming, if not already, obsolete.

Portland and Roman cements, although frequently used for similar purposes, vary materially in their qualities. The former, rapidly superseding the latter, is an artificial preparation possessing many valuable properties which recent engineering works have been instrumental in developing.

Portland cement is made from an intimate and perfect admixture of chalk and clay, in varying proportions, according to their respective values—that is to say, the relative proportions of carbonate of lime in the chalk, and silica and alumina in the clay—the other chemical constituents being too insignificant for consideration when the suitable kinds of chalk and clay are selected. Generally speaking, a proportion of 20 per cent. of clay may be considered the right quantity, provided it does not contain more than 15 per cent. of ferruginous matter in iron oxides. The best selected materials used in making this cement in England contain the following ingredients:—

Chalk.					Clay.				
Lime	..	..	..	56.5	Silica	..	..	..	68.45
Carbonic acid	..	..	..	43.0	Alumina	..	..	..	11.64
Water	..	..	..	0.5	Ca. lime	..	..	..	0.75
					Oxide of iron	..	..	..	14.80
					Soda and kali	..	..	..	4.0

The method of preparation usually adopted is to combine these two materials in the most intimate and perfect manner. To effect this satisfactorily the whole is reduced to a soluble condition by the aid of water through the agency of different mechanical arrangements, and on the perfection of this process the future success of the manufacture depends; imperfect or irregular proportions of clay or chalk resulting in a cement disastrous to the manufacturer, and dangerous if used in works of construction by the engineer or architect. The mixture is passed into reservoirs, and the water of solution drained off by decantation. After the necessary interval of time has elapsed, the raw material, as it may now be called, is desiccated, and immediately thereafter placed in suitable kilns, where it is decarbonized, and then becomes what is technically termed clinker. From the kilns it is removed to the grinding and pulverizing mills, where the final process of reduction is effected, and the cement then becomes suitable for all the varied purposes to which it may be applied.

The system of manufacture thus briefly described is simple in character, and on due and intelligent watchfulness being exercised by the manufacturer satisfactory results are easily obtained. The process is necessarily a dilatory one, and considerable time must elapse before the raw material can be converted into a marketable commodity. Under ordinary circumstances, a period of from two to three months is required to make Portland cement. This difficulty has led some manufacturers to a consideration of the question of superseding the tedious operation of washing or mixing by that of the dry process. Hitherto all our attempts at improvement in that direction have not been attended with much success. Some progress has, however, been attained in Germany by the manufacture of Portland cement without the necessity of using large quantities of water for the mixture of the raw materials. Should this improvement be capable of adaptation in England, a considerable reduction in the price of the cement will necessarily follow.

By any system of cement manufacture the primary object is the thorough amalgamation, in the minutest form, of the raw materials, so as to realize to the fullest extent the maximum value of the combination in subsequent stages of the process. For even the most accurate proportions of chalk and clay will not accomplish the desired end unless the comminution of the various particles is perfect and complete. The wet system, as the English method may be called, aims at and indeed accomplishes the required desideratum in the simplest and least expensive manner. The dry, or German system, as it may be distinctly named, likewise succeeds in thoroughly amalgamating the raw materials (chalk and clay). While the application of the wet system is limited to the manipulation of chalk or soft calcareous earths, the dry system may embrace the manufacture of Portland cement wherever materials exist containing the required proportions of carbonate of lime and clay. Indeed, it may almost be considered as capable of unlimited or universal application, as there are but few localities deficient in the necessary quantities of these materials in one form or other.

An accurate compliance with the simple conditions as above described, invariably results in the production of a Portland cement possessing all the essential qualities desired by the engineer and architect. Much attention is now being pointedly directed to the question of a good Portland cement supply, and the necessary tests are of so searching a character as to preclude the possibility of any but the best cements being used where due vigilance is exercised by those entrusted with works of construction. The questionable reputation which has for so long a time been attached to Portland cement was due as much to the professional indifference of the engineer or architect as the carelessness of the manufacturer; the one, probably impressed with a belief in the insignificance of the subject itself, and the other careless of the character attained by his commodity, so long as it brought profit to himself. Fortunately, the insistence of the engineers entrusted with the great drainage and embankment works of the metropolis, upon being supplied with Portland cement of undeniable quality, has resulted in the institution of tests, rendering the supply of faulty cement absolutely impossible where due and necessary vigilance is exercised. Experience acquired in those works has established beyond cavil that the most desirable cement is that which reaches or exceeds the following standard:—

1st. In weight not less than 110 lbs. an imperial bushel.

2nd. Exceeding fineness of powder, capable of being passed through a sieve of from 1600 to 3000 meshes to the square inch.

3rd. Equal to resist a tensile strain of 200 lbs. to the square inch, after being immersed for a period of seven days in water.

When these three conditions have been scrupulously complied with, there need be no hesitation in using Portland cement for any purpose of construction in water or the air.

Portland cement possesses in an eminent degree the valuable property of hydraulicity, or capacity of setting and hardening under water; and its many applications in the construction of harbours, docks, and breakwaters, have long since established its reputation for such purposes. It is now (1870) upwards of forty years since its first introduction, and during that period of time foreign engineers especially have devoted much attention to its properties and uses. Its appreciation in this country has not been so marked; but an awakening interest in the construction of concrete buildings is gradually leading to the question of its quality and supply.

When Portland cement is carefully and accurately manufactured, it should, on setting, be of a light grey colour, resembling Portland stone in appearance; and very probably this peculiarity had some influence on giving it the name it now bears. Any departure from this colour indicates a faulty cement, and proves that either the proportions of the materials are irregular, or that its decarbonization was incomplete. It does not deteriorate by exposure to the air, and may be stored even for years if kept in a dry place. Various proportions of sand may be mixed with it for mortar; sometimes as much as 8 parts of sand to 1 part of cement may be used if the cement is good in quality. Such a proportion, however, is not generally recommended; but one of 3 parts of sand to 1 part of cement will be found a good mixture for general building purposes. The cement when required for architectural embellishment should be worked neat, and for this purpose a quick-setting quality should be employed. The plasterer should, before using it, make a sample test in the shape of a small brick, or circular pats, which must be put in water as soon as possible after it is worked up by the trowel. If after twenty-four hours' immersion there are no faulty indications developed in the shape of cracks, the cement may be used with safety. For concrete purposes, the proportions are sometimes 1 part of cement to 8 parts of shingle or gravel. Large concrete-blocks, weighing 330 tons, have been successfully made near Dublin with proportions of 1 part of cement to 6 parts of Liffey gravel. This is probably the most striking example of the application of concrete in engineering work.

Recent experiments have proved that Portland cement continues to harden or crystallize for a lengthened period. Briquettes made of neat cement (weighing 121 lbs. a bushel), after seven days' immersion in water, bore a tensile strain of nearly 400 lbs. to the square inch; and duplicate briquettes, after five months' similar treatment, sustained a weight of nearly 600 lbs. to the square inch, showing thereby an improvement of 50 per cent. in that time. Further experiments with cement bricks, to prove their capacity of resistance to compression, resulted as follows.

Bricks three months' old, $9'' \times 4\frac{1}{2}'' \times 2\frac{3}{4}''$ resisted fracture until a pressure of 65 tons was exerted by the agency of the hydraulic press. The weight was applied to the brick on its bed, having a surface of $38\frac{1}{2}$ sq. in. Similar bricks, under like conditions, at six months' old, withstood a pressure of 92 tons. The third experiment, with a brick nine months old, resulted in 102 tons, showing upwards of 50 per cent. improved resistive value in a period of six months.

In the same series of experiments other building materials of acknowledged excellence were operated upon, and the following values were obtained:—

	Exposed Surface.	Average Crushing Weight.
Oldham red bricks	39·33 sq. in.	40 tons.
Medway gault clay bricks	40·50 "	17 "
" pressed	40·50 "	48 "
Stafford blue brick	27·90 "	50 "
Fireclay	34·85 "	65 "
Wortley blue	34·76 "	72 "
Portland stone	39·94 "	47 "
Bromley Fall stone	39·94 "	91 "
Yorkshire Landing	38·28 "	96 "

Showing thereby that at nine months old a neat Portland cement brick exceeded in resistive value the best-known building materials of this country. It is quite possible also that a greater age may yet indicate an increase of strength, an advantage our experience does not lead us to expect from bricks or stones. Induration continues in the case of Portland cement to an extent beyond the limits of our present knowledge.

In another series of experiments it was found that cement, weighing 106 lbs. a bushel, resisted a tensile strain of 210 lbs. to the square inch, and when the weight of the cement was 130 lbs. a bushel it required an exertion of 406 lbs. an inch to cause rupture—showing that by an increase in weight of 24 lbs. a bushel the strength of the cement was nearly doubled.

Heavy cement is necessarily slow-setting in character; but these experiments and the most eminent engineering practice indisputably prove that without weight you cannot obtain great strength.

The analysis of a good average sample of Portland cement should be—

Calcium	62	Alumina	8
Silica	23	Oxide of iron	4

To give full effect to the required conditions necessary to obtain a good Portland cement for building purposes, the use of a testing machine is indispensable; and on works of ordinary extent the engineer or architect should insist on its being applied to every delivery of cement sent on to the works.

About ten years ago, and indeed since then, many attempts have been made to introduce what were ostentatiously termed natural Portland cements, obtained from the blue lias lime formation of the West of England. Their indiscriminate use led to much dissatisfaction and loss, from their unfitness as a substitute for Portland cement, properly so called. The charm of cheapness for a time obtained for them a place amongst cements, and the comparative ignorance which then prevailed as to the essential qualities of a good cement enabled the manufacturers of these lias limes to hold a position in the market which a more advanced knowledge of the subject would now prevent.

The Boulogne-sur-Mer natural Portland cement differs considerably from the above, being made from a deposit of argillo-calcareous earth containing from 19 to 25 per cent. of clay; the silica and alumina of which is variable. When more than one-twentieth of sand is present in its composition it has to be rejected as unsuitable. This clay or earth is found in the inferior cretaceous formation.

The objection to all kinds of natural cements is the uncertainty in the value of their constituent parts. Their ever-varying ingredients render them unsuitable for building purposes when any degree of excellence or strength is required. No such obstacle exists in the use of sound Portland cement, and that is the reason why it lays claim to and maintains its superiority over all other kinds of cements. The manufacturers can, when duly impressed with the necessity of accuracy in manipulating the materials from which the cement is made, unerringly ensure the required results in quality and strength; the moderate limitation of which is only controlled by the cost.

In the above remarks it is not intended to convey the impression that there is any difficulty in making Portland cement of light specific gravity and colour. Portland cement can be made from 90 to 140 lbs. weight a bushel; but the value of the one is of course much less than the other; so also is its strength and quality—the light cement setting more speedily than the heavy cement. The colour also varies from a light buff to the deepest grey.

Notwithstanding the point of excellence to which Portland cement has attained, especially under the accurate and intelligent manipulation of Henry Reid, there is still much room for improvement in its manufacture. Its continually increasing application for all kinds and forms of construction points it out as a valuable agent for substituting concrete houses for the worthless brick buildings of this country. It is to be hoped that changes in the processes of manufacture will eventually result in reducing the price of an article which at present bears a very disproportionate relation to the value of the simple and inexpensive materials from which it is prepared.

Roman Cement.—This cement, although gradually giving way to its more energetic rival Portland cement, possesses nevertheless many good qualities. It differs from Portland, being a natural cement; and in consequence of there being great varieties of stones from which it is made, much care is necessary in ascertaining their exact quality before using it for building purposes. The origin of the name arose probably from its resemblance in colour and general characteristics to the mortar found in Roman remains in England. It was first introduced by Parker in 1796, who obtained a patent for manufacturing cement—named by him Roman—from the septaria nodules of the London clay found along the shores of the Isle of Sheppy, in Kent. Subsequently, Frost and other makers introduced Roman cement made from similar materials found in the clay formations of other districts in England. The term Roman is now generally applied to all natural cements of a dark brownish colour, and it is this distinguishing peculiarity which so markedly separates it from the Portland cement, which is of a grey colour. The Roman cement stone is found in many parts of England, North Wales, the Isle of Wight, and in Scotland. Several districts in France also furnish considerable quantities both from the clay and argillaceous limestone formations. There are very extensive deposits in the United States of America, from which is manufactured a cement resembling that of this country both in colour and other peculiarities. There can be no doubt that in many districts of England and Scotland this cement stone abounds; and it is only by reason of the apathy and indifference of engineers and architects on the subject that so little progress has been made towards its greater development.

The Roman cements generally sold in London are the Harwich, Isle of Sheppy, Southend, Isle of Wight, and Medina; in the North of England, the Yorkshire, Atkinson, or Mulgrave; in Liverpool, the Holywell, Flintshire, North Wales; and in Scotland, the Calderwood. In America it is extensively made in the states of Illinois, Ohio, Maryland, Virginia, and New York. Some years ago large quantities of these American cements were shipped to Australia and other places, and called Portland cements; but they differed so much from that article that their manufacturers finally abandoned their pretensions, after great loss had been incurred by the merchants who had shipped them.

In general, these cement stones contain about 60 per cent. of carbonate of lime, or magnesia, with from 30 to 40 per cent. of clay. The oxides of iron and magnesia which they contain are variable. Few of them have alumina or soda, and it is doubtless from the absence of these ingredients that they are so inferior to the artificial Portland. The clay is highly ferruginous in character, which to a great extent accounts for the rapidity with which they set; and to this cause also may be due their want of permanently indurative capacity.

The following analysis of well-known Roman cement stones will better explain the relative quantities of the ingredients:—

	Clay.		Carbonate of Lime.			
Parker's cement	45·0		55·0			
Yorkshire „	34·0		62·0			
Sheppy „	32·0		66·0			
Harwich „	47·0		49·0			
	Oxide of Iron.	Silica.	Alumina.	Carb. Lime.	Mag.	
Southend cement	9·0	12·0	3·4	64·0	1·5	
	Protoxide of Iron.	Silica.	Alumina.	Carb. Lime.	Mag.	
Calderwood „	10·2	8·8	3·4	64	2·6	

The American cement stones have more alumina and less carbonate of lime than those of this country. It is a curious circumstance that, notwithstanding their excellence and abundance, Roman cement is still sent from London to New York.

A remarkable difference between the Roman and Portland cement is the necessity for applying opposite tests in selecting the best sorts when manufactured. Portland is best when heaviest: up to 140 lbs. weight a bushel if possible. On the other hand, Roman is judged by its lightness; and when it weighs about 75 lbs. a bushel it is best. These two different properties tell, however, in a most marked manner when we come to consider which is the better cement to keep for a lengthened period without deterioration. Portland cement possesses this valuable property in a high degree, and Roman cement can lay but little claim to this excellent quality.

The stone principally used in London is that obtained from the coast near Harwich, and is delivered in London by barges at a cost, according to quality, of from 6s. to 8s. a ton.

The process of manufacture is most simple, and the only care required is to prevent its being vitrified when burnt. The great aim is to have the cements of the lowest weight; this can only be attained by a maximum amount of decarbonization in the kiln. The stones lose in weight by this process about 30 per cent. without any appreciable loss in bulk. The form of kiln used does not differ much from the commonest kind of lime-kiln. It is usually from 20 to 25 ft. high, from 9 to 12 ft. wide at top, and from 7 to 8 ft. wide at the bottom. Each kiln has four eyes, or drawing-holes, to take away the stone when burnt; it is seldom necessary to have them all in use at the same time. The stone is broken to a uniform size of from 2 to 3 in., and placed in the kilns in layers; each layer having the necessary amount of fine coal placed on it, for the purpose of decarbonizing or burning the stone. The fuel required for this purpose varies, as the stone or coal is seldom regular in quality. The experienced burner will easily regulate the necessary quantity. When a kiln is once lighted up, it may be kept burning for many months without any attention beyond the regular daily withdrawal of the burnt stone and the addition of the fresh materials so that the kiln may always be kept full. The best and most profitable kiln is one with a 70 or 80 tons capacity. Smaller kilns, however, may be used in localities where the demand for cement is limited. It is advisable to adjust the size of the kiln so that it may always be burning; such an arrangement is the most economical, as you thereby save the waste incurred in relighting after each charge has been drawn. The burnt stone may be kept for a considerable time before being ground; and it is better, therefore, if necessary, to allow it to remain in this state than to keep the powder, as in that condition it speedily and permanently deteriorates.

The grinding or pulverization of the cement should be carefully attended to. The point of reduction is seldom, in this country at least, carried beyond the No. 30 gauge; but in America the engineers insist on having it ground so that only 8 per cent. will be rejected by an 80-gauge sieve (6000 meshes to the square inch). English engineers and architects have not been so exacting in their stipulations for fine grinding, and a No. 40 (1600) gauge may be considered as the maximum of pulverization of English Roman cement.

There can be no doubt that progress in the use of Portland cement was much retarded by interested Roman cement manufacturers, in consequence of the ease with which the latter could be made. Indeed, it was and is so simple in character that the most ignorant are almost capable of preparing it for the market. The selection of the stone itself is not difficult; and when the most ordinary care was bestowed on the processes of burning and grinding, the makers run but little risk in carrying on what doubtless was, until very lately, a very profitable trade. Roman cement can be prepared for the market in a few days. That advantage, from a manufacturer's point of view at least, was considerable; whereas the conversion of the raw materials into Portland cement occupied a period exceeding two months, according to the seasons. Again, the manufacture of Roman cement requires but little, if any, scientific or advanced technical knowledge. On the other hand, Portland cement making is attended with much risk and anxiety, and cannot be successfully conducted without a perfect knowledge of the raw materials and their accurate manipulation. For these cogent reasons, therefore, the ascendancy of Roman cement was maintained for a much longer time than its merits really deserved. It was not until the professional mind was thoroughly awakened to its shortcomings and failings that it was, in important works at least, superseded by Portland cement, with good reason, as the following tests will prove.

It should be premised, to account for the variability of the results in the following Tables, that Roman cement, as already observed, is prejudicially influenced when in contact with the air and the moisture which it contains. Its highest value, therefore, can only be realized when fresh burnt and finely ground. The cement submitted to experiments was obtained from four makers of established reputation.

		AGE OF BRICKS.			
		Tensile Strain per sq. in. in lbs.			
		7 Days.	1 Month.	6 Months.	1 Year.

" 4 "		60	96	194	212
Medina		41	136	183	212

Attempts were made during the time these experiments were being tried to extend their usefulness by ascertaining the value of the cement when mixed with various proportions of sand. The results, however, were found to be so low and unsatisfactory that the further search for information in that direction was abandoned, as not being likely to lead to any useful result.

Notwithstanding the many disadvantages attending the use of Roman cement, it must be borne in mind that it is to be found in many countries and localities where it might be readily used with advantage when Portland cement or hydraulic limes could not be obtained. It is now fre-

quently used in protecting the joints of Portland cement, while setting, from the injurious action of the sea or running water in harbour and similar works. Smeaton, when building the Eddystone Lighthouse, long before the introduction of Roman cement, used plaster of Paris, in protecting the joints of his composite mortar, made from puzzolana and blue lias lime, from the violent action of the sea.

Roman cement cannot bear a greater admixture of sand than 1 to 1. For concrete, however, in foundations at least, it may be used up to 5 or 6 of gravel to 1 of cement. In the Thames Tunnel neat cement was used for the arches, 1 of sand to 1 of cement for the foundations, and $\frac{1}{2}$ sand to 1 of cement for the piers. When used for internal plastering, it requires painting to hide the unsightly reticulated appearance of its surface after having been exposed for some time to atmospheric action. Much unsightly plastering is executed in London, from a supposed economical application of Roman and Portland cements. The wall to be plastered is first coated with a layer of Roman cement, which, when dried, is covered with a thin coating of Portland to give a finish and appearance to the whole. This mode of using the two cements is highly objectionable, and can only proceed from a want of knowledge of the peculiarities of the cements, which differ so materially in their properties. It is difficult to put two layers of the same cement on each other. The joints between two coats of cement are seldom perfect.

Cement manufacturing is an important branch of our industry. Some years ago, and before Portland cement had established its position, the English Government had their attention called to the scarcity of Harwich cement stone caused by its being dredged and taken away in large quantities by foreigners. The matter appeared of sufficient importance to attract the consideration of the late Sir Robert Peel, who intended levying a tax on the stone taken out of the country. On representation being made to him, however, that this country contained inexhaustible beds of raw materials which, when operated upon, produced an artificial cement much superior to the Roman, he abandoned his intended taxation.

It is remarkable that the three perhaps most celebrated engineering works of modern times led to improvements in mortars and cements. Smeaton, while (1756) experimenting on mortars for the Eddystone Lighthouse, discovered the value of puzzolana in combination with blue lias lime in imparting great setting energy to the mixture. Indeed, at that time he established the value of clay in conjunction with the carbonate of lime, which more than eighty years afterwards led to the investigation which ultimately resulted in the discovery of Portland cement. The construction of the Menai Bridge by Telford set at rest all doubts as to the value of Aberthaw lime for hydraulic purposes. The Thames Tunnel, again, furnished conclusive evidence of the great value of Roman cement, which was almost entirely used in its construction by the Brunels.

Portland Cement.—Particulars specified by the War Office, England.—Portland cement is to be of the best quality, ground extremely fine, weighing not less than 100 lbs. a struck bushel (filled into a bushel measure as lightly as possible), and capable of maintaining a breaking weight of 450 lbs. seven days after being made into a mould of the form and dimensions given in Figs. 1881 to 1883; the specimen being immersed in water as soon as it has set, and so left during the interval of seven days.

Cement placed in the testing-mould, Fig. 1883, to be experimented upon, must be in good condition, and thoroughly mixed on a clean floor, and applied as soon as mixed.

The cement and sand have to be carefully measured in proper measures, which are kept for the purpose.

Hydraulic Cements, natural and artificial.—The term hydraulic cement is generally used in distinction to hydraulic lime. The former, containing a larger proportion of silica and alumina and a smaller proportion of carbonate of lime than the latter, does not slake, and sets generally in a few minutes even under water. Hydraulic limes, on the other hand, slake thoroughly and harden slowly under water. Some limestones exist which, when completely calcined, yield hydraulic lime; but when imperfectly calcined, yield cement. Other limestones, such as chalk, when imperfectly calcined, or too much calcined, yield fairly hydraulic limes; while, if they be calcined merely up to the point when all the carbonic acid is driven off, and no further, they yield a lime which never solidifies under water. Other limestones yield on calcination a result which can neither be termed lime nor cement, owing to its slaking very imperfectly, and not retaining the hardness which it quickly takes when first placed under water.

The natural hydraulic cement best known in England, of which we have spoken, is that which is most absurdly termed *Roman cement*, or, more sensibly, *Parker's cement*. The stone is found in the form of nodules in the island of Sheppy. The composition of these nodules is almost the same as that of the Boulogne pebbles, from which a similar cement is made. Before being burnt, the stone is of a fine close grain, of a rather pasty appearance; the surfaces of fractures being greasy to the touch. It sticks easily to the tongue; its dust, when scraped with the point of a knife, is a greyish white. During the calcination the stone loses about one-third of its weight,

and the colour becomes of a brown tinge, differing with the stones from which the cement is made. It becomes soft to the touch, and leaves upon the fingers a very fine dust; it sticks very decidedly to the tongue. When taken out of the kiln it absorbs water with much difficulty. It is usually burnt in conical kilns, and pulverized by the manufacturer, and then sold in well-closed casks. In Russia, America, India, and elsewhere, similar natural cements have been met with; but, as they are comparatively rare and expensive, much attention has been bestowed on finding or inventing a substitute for them. Carbonate of magnesia alone has been found to yield, on calcination, an excellent hydraulic cement. When mixed with $1\frac{1}{2}$ times its bulk of sand, it makes a beautiful hard plaster or stucco.

Vicat was the first to point out the method of forming an artificial hydraulic cement by the mixture of lime and unburnt clay; and General Pasley afterwards, in a most elaborate series of experiments, proved that a hydraulic cement might be formed equal to the best obtained from natural sources.

Pasley's experiments were made principally with chalk lime and the blue alluvial clay of the river Medway, near Chatham. The result he arrived at was, that a mixture of 4 parts by weight of pure chalk, perfectly dry, with 5.5 parts, also by weight, of alluvial clay, fresh from the Medway, or of 10 parts of the former with $13\frac{1}{2}$ of the latter, would produce the strongest artificial cement that could be made by any combination of these two ingredients.

From the experiments of Vicat and Pasley on making artificial cements, it would appear that the best mixture for making cement consists, before burning, of

Two ingredients of carbonate of lime	50.5	$\times 2 = 101.0$	
One ingredient of clay, of which the probable composition is—			
One equivalent of alumina	51.4		
Six ditto silica	93.0		
			$= 144.4$
			245.4

So that the composition in 100 parts is:—

Carbonate of lime	41
Clay	59
	100

The weight of the blue clay he found to be 90 lbs., and of the dry chalk powder 40 lbs. a cubic foot.

His method of proceeding was as follows:—The clay was weighed when fresh from the river (taken from about 18 in. below the surface), and was never dug unless required at once; it being found that even twenty-four hours' exposure to the atmosphere injured it. The chalk was not weighed until well dried and pounded, owing to its extraordinary retentiveness of moisture. The chalk was then mixed with water into a thick paste. The chalk and clay were then each separately divided into portions or lumps as nearly as possible equal, and put alternately into a pug mill of the ordinary description, Figs. 1884 to 1888, where they were most thoroughly and inti-

mately mixed. The raw cement thus formed was then made up into balls of about $2\frac{1}{2}$ in. in diameter, and placed in the kiln alternately with about equal layers of fuel—a layer of fuel always being at the top and bottom. The fuel used was coke, in preference to coal; and, in the small furnace or kiln used by Pasley, three hours was found to be about the average time required for burning the cement. As the calcined cement was drawn from the bottom of the kiln, fresh

cement could be put in at the top. The balls, on being raked out, could be tested by applying to them diluted hydrochloric acid. If sufficiently burned, no effervescence ensued; but if they effervesced, they were put into the top of the kiln again to be reburnt. The calcined cement balls, since they would not slake like ordinary lime, were then ground to impalpable powder, and stored for use, so that they should not be exposed to the atmosphere. The average out-turn was about 9½ measures of calcined out of 10 measures of raw cement.

The proportions just named formed the best artificial cements. Pasley, after due investigation, found that any given weight of well-burned chalk lime, and consequently of any other pure quick-lime, fresh from the kiln, combined with *twice* its own weight of blue clay, fresh from the river, will form an excellent water cement; observing, however, that the quick-lime, after being weighed, must be slaked with excess of water into a thin-nish paste, and allowed to remain in that state about twenty-four hours before it is mixed with the clay.

These proportions by weight are nearly equivalent to a mixture of 5 measures chalk powder to 2½ measures of blue clay. Since 555 grains of quick-lime are the produce of 1000 grains dry chalk, which, in a state of powder, will fill 5 measures; of which 1110 grains of clay will fill 2½ measures.

Portland cement is formed very much from the ingredients used by Pasley, but with different proportions. It takes its name from its likeness in colour to Portland stone; but it is in no way connected with it. The ingredients are chalk and the mud of the river Medway, in the neighbourhood of which it is chiefly manufactured. The process is as follows:—The chalk used contains about 7½ per cent. of clay. The mud contains about 70 per cent. of alumina and iron to 30 per cent. silica. Eight or nine parts of chalk with two parts of mud are passed through a crushing mill, into which is let a supply of water, which, running off at the side opposite that at which it enters, carries off the crushed particles into a large vat, 60' × 40' × 3'. Here the sediment settles down, and becomes tolerably solid, while the surface water is run off or evaporates. The mixture is now spread out on a drying floor to a depth of about 6 in., and is dried by coking ovens below it. These ovens, at the same time as they dry the raw cement, are converting coal into coke; and this being accomplished, both cement and coke are taken to the kiln, where they are spread in alternate layers, and burnt at a very high temperature. The cement, when burnt, is in a state of incipient vitrification: indeed, it should be over-burnt; as the particles should be just beginning to run together. This excessive burning is a distinctive feature of its manufacture. It is now crushed between two iron wheels revolving on one another, and ground between two sandstone millstones; and then the cement is complete, and is carefully packed in 3-bushel casks. The danger of the use of this cement is that it is apt to swell in the joints of masonry after being applied; but it is admirably adapted for buildings exposed to the action of water, and for external plastering, as it sets very fast and attains great hardness, and does not allow of the formation of vegetation, as the natural cements do.

Coignet's agglomerated concrete consists of a proportion of sand, a smaller quantity, perhaps ½, of lime, and a minimum quantity of Portland cement, say $\frac{1}{15}$, $\frac{1}{20}$, or $\frac{1}{30}$. Instead of mixing these ingredients with mortar, so as to form a mortar of ordinary consistency, a very small quantity only of water is added, and the mass is made to undergo a trituration of greater or less duration by means of special apparatus. By this trituration, notwithstanding the feeble quantity of water, a pulverulent mass is obtained, which acquires by a more prolonged trituration the consistency of a firm plastic paste. It is then ready for the mould, into which it is introduced in successive and very thin layers, which are submitted to a powerful ramming process. This operation of compression effects such a complete agglomeration, that each cubic metre and a-half of sand and lime is made to occupy the space of only 1 metre; and the lime, whose particles are thus mechanically brought into contact, becomes indurated with astonishing rapidity and intensity. A few days, in some cases hours, suffice for the mass to acquire the character of hard stone.

As the work of one day, with this concrete, unites perfectly with that of the preceding, it is plain that a mass of this species of masonry can be augmented indefinitely, so that a house, bridge, reservoir, or any other construction, can be made to form a monolith.

The most important building executed in agglomerated concrete is the church of Vesinet, situated in a park of the same name, near Paris. It is of Gothic style, and the entire masonry forms a single block. The division of the naves is formed by piers of grouped colonnettes in cast iron; these, together with the cast-iron responds against the lateral walls, support the weight of the roof, which is of wrought iron. The concrete of which the walling is composed contains: river-sand, 3 parts; earthy and ferruginous sand, from Vesinet, 1 part; slacked lime, in powder, from Argenteuil, 1 part; heavy cement (*ciment lourde*), from Paris, ½ part; cement forming $\frac{1}{11}$ part of the whole.

Another advantage arising from the suppression of water, the energetic trituration, and the forced aggregation of the particles of lime, in these concretes, is, that a slight difference in quality

of the lime affects but little the result obtained; therefore the nearest hydraulic lime at hand will serve the purpose; whereas, in other concretes, the best lime must be obtained, in order to secure a good mortar. In fact, M. Coignet presented to the Society of Civil Engineers, in Paris, specimens capable of receiving a high polish, composed of the worst description of lime, even ordinary quick-lime, bad and marly sands, fine sea-sand in impalpable powder unfit for common mortar.

With regard to the fact that, in masonry, mortars and concretes, when well made, are progressively and continually becoming harder, while cements do not acquire an increasing induration proportional to the energy of their original hardening or setting;—this may be explained by considering that cements contain very little free lime or oxide of calcium, being almost entirely composed of silicates formed by torrifaction at a high degree of temperature. Now, as pure lime has the property of absorbing, in order to pass into the state of carbonate, a quantity, nearly equal in weight to its own, of carbonic acid, it is plain that the more perfect a cement is—its perfection consisting in having but a trace of free lime—the less it will have the power of absorbing carbonic acid gas; whilst on the other hand the more a mortar contains of free lime, the more powerful and energetic will be the absorption, and the more the weight will be increased—that is to say, a cubic metre of mortar containing 400 lbs. to 600 lbs. of free lime can absorb nearly 400 lbs. to 600 lbs. of carbonic acid, while a cement will absorb little or none.

This action of the carbonic acid of the air has a more striking effect upon agglomerated mortars and concretes than upon ordinary ones. It is easily understood that if to a compressed concrete like Coignet's, so dense that a cubic metre contains 15 hectolitres of ingredients, with the particles so intimately blended by trituration, we add a new substance, carbonic acid, of equal weight with that of the pure lime, the increase of density of the whole mass will be great. Thus, the *bétons* agglomerated, composed of 5 parts of lime in powder, weighing 55 kilogrammes the hectolitre, and $\frac{1}{2}$ part or $\frac{1}{12}$ of cement, yield in a few days an artificial stone resisting more than 20 kilogrammes of crushing force per square centimetre; while substances, composed of 1 part of the best cement and 2 parts of sand, cannot withstand 10 kilogrammes of the same applied force. For lime mortars or concretes to harden into the state of artificial stone it requires much time.

Among the latest theories put forth by French engineers as to the cause of the setting of hydraulic cements, we may mention those laid before the Academy of Sciences, in Paris, by M. Fremy, last June. Vicat established that the hydraulicity of a cement is due to a composition formed when limestone is calcined in presence of argil. He states that this composition is a double silicate of alumina and lime, which, in hydrating, causes the setting of hydraulic cements. MM. Rivot and Chatonay, in their important work on Cements, state that the calcination of an argillaceous limestone produces aluminate of lime, the formula for which is Al^2O^3 , 3 CaO , and also a silicate of lime, represented by SiO^2 , CaO ; these two salts, in contact with water, produce the two hydrates

which become the cause of the hardening in question.

In both these two theories the hydraulicity of the cements is ascribed to a simple action of hydration, like the setting of plaster of Paris; but by M. Fremy another cause is assigned. He made extensive experimental researches on the properties and mutual action of four substances which, according to Vicat, Rivot, and Chatonay, constitute hydraulic cements:—1, silicate of lime; 2, silicate of alumina and lime; 3, aluminate of lime; 4, caustic lime, or oxide of calcium. The experiments are detailed in the memoir, which concludes with the following statement:—That the hardening of hydraulic cements is not due to the hydration of the silicate of lime, or that of the double silicate of alumina and lime; these salts *do not form any combination with the water*: that the setting of hydraulic cement is the result of two different chemical actions,—1, the hydration of the aluminates of lime; 2, the reaction of the hydrate of lime upon the silicate of lime, and upon the silicate of alumina and lime, which act in this case as puzzolana. The calcination of an argillaceous limestone cannot yield a good cement except when the proportions of argil and lime are such that these can be formed. In the first place, an aluminate of lime represented by one of these formulæ,— Al^2O^3 , CaO ; Al^2O^3 , 2 CaO ; Al^2O^3 , 3 CaO : in the second place, a simple or multiple silicate of lime, represented approximately by one of these formulæ,— SiO^2 , 2 CaO ; SiO^2 , 3 CaO ; and in the third place, pure lime capable of acting on the preceding puzzolanic silicates.

In the course of the memoir, M. Fremy states that when aluminates of lime represented by Al^2O^3 , CaO ; Al^2O^3 , 2 CaO ; Al^2O^3 , 3 CaO , are reduced to a fine powder, and slightly wetted, they solidify almost instantaneously, and produce hydrates which acquire in water a considerable degree of hardness. They have, moreover, the property of agglomerating inert substances, such as quartz, sand, and so on.

M. Fremy mixed aluminate Al^2O^3 , 2 CaO , with 50, 60, and even 80 per cent. of sand, and obtained a pulverulent mass which in water acquired the hardness and solidity of the best stone. The interest attached to these mixtures of aluminates of lime and siliceous substances is the more important in a practical point of view when we consider that blocks are required to be produced capable of resisting atmospheric influences and the powerful effects of sea-water. M. Fremy considers that the solution of the problem of constructions resisting the ravages of the sea lies probably in the employment of concretes which are formed nearly wholly of siliceous substances united together by a feeble proportion of aluminate of lime. On this point M. Fremy cites the indications given by M. Coignet on the subject of agglomeration of cements, saying that he has observed their importance himself.

Portland cements, according to M. Fremy, have no good quality unless they are produced at a very high temperature. The aluminates of lime have this character, also, of not being able to solidify under water unless they have been exposed to an intense heat; thus they seem to be the principal agents in hydraulic cements of rapid setting.

Perhaps the inferiority of some of the Portland cements of commerce may be traced to want of sufficient intensity of heat in burning. M. Fremy made the aluminates of lime, for his experiments,

with a blast furnace. See ASPHALTE. CONCRETE MACHINE. FOUNDATIONS. KILNS. LIME AND MORTAR. OVENS.

Recapitulation.—Roman Cement.—Parker's Analysis.—One part of common clay to 2½ parts of chalk, set very quick.

Concrete.—Eight parts of pebble, or pieces of brick, about the size of an egg, to 4 parts of scrap river-sand, and 1 part of lime, mixed with water and grouted in, makes a good concrete.

Lime Mortar.—One part of river-sand to 2 parts of powdered lime mixed with fresh water.

Hydraulic Mortar.—One part of pounded brick powder to 2 parts of powdered lime mixed with fresh water. This mortar must be laid very thick between the bricks, and the latter well soaked in water before laid.

Hydraulic Concrete, by Treussart.—Thirty parts of hydraulic lime, measured in bulk before slaked; 30 parts of sand, 20 parts of gravel, and 40 parts broken stone—a hard lime-stone. This concrete diminishes about one-fifth in volume after manipulation.

Asphalte Composition for Street Pavement, by Colonel Emy.—2½ pints (wine measure) of pure mineral pitch, 11 lbs. of bitumen, 17 pints of powdered stonedust, wood-ashes, or minion.

Cement for Stone and Brick Work.—Two parts ashes, 3 of clay, and 1 of sand, when mixed with oil, will resist the weather equal to marble.

Brown Mortar.—One part lime, 2 of sand, and a small quantity of hair.

Hydraulic Mortar.—Three parts of lime, 4 puzzolana, 1 smithey ashes, 2 of sand, and 4 parts of rolled stone or shingle.

Cements for Cast Iron.—Two oz. sal-ammoniac, 1 oz. sulphur, and 16 oz. of borings or filings of cast iron, to be mixed well in a mortar, and kept dry. When required for use, take 1 part of this powder to 20 parts of clear iron borings or filings, mixed thoroughly in a mortar; make the mixture into a stiff paste with a little water, and then it is ready for use. A little fine grindstone sand improves the cement.

Or, 1 oz. of sal-ammoniac to 1 cwt. of iron borings. No heat allowed to it.

The cubic contents of the joint in inches, divided by five, is the weight of dry borings in pounds (avoirdupois) required to make cement to fill the joint nearly.

The cutting device in F. B. Hunt's chaff or straw cutter, Figs. 1889 and 1890, deserves particular attention. The machine in which this device is employed consists of a spirally-arranged

1890.

knife secured to two arms upon a shaft in front of a feed-box, so that as the shaft is rotated the knife works closely over the outer edge of a metallic bed-plate attached to the feed-box. The upper roller is so arranged as to adjust itself to the varying thickness of the layer of straw or other substance pressed under it, the roller raising or falling in the arc of a circle, so as to be always at the same distance from the shaft of the cutter, and the substance to be cut will be retained in a proper position on the bed of the machine. Attached to the frame of the upper feed-roller is a guard-board or plate, which is caused to rise or fall with the upper feed-roller, so as to prevent the substance being cut from passing over the top of the roller.

In referring to Figs. 1889, 1890, it will be observed that the combination, of the cutting-bar or plate E of the single knife D and the arms c, c, attached to the driving-shaft C, operate to effect an

1889.

oblique or drawing cut. The fly-wheel E' is so attached to its shaft C that the wheel is admitted to slip on the shaft in case the motion of the cutter is arrested by any foreign substance, thus the knife or cutter is preserved. The bar *cb* is connected directly to the shaft *n*, shown in section, Fig. 1890; *n* is the shaft of the lower feed-roller G, which is connected to the shaft *p* of the upper feed-roller H by an arm *i*. The bar *cb*, Fig. 1889, has pinions *bd* attached to it, which gear with the pinions *a'e* of the feed-roller shafts *n, p*, exhibited in section, Fig. 1890. The guide-board or guide-plate *u* is attached to the plate *t* of the frame of the upper feed-roller H; *u* extends down at the back of H to a level with *p* the shaft of H.

CHEESE PRESS. FR., *Machine à comprimer le fromage*; GER., *Käsepresse*; ITAL., *Torchio da formaggio*; SPAN., *Prensa de queso*.

Dick's Anti-friction Cheese Press.—In Fig. 1891 is represented the method of applying Dick's anti-friction power to the pressing of cheese. By the use of this press the whey is entirely removed, and half the labour usually required in the manufacture of cheese is saved, it being ready for market or transportation as it comes from the press, without risk or loss to the purchaser and the consequent vexation so frequent in the case of the method originally pursued. The pressing may be carried to any extent deemed requisite without danger to the press, the working portions of the press being made of iron, and capable of sustaining the force that may be applied.

Attached to this press is the platform-scale; so that the cheese can be accurately weighed before it is removed from the press—a matter of great convenience and importance to the manufacturer and vendor of these articles, as well as to the purchaser, who can depend upon the weight marked upon it as strictly accurate. In fact, the advantages of this press, above others, must be at first view apparent, and the power such that it will come into general use.

CHEESE VAT. FR., *Éclisse à fromage*; GER., *Käsenapf*; ITAL., *Tino da formaggio*; SPAN., *Quesera*.

The objects to be attained by the use of a cheese vat are: a separation of the caseous or cheesy particles from the whey or watery particles of the milk, and the proper comminution of the latter preparatory to pressing. P. Colvin's cheese vat, Figs. 1892 to 1895, is intended to produce these results effectually, rapidly, and economically.

Fig. 1892 is a front view of the machine in perspective; Fig. 1893, an end view; Fig. 1894, a stirring-frame; and Fig. 1895, a cutting-frame; both these last operated by a crank. The vat A is semi-cylindrical and double-walled,

1891.

1892.

1893.

water being contained between the shells. Under the vat, and attached thereto, is a furnace B for heating the water, the smoke from which escapes by the pipes C.

The degree of heat admitted to the water is regulated by a sliding damper D, Fig. 1893. A coil of circulating pipes is affixed to the outer shell of the vat, connected with the water-space at the centre and ends of the vat, thus equalizing the heat in the water-space. Convenient spouts or cocks are attached for drawing off the whey, the water from the water-space, and discharging the curd.

To aid in this, one end of the machine is set on eccentrics E. For keeping the curd separate during the operations of scalding, salting, and cooling, a stirring-frame, Fig. 1894, turned by a crank, is used. This stirring-frame consists of curved paddles, and does the work usually performed by hand with a paddle; it is seen placed in the vat in Fig. 1892. The cutting-frame, Fig. 1895, seen in place in the machine, Fig. 1893, cuts the curds into small blocks by the longitudinal and transverse cutters on the rotating frame. This not only cuts the curd, but by its sweep cleans it from the inner surface of the vat. Either of these revolving frames may be lifted instantaneously from the vat, as the shafts bear at one end on a fixed pin, and at the other rest in an open box. At the discharge end of the vat, Fig. 1893, is a semicircular recess separated from the vat proper by a strainer-plate sliding in vertical grooves in the inner shell of the vat, and can be withdrawn vertically when the curd is to be discharged into the hoop of the press.

W. Ralph's cheese vat, Fig. 1896, has a false bottom D, so constructed that the water heated by the furnace E does not come in contact with the bottom of the inner vat B until the water has been in contact with the ends and sides of the vat and imparted a portion of its heat to the same. Hollow pipes F, arranged with a valve *n* and damper P, extend from the false bottom to the heated water below, and open at the top under hollow supports *g* upon which the vat rests.

CHEVAUX DE FRISE. FR., *Chevaux de frise*; GER., *Spanische oder friesische Reiter*; ITAL., *Cavalotto di frisa*; SPAN., *Caballo de friso*.

See FORTIFICATION.

CHIMNEY. FR., *Cheminée*; GER., *Schornstein*; ITAL., *Camino*; SPAN., *Chimenea*.

The appellation *Chimney Stalk* is usually applied to a lofty chimney; such stalks are erected for steam-engines, or employed to create a draught of air through furnaces.

1. Heating apparatus vary in form and arrangement with the nature of the effect to be produced, but in general they all consist of three distinct parts: the furnace or place in which the heat is generated, the place in which the heat is utilized, and the chimney.

The function of chimneys is twofold:—

1st. To discharge at a great height in the atmosphere, the heated air often charged with smoke, which would be noisome to animal life if ejected at a small altitude.

2nd. To cause a sufficient flow of air through the furnace to maintain combustion.

2. *Motion of Heated Air in Vertical Tubes.*—When a mass of air is at a temperature above that of the surrounding air, it has a tendency to rise in virtue of a force equal to the excess of the weight of the air displaced over its own weight. This is a particular case of the principle of Archimedes.

The same thing happens when the heated air is contained in a vertical tube A B, Fig. 1897, open at both ends. If we represent by P the pressure of the atmosphere in kilogrammes at the height of the point A, upon a surface equal to the section of the tube, and by *p* and *p'*, the weight of two columns of air having the volume of the tube under the atmospheric pressure, one at the temperature of the external air, the other at that of the heated air, it is evident that the pressure at the point B, exerted in an upward direction, will be $P + p$, and that the pressure at the same point, exerted in the contrary direction, will be $P + p'$. Therefore the column of heated air will have a tendency to rise in virtue of the pressure $p - p'$. It follows from this, that if the pipe A B be fixed at the bottom to a horizontal pipe B C, heated externally, Fig. 1898, the external air will enter constantly through the orifice C, and will escape through the orifice A. This flow of air takes place in virtue of the excess of the atmospheric pressure at the point C over the internal pressure at the bottom of the pipe A B.

3. To determine the velocity of ingress of the external air at the point C, supposing the section

of the tube constant, we must remember that the flow of a liquid or of a gas, the resistance depending on the form and the dimensions of the tube apart, is represented, from the point of view of velocity, by the formula $v = \sqrt{2gP}$, in which P denotes the height of a column of fluid subjected to the pressure, and which would hold this pressure in equilibrium, however it might be produced. In the case in question, P is evidently the height of a column of external air, and its value is readily found.

Denoting the height of the chimney from the centre of the section C, Fig. 1898, by H , the external temperature by θ , that of the air inside the chimney by t , and the pressure of the atmosphere at the point A, in air at θ° , by M , the pressure of the point C, from the outside inwards, measured by a column of air at θ° , will be $M + H$, and the pressure in the contrary direction, measured in the same way, will be

$$M + H(1 + a\theta) \div (1 + at).$$

Consequently, we shall have as the excess of the former pressure over the latter,

$$M + H - \left(M + \frac{H(1 + a\theta)}{1 + at} \right) = \frac{Ha(t - \theta)}{1 + at};$$

and therefore,

$$v = \sqrt{\frac{2gHa(t - \theta)}{1 + at}}. \quad [A]$$

4. It may be useful to remark that the pressure at any height in the column of heated air is equal to that at the point C. If we consider a horizontal section of the chimney at a height H' from the top, the upward

pressure which it will support, reckoned in air at θ , will be $M + H - (H - H') \frac{1 + a\theta}{1 + at}$; the

pressure in the contrary direction will be $M + H' \frac{1 + a\theta}{1 + at}$; and subtracting one from the other

we find, as before, $Ha \frac{(t - \theta)}{1 + at}$.

5. For the rate of flow of the hot air, as the velocities are in inverse proportion to the densities, we shall have

$$v' = v \frac{1 + at}{1 + a\theta}; \text{ whence } v' = \sqrt{\frac{2gHa(t - \theta)(1 + at)}{(1 + a\theta)^2}}. \quad [B]$$

6. The formulæ [A] and [B] may be put into a more convenient form for practice, by substituting for the term $\sqrt{2ga}$ its value; we shall then have

$$v = 0.268 \sqrt{\frac{H(t - \theta)}{1 + at}}; \text{ and } v' = \frac{0.268}{1 + a\theta} \sqrt{H(t - \theta)(1 + at)}.$$

The formula [A] is alone important, for the useful effect of chimneys always consists in their ability to create a draught.

7. We have supposed that the density of the air depended only upon its temperature. This is not strictly true, for the density of the air at the same temperature decreases with the increase of altitude; but it is obvious that in the highest chimneys, the variations of density resulting from variations of height are quite imperceptible. For the altitude $0^m.76$ of the barometer, the pressure of the atmosphere is represented by a column of water of $0^m.76 \times 13.6 = 10^m.336$, and by a column of air at 0° , under the same pressure, equal to $10^m.336 \div 0.0013 = 7950^m$. Thus, the density of the air at a height of 20 metres, for example, would be to that of the air at the surface of the earth in the ratio of 7930 to 7950, that is, in that of 1 to 1.0025, a variation of no importance whatever.

8. We have supposed the vertical tube cylindrical and completely open at the ends; but it is evident that the position and form of the pipe have no influence on the force produced by the ingress of external air, when the temperature of the pipe is everywhere equal to t , H representing the difference of level between the two ends of the column of heated air. If the air, in ascending the pipe, met with variations of temperature, we should have to take for t the mean temperature.

9. The formula [A] gives the velocity or rate of ingress of the external air, all resistance apart; but there is always a loss of force attributable to friction and the form of the tube. If the chimney, instead of being cylindrical, varied in section and direction, the weight or force which would cause the inward flow of cold air would be still the same; but the actual rate of ingress would be found by taking into account the resistance, by means of the general formula given. We will return to this question later.

10. To determine how the rate of ingress V of the external air varies with the increase of t , according to the formula [A], suppose $\theta = 0$; this formula becomes $v = \sqrt{2gH} \sqrt{\frac{at}{1 + at}}$. The first factor of the value of v represents the velocity acquired by a body falling from the height

H; and, as the second factor is always less than unity, the rate of ingress is never more than a fraction of this velocity. Taking successively for t 50° , 100° , 150° , 200° , 250° , 300° , 350° , 400° , 500° , 1000° , 1500° , 2000° , we find as the values of the second factor, $0\cdot39$, $0\cdot51$, $0\cdot57$, $0\cdot64$, $0\cdot68$, $0\cdot71$, $0\cdot74$, $0\cdot76$, $0\cdot80$, $0\cdot88$, $0\cdot91$, $0\cdot93$. These numbers divided by the first, $0\cdot39$, give the ratios: 1 , $1\cdot31$, $1\cdot51$, $1\cdot65$, $1\cdot76$, $1\cdot83$, $1\cdot90$, $1\cdot96$, $2\cdot06$, $2\cdot25$, $2\cdot34$, $2\cdot38$. Thus the rate of ingress of the cold air increases constantly with t , but this increase has a limit; for as t increases, the ratio $\frac{at}{1+at}$, which is equal to $\frac{a}{\frac{1}{t}+a}$, constantly approaches unity, and consequently, the rate of ingress

of the cold air, from $t = 50^\circ$ to $t = \infty$, varies in the ratio of $0\cdot39$ to 1 , or in that of 1 to $2\cdot56$.

It follows from this that the rate of ingress of the cold air increasing very slowly with the temperature, the useful effect of the chimney costs in fuel an amount proportionate to the temperature within the chimney.

The maximum rate of ingress of the outside air being $\sqrt{2gH}$, for chimneys of 5^m , 10^m , 20^m , 30^m , 40^m , it is equal to $9^m\cdot9$, $14^m\cdot0$, $19^m\cdot8$, $24^m\cdot3$, $28^m\cdot0$, and for an excess of temperature of 300° , the rate would be only $0\cdot71$ of the maximum. The velocity is besides considerably reduced by the resistance experienced by the heated air when in motion, as we shall see later.

11. We have supposed that the air, entering the vertical pipe, underwent, while being heated, no other change of density than that resulting from the change of temperature. But usually the heat is caused by combustion, the nature of the gas is changed, and it is necessary to see what the formulæ [A] and [B] become when the tabular density of the gas is equal to δ , instead of being equal to unity.

In this case, the height of the inner column, reduced to θ° , and to the density of the outer air, will be $\frac{H\delta(1+a\theta)}{1+at}$, and the difference of the two columns, or the force, will become

$$H - \frac{H\delta(1+a\theta)}{1+at} = \frac{H[1-\delta+a(t-\delta\theta)]}{1+at}; \text{ or, } \frac{H(1-\delta+a\theta)}{1+at}$$

by rejecting the term $\delta a\theta$.

If, for example, the whole of the oxygen were transformed into carbonic acid, the density of this latter gas being $1\cdot529$, and that of ozone $0\cdot976$, the density of the mixture would be

$$0\cdot21 \times 1\cdot529 + 0\cdot79 \times 0\cdot976 = 1\cdot091;$$

if only half the oxygen were transformed into carbonic acid, which is the ordinary case, the density would be only $1\cdot04$. Neglecting θ in the expression of the force, it would become in the two cases, $\frac{H(at-0\cdot091)}{1+at}$; and $\frac{H(at-0\cdot04)}{1+at}$: and these would be the same if the values of t were diminished by 25° in the first case, and by 11° in the second. These variations are of small importance, especially when t is considerable. Besides, as the gases which are evolved in the furnaces always contain a certain quantity of steam obtained from the water held by the combustibles, and as the density of steam is equal to $0\cdot621$, its pressure diminishes the effect of the carbonic acid.

Thus we may admit, as an approximation amply sufficient in practice, that the effect produced by a column composed of air and gases, resulting from combustion, is the same as if the column were of pure air.

12. *Motion of Heated Air in a Pipe consisting of several Vertical Tubes successively passed through.*—If the heated air traverses successively, ascending and descending, several vertical tubes in which the temperature is not the same, the force or pressure at the beginning of the pipe will depend at once on the heights of the tubes and the temperatures of the heated air. We will endeavour to determine it in a general manner.

13. Let us, in the first place, consider a chimney A B, Fig. 1899, extending horizontally in the direction B C, and descending again vertically in the direction C D, so as to form a syphon.

If we represent by t and t' the temperatures of the air in the portions A B and C D, by θ that of the external air, by p and p' the pressures of the atmosphere at the points A and D reckoned in air at θ° , under the normal pressure, and by m and m' the heights of the columns of air at θ° , equivalent to the columns of heated air A B and C D, the force in air at θ° , which will produce the rush of cold air at the point A, will evidently be equal to $p - m + m' - p'$; and as the pressure of the external air at the point D exceeds that at the point A by a column of external air equal to $H' - H$, we shall have as the force in air at θ° , at the point A,

$$p - \frac{H(1+a\theta)}{1+at} + \frac{H'(1+a\theta)}{1+at'} - (p+H'-H) = \frac{Ha(t-\theta)}{1+at} - \frac{H'a(t'-\theta)}{1+at'}.$$

Thus the force is equal to the difference of the corresponding forces at the two branches supposed alone. The flow will evidently take place in the direction A B, as we had supposed, if the preceding expression be positive. Taking the external air at θ° , and rejecting the terms $H a^2 t t'$ and $H' a^2 t t'$, which are always small, seeing that $a^2 = 0\cdot000134$, the value of the force

in external air becomes $\frac{a(Ht-H't')}{1+a(t+t')}$, an expression that is positive when

Ht is greater than $H't'$, a circumstance which may always be obtained, whatever H' may be, by diminishing t' . This may be effected by cooling the air in the tubes B C and C D. Thus the

gases evolved in the furnace may always be discharged at any height, even beneath the level of the furnace.

14. If there were a third column EF, Fig. 1900, denoting its height by H'' , and the mean temperature of the air in it by t'' , by m'' the height of a column of air at θ° producing the same pressure, and retaining the preceding notation, the force at the point A would be $p - m + m' - m'' - p'$; but we have $p' + H'' - H' + H = p$, and therefore the force at the point A in air at θ° will be

$$p - \frac{H(1+a\theta)}{1+at} + \frac{H'(1+a\theta)}{1+at'} - \frac{H''(1+a\theta)}{1+at''} - p - (H'' - H' + H) \\ = \frac{Ha(t-\theta)}{1+at} - \frac{H'a(t'-\theta)}{1+at'} + \frac{H''a(t''-\theta)}{1+at''}.$$

The flow will take place in the direction AF, when this expression is positive. Rejecting, as before, the terms containing a^2 , and *a fortiori* a^3 , and supposing $\theta = 0$, the preceding expression is reduced to $\frac{a(Ht - H't' + H''t'')}{1 + a(t + t' + t'')}$, an expression which will be positive when $Ht + H''t''$ is greater than $H't'$.

It would be easy from this to find the formula for any number of tubes.

15. Let us now suppose the pipe to have the form of a syphon reversed, Fig. 1901; retaining the same notation, the force at the point A, in air at θ° , will be $p + m - m' + p'$; or

$$p + \frac{H(1+a\theta)}{1+at} - \frac{H'(1+a\theta)}{1+at'} - p + H' - H = -\frac{Ha(t-\theta)}{1+at} + \frac{H'a(t'-\theta)}{1+at'}.$$

As in the preceding case, the effect produced is equal to the difference of the effects which the two branches would produce alone. Rejecting the terms containing a^2 , and making $\theta = 0$, the value of the force is reduced to $-\frac{a(Ht - H't')}{1 + a(t + t')}$, a value which will be positive when $H't'$ is greater than Ht ; this condition may always be satisfied by increasing H' , and by preventing the cooling of the air in the horizontal portion BC.

16. If the pipe were formed of three tubes, Fig. 1902, the force at the point A, in air at θ° , would evidently be $p + m - m' + m'' - p'$; or

$$p + \frac{H(1+a\theta)}{1+at} - \frac{H'(1+a\theta)}{1+at'} + \frac{H''(1+a\theta)}{1+at''} - (p + H - H' + H'') \\ = -\frac{Ha(t-\theta)}{1+at} + \frac{H'a(t'-\theta)}{1+at'} - \frac{H''a(t''-\theta)}{1+at''},$$

or on the hypothesis $\theta = 0^\circ$, $\frac{a(-Ht + H't' - H''t'')}{1 + a(t + t' + t'')}$.

The force for any number of tubes may be readily calculated in the same way.

In general, the effect produced is equal to the sum of the effects produced separately by the tubes in which the heated air rises, diminished by the sum of the effects produced by the tubes in which the heated air descends.

17. It is of importance to remark that in the case in which the heated gas begins by descending, supposing the expression of the force to be positive, motion will not take place until the system of syphons has been put into action by heating some of the branches in which the air ascends. It is

evident that this precaution will not be needed in the case in which the heated air ascends in the first column.

18. *Motion of Heated Air in a Pipe consisting, throughout a certain length, of several Vertical Tubes traversed simultaneously.*—Let us consider, in the first place, a vertical pipe, Fig. 1903, consisting, throughout a certain length, of two equal and parallel branches. If both contain air at an equal temperature, everything else being equal in the two branches, the ascending heated air will traverse them with the same velocity; but however little difference there may be in the diameters, the resistance, or the causes of cooling, this equality of velocity, should there be any difference, will not exist; and if the section of each of them is equal to the section of the end tubes, the motion will take place through one only, that one which offers the least resistance. This phenomenon will evidently occur, whatever the number of the tubes may be.

19. If the pipe were only enlarged throughout a portion of its length, Fig. 1904, the current of heated air could not necessarily fill the enlarged portion of the pipe; if it filled it at first, the cooling of the sides would soon cause a decrease of temperature from the centre to the circumference; there would occur, in the elementary veins and in the same direction, variations of velocity which would go on increasing, so that the vein of heated air would soon traverse the enlarged space, without much increasing in section.

20. Suppose now that the heated air drawn by the chimney descends a pipe consisting of two parallel branches, Fig. 1905. In this case, the heated air will separate itself equally in the two branches, and the equality of velocity will be maintained in spite of the inequalities of cooling which the air may undergo. Indeed, in each branch, the force which produces the motion is equal to the difference of the pressures in the chimney and in the pipe under consideration, supposing them isolated; and, consequently, if in one of the branches the cooling was greater than in the other, the velocity there would become greater. The same thing would occur in the case of any number of parallel tubes.

21. If the pipe through which the heated air descends were enlarged, Fig. 1906, the elementary veins in the enlarged portion would assume and retain the same temperature, for the same reason as in the preceding case.

These facts, which have been many times proved by experience, are of great importance in the construction of heating apparatuses, as we shall see later.

22. It must be remarked that in all the preceding considerations relative to the velocity of the gases in chimneys, we have left out of the question the resistance experienced by the air when in motion. But as this resistance is always considerable, there will be a greater or less reduction of the velocity. When the descending pipe is single, friction takes place against the surface; therefore, on this account alone, the velocity would there be less than in the other points of the section; but the cooling which the heated air there undergoes tends to diminish the difference of velocity which would naturally arise in the veins, and this difference will be still more diminished by the gradual transmission of the resistance and the temperature. If the descending pipes were formed of several tubes having the same section and the same length, the same phenomena would occur, and the heated air would have the same velocity in each of them. But if the tubes have different sections, the velocity will be modified by the cooling which tends to increase it and by the friction which tends to diminish it. The friction varies in proportion to the square of the velocity, whilst the cooling is proportional to the diameter and depends also upon the velocity; it is, therefore, not

easy to foresee and to calculate in a general manner what will happen. The cooling is, however, small in general, and the influence of friction will in almost all cases exceed it, so that the actual velocity will decrease with the diameter of the pipes, a theoretical result that is in perfect accordance with the results of experience. The difference of the velocities will evidently decrease with the velocities themselves.

23. *Former Theory with respect to the Drawing of Chimneys.*—Hitherto it has been admitted that the force in air at θ° , $H a (t - \theta) \div (1 + a t)$ was applied directly to the heated air, and the result of this was, that the force in air at t° being $H a (t - \theta) \div (1 + a \theta)$, the velocity of the heated air was

$$v_1 = \sqrt{\frac{2g H a (t - \theta)}{1 + a \theta}}; \text{ and the rate of ingress of the cold air was}$$

$$v_1 = v_1' \frac{1 + a \theta}{1 + a t} = \sqrt{\frac{2g H a (t - \theta) (1 + a \theta)}{(1 + a t)^2}},$$

formulae which differ widely from the formulæ [A] and [B], for we have evidently

$$v_1' = v' \sqrt{\frac{1 + a \theta}{1 + a t}}; \text{ and } v_1 = v \sqrt{\frac{1 + a \theta}{1 + a t}};$$

which give for v_1' and v_1 velocities less than v' and v . Besides this, the value of v_1 offers a circumstance that is not found in the value of v . If θ remaining constant, the value of t be progressively increased, v_1 increases at first, reaches a maximum for $t = \frac{1}{a} + 2\theta = 274 + 2\theta$, and afterwards decreases indefinitely.

24. But the force in air at θ acts directly upon the cold air which is entering the chimney and not upon the heated air, and it is the velocity of the cold air that is afterwards transmitted to the heated air. Thus the formulæ which we have just given, for a considerable time admitted by all who have studied the question and by Péclet in the second edition of his work, do not represent the phenomena as they actually are. This discovery, due to Péclet, resulted from a more careful examination of the facts and from several experiments which we here relate, taken from Péclet's 'Traité de la Chaleur.'

25. Taking the case of a horizontal pipe through which air coming from a gasometer flows, let L and D denote the length and the diameter of the pipe; P the excess of pressure in the gasometer over the pressure of the atmosphere; p the force corresponding to the velocity of flow at the end of the pipe, both expressed in air at the external temperature θ° ; and A the coefficient of the loss of force at the orifice. The pipe being at the external temperature, we shall have

$$P - p = \left(A + \frac{KL}{D} \right) p, \text{ and } V = \sqrt{\frac{2gP}{1 + A + \frac{KL}{D}}}. \quad [a]$$

Suppose now the pipe heated so as to raise its temperature to t° ; admitting that the flow of heated air takes place by the force in heated air, this force will be $P \frac{(1 + a t)}{1 + a \theta}$, and the velocity of flow v_1 of the cold air from the gasometer will be

$$v_1 = \frac{1 + a \theta}{1 + a t} \sqrt{\frac{2gP(1 + a t)}{1 + a \theta}} \cdot \frac{1}{1 + A + \frac{KL}{D} \left(\frac{1 + a t}{1 + a \theta} \right)}; \quad [b]$$

and as, by placing the whole under the radical sign, the first factor becomes $2gP \frac{1 + a \theta}{1 + a t}$, we see

that the ratio of V to v_1 is greater than the square root of $\frac{1 + a}{1 + a \theta}$.

In the new theory, we have as the velocity v of the cold air,

$$v = \sqrt{\frac{2gP}{1 + A + \frac{KL}{D} \left(\frac{1 + a t}{1 + a \theta} \right)}}; \quad [c]$$

and the ratio of V to v decreases but slowly, in proportion as t increases, and only by the increase of resistance due to friction, and which is caused by the elevation of the temperature.

26. To determine the influence of the heating of the air in the pipe AB , Péclet had recourse to the arrangement shown in Fig. 1907. AB is a copper pipe 1 metre in length and 0.01 in diameter, communicating with a gasometer; throughout a portion of its length it was enclosed by another concentric tube CD ; the space between the two tubes was closed at the ends by cocks, and steam introduced by the pipe a , and let out by the pipe b .

When the pipe AB was not heated, a certain volume of air flowed through in 612"; and when the pipe was heated, the same volume of air, under the same pressure and at the same temperature, flowed through in 618".

27. To obtain a higher temperature, Péclet adopted the arrangement shown in Fig. 1908. A B is a glass tube of 0^m·322 in length and 0^m·0047 in diameter, fixed to the end of an iron tube B C of

0^m·90 in length and 0^m·011 in diameter; beneath the iron tube was placed a stove D E of nearly the same length, for the purpose of holding burning charcoal. For this arrangement, the equations [a], [b], and [c] were replaced by the following:

$$V = \sqrt{\frac{2gP}{1 + A - B + \frac{Kl}{d} + \frac{KL}{D} \cdot \frac{d^4}{D^4}}} \quad [a']$$

$$v_1 = \frac{1 + a\theta}{1 + a} \sqrt{\frac{2gP(1 + a)}{1 + a\theta}} \cdot \frac{1}{1 + A - B + \frac{Kl}{d} + \frac{KL}{D} \cdot \frac{d^4}{D^4} \left(\frac{1 + a}{1 + a\theta} \right)^2} \quad [b']$$

$$v = \sqrt{\frac{2gP}{1 + A - B + \frac{Kl}{d} + \frac{KL}{D} \cdot \frac{d^4}{D^4} \left(\frac{1 + a}{1 + a\theta} \right)}} \quad [c']$$

in which V represents the velocity of flow in the small tube when the air is not heated; v_1 and v , the velocities of the cold air when the air is heated in the large tube, for the old and new theories; l, L, d, D , are the lengths and the diameters of the tubes A B and B C; A and B are the coefficients of the variations of force at the orifice, and at the point in which the tube is suddenly enlarged.

In this case, as in the preceding, the ratio of V to v_1 is greater than the square root of $\frac{1 + a}{1 + a\theta}$, whilst the ratio of V to v differs but little from unity.

The iron tube being at the external temperature, a certain volume of air flowed through in 620"; and when it was heated to a dark red, the same volume of air, in the same circumstances, flowed through in 650". The iron tube having been replaced by another of 0^m·013 in diameter and 1^m·16 in length, the same volume of cold air flowed through in 615"; and when the tube was heated red hot, the time of the flow, in the same circumstances, rose to 648". The external temperature was at 14°.

These experiments do not enable us to determine exactly to which of the two formulæ [b] and [c] or [b'] and [c'] they conform most, because it was impossible to measure the temperature of the air on issuing, and because the increase of resistance took place successively, which prevented the calculation of the resistance in the tube A B. It is, however, plainly seen that the equations [b] and [b'] are incompatible with the equations [a] and [a'].

28. In the first experiment, the ratio of the velocities of the cold air, when the second tube is cold and when it is heated, is equal to $\frac{618}{612} = 1.0099$; and, according to the formulæ [a] and [b],

supposing the air at 100°, this ratio should be greater than the square root of $\frac{1.366}{1.0366}$, which is equal to 1.1471. Neglecting the increase of resistance in the tube A B, which increase augments the ratio in question, we should have to admit for formula [b], in order to make it agree with experience, $t = 150.7$; but this is impossible, for the temperature must have been near 100°. In the

second experiment, the ratio of the velocities in question was equal to $\frac{650}{620} = 1.0483$; and, according to formula [b'], supposing only the air at 400°, this ratio should exceed the square root of $\frac{2.464}{1.05124}$, which is equal to 1.53. Neglecting the increase of resistance in the tube A B, to make

formula [b'] agree with experience, we should have to suppose $t = 420.4$. But this is impossible, for we find in the register of the experiments these words: *The air issuing is burning; a thermometer held in it rapidly rises to 150°.* And it could not have been otherwise, for the iron tube was red hot. In

the third experiment, the ratio of the velocities was $\frac{648}{615} = 1.0536$; and, according to formula [b],

supposing only the air at 600°, this ratio should exceed the square root of $\frac{3.196}{1.0512}$, which is equal to 1.743. Neglecting as before the increase of resistance in the tube A B, to make formula [b'] agree with experience, we should have to suppose $t = 450.5$. This again is impossible, for the air issued hotter than in the preceding experiment.

The discrepancies which we have found between the results of the formulæ [b] and [b'] and those

of experience, are too great to be attributed to errors of observation. For example, for the first experiment, neglecting the resistance due to the increase of friction, the time of the flow should have been $612 \times 1.1471 = 900''$, instead of $618''$; that is, greater by $900 - 618 = 282''$; and this difference should have been much greater for the others; now, each experiment was repeated twice with the same result each time.

29. It follows evidently from all these experiments that the formulæ [b] and [b'] cannot be admitted; that is, when air flows in a horizontal tube in virtue of a pressure, and the air at a certain distance is heated, the velocity of the cold air cannot be deduced from that of the heated air by taking as the force of this flow of cold air, the force in heated air. But if we suppose that the external force is applied to the cold air, the velocity will undergo only a small diminution resulting from the increased resistance of the heated air, and this agrees with the experiments.

That which we have just affirmed must evidently be true, whatever the nature of the pressure exerted on the cold air on its entrance into the tube may be; therefore, if it is vertical and heated externally, the pressure resulting from the two columns of air of the same height, one at the external temperature θ° , and the other at the mean temperature t , is the force which acts directly on the cold air entering the chimney; this force should be measured in air at θ° , and it is this velocity which is afterwards transmitted to the heated air, as we have already explained (3).

30. *Former Experiments on the Flow of Air in Chimneys.*—Many years ago Pécelet made a long series of experiments on the flow of air in chimneys. He employed pipes of sheet iron, cast iron, and earthenware, of various heights and sections. The apparatus was arranged in the following manner: the stove was large and partly covered with charcoal for the purpose of rendering the resistance of the fire-place nearly nul; the chimney was above the stove. The temperature of the air in the chimney was shown by two thermometers placed, one at the bottom, the other at the top. As anemometers were unknown in those days, Pécelet determined the velocity of the air by introducing rapidly through the opening in the ash-pan under the stove, a piece of burning tow which had been previously dipped in turpentine and fixed to the end of an iron rod. Withdrawing immediately the burning tow, a small quantity of smoke was produced in the fire-place and carried upwards by the heated air. By observing the time when the smoke was produced and the time when it appeared at the top of the chimney, the velocity of the current of air in the chimney was ascertained. The experiments were repeated with the chimney more or less closed at the top, and at the bottom by diaphragms formed of a sheet of iron pierced with a circular orifice. The method of observation was too imperfect to give exact results, yet these experiments enabled the experimenter to ascertain some important facts of which we will speak later.

31. *General Considerations on Factory Chimneys.*—In order to study in a complete manner the phenomena which occur in chimneys, it is necessary to have a clear notion of the general arrangement of heating apparatuses. As we have said already, they consist of the furnace, the space in which the heat is utilized, and the chimney. Furnaces are usually formed of cast-iron bars placed in a horizontal plane, or slightly inclined, separated from each other by small intervals, and upon which the fuel is placed. Beneath is a space communicating freely with the air, and known by the name of the "ash-pit."

The space comprised between the furnace and the chimney, and where a portion of the heat produced passes into the body which it is wished to heat, has forms and dimensions varying with the nature of the effect to be produced.

Chimneys are always vertical tubes or channels, constructed of brick or sheet iron, and designed to discharge the burned air, and to create a draught through the furnace, which draught is necessary to support combustion.

32. The inward rush of external air caused by the temperature of the burned air and by the height of the chimney is called the *draught*. The draught of a chimney, as we have calculated it, is always diminished, in a very large proportion, by the resistance of the bars, and so on, of the furnace, the sudden or continuous changes of section and direction, and by friction.

The phenomena which occur in heating apparatuses are very complicated and very varying, chiefly with the condition of the furnace; but we may determine the influence of the various circumstances which modify the draught. We will suppose, in the first place, that the circuit has everywhere the same section, from the opening of the ash-pit to the top of the chimney. This hypothesis differs but little from ordinary facts; even to the sum of the free orifices of the furnace-bars a surface is given differing but little from the horizontal section of the chimney. Denoting, then, the section of the air-channel which conducts the air under the furnace-bars by S , the rate of ingress of the cold air by v , Sv will represent the volume of cold air entering per second. Putting G for the resistance of the furnace, C for that of the circuit preceding the chimney, and H and D for the height and diameter of the chimney, the friction in the chimney will be $KL(1+t)^2 \div D(1+\alpha\theta)^2$, and would be exactly the same if the section of the chimney were the square circumscribed about the circle. Applying here the laws relative to the motion of compressed gases, we shall have, supposing the temperature outside equal to 0° ,

$$P - p = (G + C)p + \frac{KH}{D}(1 + \alpha t)^2 p;$$

whence

$$v = \sqrt{\frac{2gH\alpha t}{(1 + \alpha t) \left[1 + G + C + \frac{KH}{D}(1 + \alpha t)^2 \right]}}.$$

33. The examination of this formula leads to several consequences of great importance in practice.

1. When the values of G and C are very great relatively to the friction in the chimney, which is almost always the case, the draught is proportional to the square root of the height.

2. If we supposed G and C nul, which would happen only in the case in which the furnace is placed at the bottom of the chimney, the grating occupying only a small portion of the section, and the air experiencing no resistance on entering the chimney, the draught would vary very little with the height of the chimney; it would be nearly independent of it when $KH \div D$ is very great relatively to 1. These are circumstances which occur rarely in practice, but they were present in the experiments to which we have alluded (30). The height of the chimney had hardly any influence upon the draught, because the air experienced hardly any resistance.

3. Suppose again that, nothing being changed in the dimensions of the apparatus, the temperature t varies. If G and C be supposed constant, the friction in the chimney being in general very small relatively to $G + C$, the draught, will vary nearly proportionally to the square root of

$\frac{t}{1 + at}$; that is, in the same ratio as the theoretical draught. Thus, in the supposition which we have made, the ratio of the actual to the theoretical draught would be a constant number, depending only on the dimensions of the apparatus. But, in an apparatus in operation, t can rise only by the increase of the velocity of the current, and this increase can take place only by the diminution of the resistance, which, in the case supposed, can result only from the condition of the furnace or from the raising of the register; the draught in that case increases in a greater ratio than in the supposition of G and C constant, only there is at the same time a certain increase in the value of C , resulting from the increased velocity. In like manner, the value of t could decrease only by the increase of resistance in the grating, or by the lowering of the register, and the diminution of draught would then be more rapid than if the resistance did not vary.

34. Let us now see what would happen if the circuit were interrupted by a diaphragm. This is a circumstance that occurs in every heating apparatus, for all are provided with registers for the purpose of regulating the draught or of stopping it altogether during the interruptions of work. We will first suppose that the diaphragm is placed in that portion of the air-channel which conducts the external air beneath the grating. Denoting the orifice in the diaphragm by d its diameter, we shall have

$$P - p = (G + C)p + \frac{KH}{D}(1 + at)^2 p + \left(\frac{D^4}{d^4} - 1\right)p;$$

$$\text{whence } v = \sqrt{\frac{2gH at}{1 + at}} \sqrt{\frac{1}{1 + G + C + \frac{KH}{D}(1 + at)^2 + \frac{D^4}{d^4} - 1}},$$

neglecting the loss at the entrance into and the gain at the issue from the orifice, which are both very small relatively to the denominator of the second radical in the value of v .

It follows from this formula that the influence of the diaphragm becomes smaller as the total resistance of the circuit becomes greater. In large steam generators, the actual rate of ingress is less than a fifth of the theoretical rate. Supposing it equal to this fraction, we shall have nearly

$$v = \sqrt{\frac{2gH at}{1 + at}} \sqrt{\frac{1}{25 + \frac{D^4}{d^4} - 1}}.$$

If we suppose that the ratio of the sections of the chimney and of the orifice $\frac{D^2}{d^2}$ becomes successively, 2, 4, 6, 8, 10, 20, 40, 60, 80, 100; the values of the second radical will be 0.189, 0.158, 0.130, 0.1066, 0.09, 0.048, 0.025, 0.0166, 0.0125, 0.01. The value of the radical without the diaphragm is 0.20, and by the influence of the diaphragm it is reduced in the proportion, 0.945, 0.75, 0.64, 0.53, 0.45, 0.24, 0.12, 0.083, 0.062, 0.059. Thus, as it was easy to see by inspection from the formula, diaphragms diminish the draught in a proportion much smaller than the ratio of the sections; a diaphragm which reduces the section to a tenth reduces the draught by only the half. This small influence is due to the retardation of the velocity by the diaphragms, and, consequently, the diminution of resistance in the rest of the circuit.

35. The diaphragm reducing the rate of flow in a proportion less than the ratio of its section to that of the chimney, it follows that the velocity of the air in the orifice of the diaphragm must increase in proportion as its surface decreases. In the general case, the velocity of the air in the diaphragm is:

$$v = \sqrt{\frac{2gH at}{1 + at}} \cdot \frac{D^2}{d^2} \cdot \sqrt{\frac{1}{1 + G + C + \frac{KH}{D}(1 + at)^2 + \frac{D^4}{d^4} - 1}};$$

and in the particular case which we have examined, we have

$$v' = \sqrt{\frac{2gH at}{1 + at}} \sqrt{\frac{\frac{D^4}{d^4}}{25 + \frac{D^4}{d^4} - 1}}.$$

Taking as the ratio of the sections $\frac{D^2}{d^2}$ the same numbers as before, we find as the value of the second radical, 0.378, 0.632, 0.77, 0.85, 0.90, 0.97, 0.992, 0.996, 0.998, 0.999; and as the value

of this radical without the diaphragm is 0.20, the velocities in the diaphragm with respect to the velocity in the circuit are, 1.89, 3.16, 3.87, 4.26, 4.49, 4.85, 4.96, 4.98, 4.99, 4.99.

Thus this ratio approaches 5 as the diameter decreases, because the actual velocity without the diaphragm is $0.2 = \frac{1}{5}$ of the velocity due to the force, and, the diaphragm retarding the velocity in the chimney, diminishes the friction. It is evident that if the velocity of the current of air were a fraction $\frac{1}{m}$ of the velocity V due to the force, the ratio in question would continually approach m as the diameter of the diaphragm diminished.

36. If there were in that portion of the air-channel which conducts the air to the ash-pit several diaphragms at a sufficient distance apart to allow the vein of air, after having traversed each of them, to fill the space in which they are placed before meeting with the next, the velocity would become

$$v = \sqrt{\frac{2gH\alpha t}{1+\alpha t}} \sqrt{\frac{1}{1+G+C+\frac{KH}{D}(1+\alpha t)^2+m\left(\frac{D^4}{d^4}-1\right)}},$$

and if $\frac{D^4}{d^4}$ were very great relatively to the terms which precede, for the same value of $\frac{D^2}{d^2}$ the value of v would vary in an inverse proportion to the square root of m .

37. We have supposed that the diaphragms were placed in the current of cold air before it reached the grating of the furnace; let us now suppose them placed in that portion of the circuit traversed by the heated air. As the velocities are inversely as the densities, we shall have in general

$$P-p = (G+C)p + \frac{KH}{D}(1+\alpha t)^2 p + m\left(\frac{D^4}{d^4}-1\right)(1+\alpha t)^2 p;$$

$$\text{whence } v = \sqrt{\frac{2gH\alpha t}{1+\alpha t}} \sqrt{\frac{1}{1+G+C+\frac{KH}{D}(1+\alpha t)^2+m\left(\frac{D^4}{d^4}-1\right)(1+\alpha t)^2}}.$$

Thus diaphragms placed in the current of heated air reduce the draught more than when they are placed before the ash-pit, because the velocity of the heated air is greater than that of the cold air.

38. Experiments made by M. Combes confirm the consequences which we have drawn from the general formula. It was found that by closing the orifice for the ingress of the air into the ash-pit of a generator, by means of a sheet of iron pierced with holes, the velocity of the air traversing the aperture, measured by an anemometer, continued to increase with the decrease of the size of the holes. The following are the details of this experiment.

The chimney was 20 metres in height; its section at the bottom being 0.383 square metre, and at the top 0.196 square metre. The surface of the furnace-grating was 0.6525, and the sum of the spaces between the bars 0.168 square metre. The mouth of the ash-pit was covered with a sheet of iron pierced with six square holes of 0^m.167, and having a surface of 0.028 square metre each, and altogether a surface equal to the whole open surface between the bars.

The velocity was first ascertained by means of an anemometer with all the holes open, immediately after the fire had been made up, and again after it had been stirred. Two experiments made in succession gave as the velocities 0^m.5275, 1^m.68, 0^m.86, 1^m.15; mean, 1^m.17. With two of the holes closed, under the same circumstances, the velocities were 1.607, 1.99, 1.89, 2.05; mean, 1^m.88.

When four of the holes were closed, the velocities under the same circumstances were 3.51, 4.05, 2.68, 3.46; mean 3^m.42.

In these three series of experiments, the surfaces for the ingress of the air were 0.168 × 0.65 = 0.1092; 0.0728 and 0.0364 square metre; and the mean velocities 1.17, 1.88, and 3^m.42. Thus the velocities increase rapidly with the decrease of the sections of the orifices; for orifices in the proportion of 3, 2, and 1, the velocities increased 1.26, 1.65, 3.

39. *Lateral Pressure in Chimneys.*—Suppose a chimney placed beyond a furnace of any form, and an opening made in it at a certain height; it is evident that the external air will enter with a velocity greater in proportion to the nearness of the aperture to the ground. At the top, this velocity is nul. This rush of external air would occur if the aperture were in any part of the heating apparatus. Therefore care should always be taken in building to avoid an ingress of external air through fissures in the masonry, because they always occasion a loss of draught and often diminish the useful effect of the fuel.

40. It follows necessarily from what we have said, that inside the furnace and chimney there is a negative pressure, that is, smaller than that of the atmosphere, and that this negative pressure continues to increase from the ash-pit to the bottom of the chimney, and decreases in like manner to the top of the chimney where it is nul.

41. *Effects produced by the Meeting of Currents.*—When several pipes enter the same channel, the currents of air project themselves beyond the orifices, and in certain circumstances they may, by their mutual action, modify the velocities of the air in the pipes. If, for example, two pipes entered a third exactly opposite each other, the third pipe being perpendicular, the influence of the currents would be nul if they had the same velocity; for the effect would be the same as if the currents flowed against a fixed plane placed between them. But if the velocities were unequal, the current having the greater velocity would diminish that of the other, and close more or less the orifice through which it flowed. A vast number of phenomena leave no doubt on this fact;

besides, these currents must act upon each other in nearly the same manner as currents of water, and it is known, from the experiments of Savart, that when two currents of the same section act in contrary directions and one of them has a very small excess of velocity over the other, the latter is driven back to the mouth of the vase, and the flow ceases completely. The effects resulting from this collision may be prevented by placing in the pipe a diaphragm P, as shown in Fig. 1909.

42. Phenomena of the same kind would occur if the two pipes were at right angles to each other, Fig. 1910, with the additional complication caused by the effect of the lateral pressure. But these effects may be wholly avoided by means of the diaphragm P.

If the pipe were enlarged, as in Fig. 1911, the narrowing of the pipe in front of mouth of the lateral pipe would have the effect of a diaphragm; the influence of the collision of the currents might be neglected, but that of the diminution of pressure, due to the enlargement of the pipe, might be very great.

43. In the case of a current of heated air flowing horizontally into a vertical chimney, it may happen that the draught is completely stopped, though the section of the chimney is larger than that of the current of heated air, when the velocity of the latter is very great, because in that case it will close the chimney like a plug. This is a fact which Péclet has had occasion to remark several times, and especially in the case of a chimney which he had built in a soda manufactory, and which formed a portion of a condensing apparatus. This chimney was $13^m \cdot 30$ in height, and had a section of about $0 \cdot 75$ square metre; the smoke-channel entered it horizontally, Fig. 1912. When the fire in the furnace

1912.

was kindled, the draught existed; it increased for some time, and then gradually decreased, till finally it ceased. Péclet soon discovered the cause of this singular phenomenon, and removed it by a vertical partition A placed in the chimney so that the heated air did not come in contact with the gases of the chimney until it had taken the same upward direction.

Thus, it is necessary

to take the greatest care, in all draught chimneys which receive currents of air perpendicularly or variously inclined, to direct them according to the axis of the chimney before they come in contact.

44. *Loss of Heat occasioned by Chimneys.*—The quantity of heat lost by chimneys is very considerable, because the burned air is allowed to escape at very high temperatures, always higher than that of the heated body. This quantity varies with the temperature of the air which escapes, with the volume of cold air entering the furnace, and with the weight

of water contained by the fuel, or produced by its combustion, for the gases are almost always evolved at too high a temperature to allow the condensation of the steam. This loss may be computed approximatively, however, by comparing the temperature of the burned air in the chimney with that which it would have if all the heat produced were employed to heat it. In this calculation it may be assumed that the burned gases possess the calorific capacity of air.

For example, in steam generators the burned air is discharged at about 300° , and on an average 18 cubic metres of air is employed per kilogramme of coal, or $18 \times 1.3 = 23.4$; taking 0.24 as the calorific capacity of the gases produced, the temperature to which the gases would be raised by the 8000 calories or units of heat, resulting from combustion, would be equal to $8000 \div (23.4 \times 0.24) = 1425^{\circ}$; consequently, the loss is equal to $300 \div 1425 = 0.21$. This loss would evidently be doubled or trebled if twice or three times the quantity of air were employed, and it would be reduced to 0.1 if only that volume of air were employed which is rigorously necessary to combustion. Under ordinary circumstances, the loss must be reckoned at not less than 0.25, on account of the steam produced.

In furnaces for melting metals and for the production of coal-gas, the burned air is allowed to escape at a much higher temperature, on account of the high temperature of the substances heated, and the loss of heat is much greater. The loss often amounts to 0.80 or 0.90, even when the volume of air which escapes combustion is very small; but the heat thus lost may, in general, be utilized, at least in a great measure. The utilization of this lost heat is a question of the highest importance in factories, for the cost of fuel is nearly always a considerable item in the cost of the productions. We will return to this subject later.

45. *Arrangements for utilizing the whole of the Heat produced by a Furnace.*—In the apparatus generally employed, the chimney is placed beyond the furnace, which causes, as we have seen, a loss of heat that may be avoided by certain arrangements.

Let us suppose that above or beyond a furnace, well enclosed, there is a chimney of 3 or 4 metres in height, of considerable thickness, and constructed of badly-conducting material. The burned air in this chimney will have a very high temperature, and will acquire an ascending velocity much greater than that necessary to support combustion. Suppose, again, that above this chimney, in its continuation or at the side of it, is the boiler or body to be heated: the course of the smoke may be lengthened, so as to cool it completely or almost completely; and on leaving the heating surfaces it may be allowed to escape immediately into the air, or conducted to a chimney, the use of which is merely to discharge it at a convenient height in the atmosphere.

A similar arrangement is adopted in certain kinds of glass-works; the height of the draught chimney is equal to the distance from the furnace-grating to the roof of the furnace, and the burned air may give up all its heat in the arch if the latter is of sufficient length.

46. At first sight, this method seems applicable only when the bodies to be heated are to be raised to a temperature exceeding but little the ordinary temperature, since the burned air cannot be ejected at a temperature lower than that of these bodies. But by moving the bodies to be heated in a direction contrary to the motion of the heated air, it is evident that, in almost all cases, nearly the whole of the heat of this air may be utilized, and the temperature reduced to that of the atmosphere.

47. This method, which consists in placing the chimney in front of the heating surface, has a disadvantage which we ought to point out. The heating surface must be larger than in the ordinary arrangement, because it is not heated directly by the radiation of the fuel; notwithstanding this disadvantage, however, there are many cases, as we shall see later, in which this method may be adopted with profit.

48. The apparatus may be arranged so as to produce the draught through the heating surface. The arrangement consists in placing the body to be heated in the chimney. If the channels of circulation are narrow, and the heating surface large, the burned air will reach the top of the chimney at a temperature but little above that of the heated body, although the draught be very strong, because the ascending velocity will depend on the mean temperature of the burned air in the channels of circulation, and the temperature at the bottom will be that of the furnace. This arrangement is seen in lime-kilns.

49. *Dimensions of Factory Chimneys.*—The work of a chimney consists, as we have said, in drawing into the furnace the volume of air necessary to combustion. The weight of fuel to be burned per hour is always given; the height of the chimney is, in general, determined by particular conditions, but the section depends on the volume of air employed in consuming each kilogramme of fuel, on the mean temperature which the air will have in the chimney, on the loss of force occasioned by friction, on the changes of section and direction, and on the resistance of the furnace-grating. The phenomena occurring in the draught of a heating apparatus are so complicated, that we cannot hope, by means of simple theoretical considerations, to calculate exactly and for every case the section which should be given to a chimney to produce a given effect. These calculations would be rendered more inexact by the facts that we do not know beforehand the temperature of the air in the chimney, the mean temperature of the air which circulates around the body to be heated, nor the resistance of the grating, and that these three elements, which it would be necessary to know before calculating anything, vary with the condition of the fuel in the furnace, and with its thickness upon the grating. Thus, in every case, we must consider the results of experience to ascertain what section should be given to a chimney; but it is important to remark that there will always be an advantage in giving to chimneys an excess of section, because this produces an excess of draught which may be necessary in certain cases, and which may always be regulated by means of a register.

50. For fixed steam generators, arranged in the usual way, Pécolet discovered, by bringing together a large amount of information, and by some experiments, that for chimneys having 10, 20, and 30 metres, containing air at 300° , with gratings, the open spaces of which are equal to the section of the chimney, and upon which is burned 1 kilogramme of coal an hour per square deci-

mètre, circumstances of ordinary occurrence, the rate of ingress of the cold air is about $0.18v$, $0.17v$, $0.16v$, v being the theoretical rate.

For the heights of 10, 20, and 30 mètres, which we have supposed, and for a mean temperature of 300° in the chimney, the rates of ingress of the cold air, deduced from the formula

$$V = \sqrt{\frac{2gH\alpha t}{1 + \alpha t}}, \text{ are } 10.13, 14.33, 17.55 \text{ mètres, and, consequently, the actual rates are}$$

$0.18 \times 10.13 = 1.82$, $0.17 \times 14.33 = 2.44$, $0.16 \times 17.55 = 2.80$. The volumes of air drawn an hour per square decimètre of section being $v \times 0.01 \times 3600$, will be for the three heights, 65.52, 87.84, 100.8 cubic mètres; and assuming that only the half of the air is transformed into carbonic acid, and, consequently, that the volume of air required to burn 1 kilogramme of coal is equal to 18 cubic mètres, the weight of coal an hour per square decimètre of section will be represented by the preceding numbers divided by 18, that is equal to 3.42, 4.71, 5.50 kilogrammes. These numbers differ but little from those adopted by the most experienced engineers; by employing them we may be sure of having a considerable excess of draught, but no disadvantage can result from this, as we have shown above.

The proportion of the section of the chimney to the consumption of fuel necessarily supposes that the resistance remains constant, an hypothesis that may be admitted; for the resistance caused by the grating and by changes in the direction of the current, undergoes but little variation, and that occasioned by friction has, in general, but little influence on the total resistance.

51. According to the foregoing, denoting the sum of the resistances experienced by the air in its course by R , we have in the three cases considered,

$$v = 0.18V = V\sqrt{\frac{1}{1+R}}; v = 0.17V = V\sqrt{\frac{1}{1+R}}; v = 0.16V = V\sqrt{\frac{1}{1+R}};$$

and the values of R are 29.98, 33.49, 38.29. These numbers represent the sum of the resistances due to friction, to changes of direction, and to the grating.

Comparing the dimensions of a large number of generators, we find that, for the three heights of chimney given above, the values of $\frac{KL}{D}$ are equal to 1.5, 2.37, 3.57: as there are usually eight changes of direction at right angles, assuming that these changes take place in a continuous manner, the corresponding losses would be represented by 4; and considering the velocity in the chimney as double that of ingress, which is not far from the truth, the sum of these two kinds of resistances would be 5.5×4 , 6.37×4 , 7.57×4 , or 22.0, 25.48, 30.28; the resistance of the furnace would then be represented by 8. But these calculations must be considered as only rough approximations, sufficient to give an idea of the value of the different kinds of resistance which take place.

52. *Sections of the Chimneys of Generators for different kinds of Fuel.*—Let us consider two generators having the same form and dimensions, the furnaces of which are supplied with different kinds of fuel, containing only carbon and fixed matter. It is evident that, if for each of them the same portion of air escaped combustion, the phenomena would be the same; the only difference would be that resulting from the unequal quantities of radiated heat, and from the unequal resistance of the furnace; but these differences would be of small importance, and could occasion but little in the weight of carbon burnt per square decimètre of chimney. But if one of the kinds contain water or produce it, the sections of the chimneys, for the same weight of fuel, will no longer be the same. In this case, we may admit, as an approximation sufficient for practice, that the sections of the chimneys are proportional to the volumes of the gases to which they are to give a passage for the combustion of the same weight of the different kinds of fuel. If we denote by S the section of chimney necessary to consume a weight P of coal, by S' the section of chimney corresponding to the combustion of a weight P of another kind of fuel, by V and V' the volumes of the gases which are evolved by the combustion of a kilogramme of the two kinds, we shall have $S' = \frac{S \times V'}{V}$; from this we obtain the following results:

Dry wood		$S' = S \times \frac{10.08}{17.28} = 0.59 \times S.$
Wood with 0.20 of water		$S' = S \times \frac{7.42}{17.28} = 0.43 \times S.$
Dry turf with 0.05 of ashes		$S' = S \times \frac{12.01}{17.28} = 0.69 \times S.$
Turf with 0.20 of water		$S' = S \times \frac{8.78}{17.28} = 0.51 \times S.$
Charcoal		$S' = S \times \frac{15.28}{17.28} = 0.88 \times S.$
Coke with 0.02 of ashes		$S' = S \times \frac{17.40}{17.28} = 1.00 \times S.$
Coke with 0.15 of ashes		$S' = S \times \frac{15.10}{17.28} = 0.87 \times S.$

These numbers necessarily suppose that the resistance of the gratings is the same for all kinds of fuel; this is not strictly true, for all kinds of fuel do not encrust the bars so much as most

kinds of coal; but, as we shall see later, smaller surfaces of grating are employed for coke, wood, charcoal, and turf, so that the resistance of the gratings ought not to differ much. They suppose also that the other resistances do not change with the section, for it is on this condition that the volumes of air are proportional to the sections; but when the forms of the generators are alike, there is the same number of changes of direction, and the differences of section have only a small influence on the total resistance. But these numbers must be considered as approximative values, representing, however, sections producing an excess of draught.

53. It is important to examine what would happen if the chimney only or the whole of the circuit had a section greater than that resulting from the preceding considerations.

Suppose, in the first place, that a larger section is given to the chimney alone; the draught will increase on account of the expansion which the heated air will undergo on entering it, and on account of the diminution of friction. But in general this increase of draught will be small, and, if the chimney is too large, the velocity of the heated air may be diminished to such a degree, that the draught will be modified by the influence of the wind. It might even happen, if the section of the chimney were much too large, that the current of heated air did not completely fill it, and in that case downward currents of air would be caused which would greatly diminish the draught. To remedy this, it would be necessary to reduce the section of the chimney by a register placed in the upper portion.

If, on the contrary, the section of the chimney were diminished so as to make it much smaller than that of the gatherings, there would be a loss of force which could be compensated only by an increase of temperature of the heated air. Even this compensation could not be effected without difficulty, and would be confined within narrow limits.

54. If the gatherings, the furnace-grating, and the chimney had a section much larger than those we have indicated, it is evident that, for a constant consumption of fuel obtained by closing the register in a greater or less degree, the resistance would diminish in proportion as the section increased, and finally we should obtain as the rates of ingress and egress of the gases the theoretical rates. To effect this, it would not be necessary to make the diameter of the air-channel very large; for if it were only five times the diameter calculated, the velocities would be twenty-five times smaller, and every kind of resistance $25 \times 25 = 625$ times less. This would be, therefore, a certain means of suppressing every kind of resistance; but in that case, to protect the draught from the influence of the wind, the register would have to be placed at the top of the chimney. This arrangement would largely increase the cost of construction and the loss of heat; for this reason it is never adopted.

55. *Various Methods that have been proposed to determine the Section of Chimneys.*—Montgolfier was the first who endeavoured to determine the section of a chimney, taking as starting-points its height, the volume of air necessary to combustion, and the temperature of the burned air. But he did not consider either the friction of the air against the sides or the resistance of the grating. The section thus determined was much too small.

Clément, in his lectures at the Conservatoire, gave Montgolfier's method; but he took only the fifth of the velocity calculated, which gave too large a section. Tredgold, in his 'Treatise on the Steam Engine,' gives a complicated method founded upon singular suppositions. He starts from the theoretical velocity, on the supposition that for boilers the temperature of the smoke is equal to that of the steam; and he multiplies the velocity obtained by 0.65, which represents the flow of air through orifices in a thin material.

According to M. Darcet, chimneys should be 10 mètres in height, and have a section such that each square decimètre may correspond to a consumption of 3 to 3.3 kilogrammes of coal an hour; the surface of the furnace-grating should be three times greater than the section of the chimney. These results differ but little from those we have indicated.

56. *Influence of the cooling of the outer surface of Chimneys upon the Draught.*—It might be thought that in isolated chimneys, traversed by air at a temperature of about 300° , the quantity of heat emitted by the surface being considerable, the air undergoes a great lowering of temperature, which must diminish the draught; but this is not the case. The quantity of heat carried away by the heated air is always very great relatively to that lost through the surface of the chimney, and the cooling of the air has no appreciable effect. Let us, by way of example, consider a chimney of 20 mètres in height, 0.5 in diameter, and 0.196 square metre in section, containing air at 300° . The theoretical rate of ingress of the cold air through a channel having the section of the chimney will be $11^{\text{m}}.93$, the actual rate $11.93 \times 0.165 = 1^{\text{m}}.968$, the volume of air entering an hour, $1.968 \times 3600 = 7084$ cubic metres, the weight of which is $7084 \times 1.3 = 9209$ kilogrammes, and the quantity of heat carried away an hour about $9209 \times 300 \div 4 = 553175$ units of heat. Now, according to the formulæ of the cooling, which we shall see later, the quantity of heat emitted an hour, a lineal metre, under these conditions, is 1587; for the 20 metres, therefore, the loss will be $1587 \times 20 = 31740$. The ratio of 31740 to 553175 is 0.057. Thus the loss of heat through the chimney is not $\frac{1}{10}$ of the heat carried away by the air; consequently, the temperature of the air will not be lowered by 0.06—that is, it will remain above 282° , and the draught will not be affected in an appreciable degree.

57. For an iron chimney of the same dimensions, the quantity of heat emitted would be, according to the formulæ, 8037 a lineal metre, and 160740 for the 20 metres. The ratio of the heat lost to the heat carried away by the air would then be $160740 \div 553175 = 0.29$. Thus, the temperature would be reduced by 87° , and the heated air would escape at about 213° , which corresponds (10) to a diminution of 0.1, nearly, in the draught.

58. *Calculation of the Diameter of Chimneys in the general case.*—All that we have said respecting the section of chimneys, designed to produce the combustion of a given weight of fuel, is applicable only to chimneys of fixed generators in ordinary conditions, when the temperature of the air is about 300° , and when about 1 kilogramme of coal is burned an hour and on a square decimètre of surface of grating. But, if the circumstances were different, the sections recommended would not

be suitable. As it is of great importance to be able to calculate them, at least within a certain degree of approximation, in every case that may occur, Péclet has endeavoured to find a simple method of accomplishing it.

59. We will suppose that the consumption of coal a square decimètre of grating is always about 1 kilogramme an hour. We have seen (51) that, for generators having chimneys of 10, 20, and 30 mètres in height, the resistance is about equal to 8.

Supposing the section of the air-channel constant and square, and denoting its length by L , the side by D , the number of changes in direction at right angles by N , we shall have as the rate of ingress of the cold air,

$$v^2 = \frac{2gH\alpha t}{1+\alpha t} \cdot \frac{1}{1+8+\left(\frac{KL}{D}+N\right)(1+\alpha t)^2}. \quad [1]$$

But denoting by V the volume of cold air required a second, which volume may be easily deduced from the weight and nature of the fuel to be consumed in the same time, and by S the section of the conduit, we shall have

$$V = Sv; \text{ and } v^2 = \frac{V^2}{D^4}. \quad [2]$$

Equating the values of v^2 in the equations [1] and [2],

$$V^2 = \frac{2gH\alpha t}{1+\alpha t} \cdot \frac{D^4}{9D+(KL+ND)(1+\alpha t)^2},$$

if t were known, putting in the place of V, g, H, α, N , their values, the last equation would assume the form

$$D^5 = A + BD, \quad [3]$$

an equation that may be solved approximatively, by neglecting at first A or B , substituting the value of D , thus found, for D in the second member of equation [3], and successively for D the last value obtained, until two consecutive values differ only by a quantity smaller than the approximation required.

If the temperature t were not known, we should have to assign to it a certain value found by experiments on similar apparatus. We will remark here that great accuracy in the value of t is of no importance; for, as we have seen (10), the draught varies only in the ratio of 57 to 71, for $t = 159^\circ$ and $t = 300^\circ$.

60. As an example of these calculations, suppose it be required to burn 50 kilogrammes of coal an hour; let $L = 40$ mètres, $t = 150^\circ$, and let there be ten changes of direction at right angles, we shall have $V = 50 \times 18 \div 3600 = 0.25$; $2gH\alpha t = 161.40$; $1 + \alpha t = 1.55$; $KL = 0.96$; and the formula [3] becomes $D^5 = 0.00057 + 0.0114D$. Neglecting, at first, the first term, and operating by successive approximations, we find for D the values $0.325, 0.335, 0.337, 0.338, 0.338$. Thus the second substitution gives the value of D within a centimètre. The section being about 13 square decimètres, the consumption of fuel the square decimètre would be about 3 kilogrammes.

61. We have supposed that the resistance of the furnace-grating was constant and equal to 8; this will be the case when the consumption of coal the square decimètre and by the hour, is 1 kilogramme. If this consumption were less, the velocity of the air traversing the grating would be smaller, as well as the resistance, and consequently the section of the chimney calculated in the manner described would be too large. In the contrary case, it would of course be too small. In every case, it may be admitted that the resistance of the grating is proportional to the square of the velocity of the air traversing it; thus, denoting by n the number of kilogrammes of coal burned an hour the square decimètre, the resistance would be equal to $8n^2$.

62. The results of these calculations must be considered as only approximative, because they rest upon hypotheses relative to the resistance of the grating and to the temperature of the air in the chimney, and because the numbers admitted may therefore be considerably from the truth.

63. The preceding remarks suppose not only that the air-channel retains its section throughout, but that it is not divided into several branches traversed simultaneously by the gases from the furnace. For if it were so, the sum of the resistances in the partial channels would be greater than that which the air would meet with in a single channel having the same section. When the air traverses simultaneously a large number of equal pipes, as in locomotive engines, the resistance is represented by $KLS^2 \div dS_1^2$, or by $KL D^4 \div n^2 d^5$, S denoting the section of the whole channel, S_1 that of the tubes, D the diameter of the channel, d that of the tubes, and n the number of the tubes.

64. If in a long circuit, from a generator or any other apparatus, there happened to be a number of tubes, we could not, without modification, employ the method indicated (59), to calculate the diameter of the chimney, because this method supposes the channel single throughout its length and constant in section. It might, however, be used tentatively. In fact, the resistance of a number of tubes is equivalent to that of a single pipe of a diameter D , the L of which is given by the equation

$$\frac{KL D^4}{n^2 d^5} = \frac{KL}{D}; \text{ whence } L = \frac{D^5}{n^2 d^5}. \quad [a]$$

Taking first a certain approximative value of D , we deduce from it the value of L by means of the equation [a]; the equation [3] (59) will give a new value of D , which will enable us to find a new value of L , and so on, till a constant value of L is found, and consequently of D . Besides, as in general we need only a rough approximation, and as in generators with tubes the course of the smoke is always very short, the increase of resistance in the tubes is nearly compensated by the

diminution of length of circuit, and by the increase of the sum of the sections of the tubes, so that we may take as the section of the chimney that indicated in (59).

65. *Chimneys common to several Furnaces.*—In most large factories there is only one chimney for all the furnaces. Two advantages are derived from this arrangement—1, a saving in the cost of construction; 2, uniformity of draught, which does not exist in a chimney communicating with only one furnace. The saving is obvious, for one chimney costs less to build than several, supposing the section of the single chimney equal to the sum of the sections of the others. With regard to the second advantage, it must be remarked that, in a furnace having a special chimney, the draught is very variable; it is small immediately after the fire is made up, and increases in proportion as combustion becomes more active. It is diminished in a high degree by opening the furnace-doors. But if several furnaces communicate with a common chimney, and care be taken to make up the fires successively, a mean draught will exist in the chimney, which will increase in regularity with the number of the furnaces.

A common chimney has usually a section equal to the sum of the sections of the partial chimneys that would correspond with each furnace. The section thus obtained is certainly too great, because the resistance is much smaller than the sum of the resistances in the partial chimneys which it replaces. But this excess of draught, which may be modified at will, offers no inconvenience.

66. *Chimneys in which the Smoke, or the Gases soluble in Water, are precipitated or absorbed by Injections of Water.*—It has been proposed to precipitate the smoke and to dissolve the soluble gases, which, in certain circumstances, are found mingled with the gases from the furnace, by dropping water under the form of very fine rain into horizontal pipes traversed by the gases before reaching the chimney; but the gases being almost completely cooled, it became necessary to reheat them to produce the draught.

Hedley, an ironmaster at Newcastle-on-Tyne, invented the plan of making the smoke pass through a series of vertical pipes, ascending and descending, and into each of the pipes in which the smoke descended he dropped a small quantity of water. In spite of the cooling caused thereby, the draught was very strong, even in pipes of 3 or 4 metres in height. By this means, all the matters carried off by the gases may be stopped, and especially the soot which floats upon the heated air. This arrangement has been successfully applied to a locomotive of the Sunderland and Durham Railway. Although this mode of condensation has long been known, it has never been generally adopted, because it is complicated and necessitates a certain amount of labour to raise the water required for the purpose of condensation, and because this water, if not clean, would often be a source of embarrassment. But this arrangement would possess great advantages when in the gases which escape from the furnace there are, independently of those involved by combustion, noisome gases and vapours, such as those evolved in the manufacture of soda, or solid matters carried off by the current and which it is profitable to arrest, as in the case of lead or zinc works.

67. *Draught Chimneys.*—All chimneys are, strictly speaking, draught chimneys; but we denote in a more special manner by this name chimneys constructed for the purpose of rendering certain situations wholesome by ventilation. In these, the phenomena that happen are much more simple than in factory chimneys. Indeed, the air drawn through them, being usually only slightly heated, is not all found to pass through the furnace-grating, which occupies only a small portion of the section of the chimney. Sometimes even the furnace is placed laterally, so that the section of the chimney is not sensibly changed in the vicinity of the grating; the resistance of the latter may, in this case, be wholly neglected, and the results of calculation are then very accurate. When a grating is wholly covered with fuel, and the whole of the air drawn by the chimney is forced to pass through it, if there is no appreciable loss of heat by radiation, the temperature of the air beyond the grating is about 1200° , and the volume of air drawn per kilogramme of coal is 18 cubic metres. For draught chimneys, on the contrary, the air is rarely heated above 20° ; the heat which it absorbs the cubic metre is $1^{\circ} \cdot 3 \times 20 \times 0 \cdot 25 = 6 \cdot 5$, and, consequently, the volume of air drawn by 1 kilogramme of coal is $8000 \div 6 \cdot 5 = 1230$ cubic metres.

68. To begin with the simplest case, let us consider a draught chimney of a height H and a diameter D , communicating in its lower portion with a cylindrical channel of a length l and a diameter d smaller than D ; denoting the temperatures of the air in the chimney and the air in the channel or pipe by t and θ , the negative pressure at the bottom of the chimney will be $H a (t - \theta) \div 1 at$; denoting it by P , and calling p the force corresponding to the effective velocity, we shall have $P - p = \frac{Kl}{d} p + \frac{KH}{D} \cdot \frac{d^4}{D^4} p + p + (A - B)p$. The first two terms of the second equation represent the resistance occasioned by friction in the pipe and in the chimney; the third, the loss of force due to the sudden change of direction; the last, the loss of force at the entrance of the pipe and the increase of force at the entrance of the chimney. But in general the conducting-pipes are long enough to render their resistance very great relatively to the value of $A - B$. Thus the second member of the equation may be reduced to the first three terms, which gives as the rate of ingress,

$$v = \frac{\sqrt{2gHa(t-\theta)}}{1+at} \sqrt{\frac{1}{\frac{Kl}{d} + \frac{KH}{D} \cdot \frac{d^4}{D^4} + 2}}. \quad [1]$$

69. Suppose, for example, a square chimney communicating with a pipe having also a square section; taking $H = 30$ metres, $D = 1$ metre, $d = 0^{\text{m}} \cdot 5$, $l = 500$ metres, $\theta = 15^{\circ}$, $t = 35^{\circ}$, the formula becomes

$$v = \sqrt{\frac{19 \cdot 62 \times 30 \times 0 \cdot 00366 \times 20}{1 + 0 \cdot 00366 \times 35}} \sqrt{\frac{1}{21 + 0 \cdot 72 + 2}} = 6 \cdot 18 \times 0 \cdot 193 = 1^{\text{m}} \cdot 19.$$

The section of the pipe being 0.25 square mètre, the volume of air drawn per second will be $1.19 \times 0.25 = 0.297$ cubic mètre; the expenditure of heat will be about $1069 \times 1^{\circ} 3 \times 20 \times 0.24 = 6670$ an hour, a quantity of heat only slightly less than that produced by the combustion of 1 kilogramme of coal.

70. Let us now consider the most general case. Suppose a chimney, still prismatic, communicating with a pipe turning in all directions, the several parts of which are at different temperatures. The variations of temperature will act in two ways: 1st, by modifying the force which occasions the flow; 2nd, by causing variations of velocity, and, consequently, variations in the resistance due to friction. But, as the influence of the variations of temperature upon the velocity, and, consequently, upon the friction is very small, we may suppose that the velocity varies only inversely as the sections. Then, denoting the force and the total sum of the resistances by P and R, the

velocity of flow will be given by the formula $v = \sqrt{\frac{2gP}{1 \times R}}$.

The value of R may be found by the methods indicated when treating of the flow of compressed gases.

71. *Construction of Chimneys.*—As the height and the section of chimneys may be determined by the preceding considerations, we have now only to examine the nature of the materials, the thickness, and the general arrangements to be adopted.

72. *Factory Chimneys.*—Factory chimneys always stand alone; they are constructed of bricks or of iron, and with either of these materials they produce the same effects, because the cooling which the air undergoes in iron chimneys has no appreciable influence upon the draught (57).

73. The best form of section, from the point of view of diminishing the resistance, is that which, for a given surface, has the least perimeter or circumference. This is, of course, the circular form, and next the polygonal with a large number of sides. Iron chimneys have always the circular form. In brick chimneys, the section is circular, square, or octagonal. Round chimneys are generally preferred; they require, for an equal section, less material.

74. Let us now examine the form of the vertical section passing through the axis. When chimneys are of small height, they are made prismatic internally, and the walls have a greater thickness at the base than at the summit, Figs. 1913, 1914. But when they are of great height,

75. In large factory chimneys, the internal diminution, a lineal mètre, is about 0^m.012 to 0^m.018; and the external diminution varies from 0.025 to 0.035. The thickness of the masonry at the top is from 0.11 to 0.22, the breadth or length of an ordinary brick. Thus, if we denote the interior diameter at the top of a chimney by d , its exterior diameter by d' , and the interior and exterior diameters at the bottom of the chimney by D and D' , we shall have $d' = d + 0.22$, or $d' = d + 0.44$, $D = d + 2Hm$, $D' = d' + 2Hm'$, m being included between 0.012 and 0.018, and m' between 0.025 and 0.035.

Suppose, for example, a chimney of 20 mètres in height and 0.60 in interior diameter at the top; the interior diameter D at the bottom will be, taking $m = 0.014$, $1^{\text{m}}.16$; the exterior diameter d' at the top will be $0.60 + 0.22 = 0.82$; and the exterior diameter D' at the bottom, taking $m = 0.03$, will be $2^{\text{m}}.02$.

The chimney of the tobacco manufactory at Paris, which is constructed to burn 700 kilogrammes of coal an hour, which corresponds to more than 150 horsepower, is 29 mètres in height; internally it is $1^{\text{m}}.03$ in diameter at the top, $2^{\text{m}}.15$ at the base; and externally, at the top, $1^{\text{m}}.30$, and at the base $3^{\text{m}}.45$. The diminution is, in this case, both externally and internally, too great.

76. If it were required to construct conical surfaces internally and externally, the execution of the work would be rather difficult, and we should be obliged to cut a large number of the bricks, which would entail considerable expense; besides, bricks do not resist so well when they are broken as when they are whole, because their external crust has much greater tenacity than their inner portions.

Conical or prismatic chimneys may be constructed by a series of cylinders or prisms, which would occasion sudden retreats, both on the inside and on the outside; but the arrangement shown

in Fig. 1916 is generally preferred. The chimney is conical or pyramidal on the outside, and the thickness of the masonry varies by sudden leaps on the inside; the retreats occur every 11 centimètres, the breadth of a brick.

77. Brick chimneys are usually from 20 to 30 mètres in height; sometimes, but rarely, 40 mètres. M. Grouvelle mentions a chimney at Manchester that is 125 mètres in height, 7·50 in exterior diameter at the base, and 2·70 at the top; 4,000,000 bricks were employed in its construction.

78. Brick chimneys are usually placed upon prismatic socles, pierced on opposite sides with two apertures; one is designed to receive the channel which conducts the smoke to the chimney; the other, which is usually closed up by a thin brick wall, serves to admit the workman when the chimney needs sweeping or repairs. To facilitate this labour, the chimney is furnished with horizontal bars placed 0·50 apart, forming a kind of ladder.

79. It is of the highest importance that a chimney should stand upon a firm foundation, for the sinking often takes place unequally; and, when this is the case, the chimney either falls, or stands very insecurely. This is a point to which builders do not pay sufficient attention.

80. In chimneys intended to receive air at a very high temperature, as those of reverberatory furnaces, fire-bricks must be employed, and the interstices between them filled with brick clay. In chimneys which are intended to receive vapours at a temperature rarely exceeding 300°, as in the case of steam-boilers, ordinary bricks may be used, bound together by mortar containing siliceous sand; it would be well, however, to employ fire-bricks for the casing of the inner portion at the bottom of the chimney. Plaster should never be used when the temperature of the heated air exceeds 100°, because at this temperature it begins to lose the hygrometric water which it contains, and, consequently, its tenacity.

81. Tall chimneys, when standing alone, may be built without exterior scaffolding, if their diameter is considerable; the workman in this case raises himself upon supports fixed on the inside of the chimney. A good workman accustomed to this kind of work, assisted by a boy, may, in this way, in about a fortnight, raise a pyramidal chimney of 13 or 14 mètres in height, 2 mètres and 1 mètre in exterior and interior diameter at the base, and 0·80 and 0·60 in exterior and interior diameter at the top.

82. Chimneys usually terminate in a portion having a greater diameter, and resembling the chapter of a column; this portion of the chimney is designed only as ornament. The chapter is often of bricks like the rest of the chimney; sometimes it is of cut stone.

83. Brick chapters, if they were not protected, would allow the rain to penetrate the masonry; to prevent this they are covered with plate iron, which extends over the outside and inside by 0·10 to 0·15 mètre.

84. Fig. 1917 represents a section of the arrangement adopted for large iron chimneys. The chimney itself is bolted to an iron socle or base, fixed upon a mass of masonry by four stout bolts passing through the masonry. When these chimneys are very high, they are tied externally to the ground or to some neighbouring buildings. To prevent the rusting of the metal, the

chimney is covered with coal-tar, which will bear a high temperature without alteration.

85. Tall factory chimneys attract the lightning, both by their great height and by the great conducting power of the soot which covers their inner surface; it is, therefore, necessary to protect them by means of a conductor. Figs. 1918 and 1919 show the usual arrangements in such cases. In the first, four rods, riveted to the iron plate at the top of the chimney, support the conductor; one of the rods is produced horizontally and fixed at its extremity to the conducting-wire. The second represents a lightning conductor upon an iron chimney. The conductor is supported by

three rods riveted to the edge of the chimney, which serves instead of a conducting-wire, and the chain which establishes communication with the ground is fixed to its lower portion.

86. When single chimneys are very high, and are designed to receive air at a high temperature, it is necessary to strengthen them. We see an instance of this strengthening in the square section chimneys of puddling furnaces. When chimneys are conical, iron hoops are built into the masonry.

In the rectangular chimneys of steam-boilers, flat iron bars having a kind of hook at each end of sufficient dimensions to take in two or three rows of bricks are built into the masonry in alternate directions, as shown in Fig. 1920.

87. Figs. 1921 to 1923 represent a large factory chimney of a circular section, built according to the plans of MM. Thomas and Laurens. This chimney is 40 mètres in height; the diameter is at the base 3·35 and at the top 2^m·02; therefore the diminution of section is on the inside 0·016 a metre; the exterior diameter at the base is 5·65, and at the top 2·52; consequently the external diminution is 0·030 a metre. The chimney is formed of five cylinders having each a height of about 8 mètres, and conical both on the inside and on the outside. The thickness of the masonry is 3 bricks for the first portion, and is successively reduced to 2½ bricks, 2 bricks, 1½ and 1, for the other portions. Thirty-eight iron hoops $h h'$, $i i'$, are built into the

masonry. The first portion of the chimney has an inner casing of fire-bricks. The top is covered with an iron plate *a b*, composed of four pieces bolted together.

The engineers above alluded to, often place in their chimneys at the points *cc'*, *dd'*, *ee'*, *ff'*, *gg'*, the base of each of the cylinders, bands of coloured bricks; and the spaces between those bands are filled with bricks of several colours, worked into various patterns for ornamental purposes.

88. *Registers*.—In every heating apparatus, whatever its dimensions and purpose may be, it is requisite to place, either at the top or at the bottom of the chimney, an iron plate, by means of which the draught may be diminished, and the chimney closed entirely during the suspension of work in the furnace. Registers are of great service in apparatuses which are only occasionally in operation, because, the current of air being intercepted, the furnace cools very slowly.

89. They may be arranged in a great variety of ways. In apparatuses of small dimensions, having iron chimneys, the opening in the chimney is regulated by a disc, Fig. 1924, turning about an axis traversing the opposite sides of the pipe, and worked from the outside.

90. This arrangement might with equal advantage be adopted for larger chimneys; but as the friction of the axis in its bearings would not alone be sufficient to keep the disc in its position, we should have to affix to it, on the outside of the chimney, a rod or handle perpendicular to its direction, by which it might be fixed as shown in Fig. 1925. The disc should be of cast iron, as wrought iron is more liable to rust, and should have considerable thickness to prevent warping. When the air-channel is horizontal, the arrangement shown in Fig. 1926 may be adopted. The register, in this case, is a cast-iron plate *b*, turning about an axis upon a pivot *c*, and which is moved in an iron frame by means of a crank *a*.

91. Horizontal, sliding trap-doors are sometimes employed; but in large chimneys it is more usual to employ those which move vertically, and which are held by a counterpoise. Fig. 1927 is a section of this arrangement through the length of the air-channel. *R* is a cast-iron plate sliding in grooves, also of cast iron, fixed in the masonry. It is held by a chain which passes over a pulley *P*, and is attached to a weight *M*.

92. This last arrangement is the one generally adopted; it has, however, one great objection, namely, a considerable space between the edges of the plate and the grooves of the iron frame in which it moves; this allows a rush of cold air into the chimney, whereby the draught is considerably diminished in the furnace. This rush of cold air may be prevented when the register is lowered by constructing it with projecting arms at the top, made to fall into a groove filled with sand.

93. When the temperature of the heated air exceeds 500° or 600° , the contrivances which we have been considering cannot be employed, because the iron would be quickly warped or rusted. The best method of regulating the draught of a chimney in such cases, is to place the register at the top of the chimney, where the disc, or plate, being always exposed on one side to the air, becomes heated in a very much smaller degree. This arrangement is shown in Fig. 1928; *c* is a cast-iron disc affixed to a vertical rod, connected by a joint to the end of the lever *ab* turning about the point *d*; a chain *g* is attached to the extremity *a*, by means of which the distance of the disc from the top of the chimney is regulated. This arrangement has the disadvantage of requiring a workman to ascend to the top of the chimney when the apparatus is got out of order.

COAL-CUTTING MACHINE. FR., *Machine à tailler des houilles*; GER., *Kohlenbreck Maschine*; ITAL., *Macchina da spezzare litantrace*; SPAN., *Máquina para cortar carbon de piedra*.

The objects, says John Fernie, of Leeds, to be gained by the application of machinery to coal cutting are, firstly, the cheapening of the work; secondly, the saving of a large quantity of coal, which, in the ordinary process of holing or undergoing by hand labour with the pick, is broken up into slack and dust; thirdly, the removal of the danger attendant upon undergoing by hand labour; fourthly, the getting of a larger quantity of coal out of the pit with the same length of working faces opened; and fifthly, in the case of machines worked by compressed air, the collateral advantage of better ventilation and a cooler atmosphere in the mine, owing to the discharge of the compressed air after each stroke of the tool. The difficulties attending the application of machinery to work previously performed by hand are greatly increased in the case of coal-cutting machines, by their having to work at great depths below ground, and in the very confined passages of a mine.

Fernie, in the 'Institute of M. E.,' described two coal-cutting machines driven by compressed air, one having a pick worked by a bell-crank lever, with an action like that of the ordinary pick used in hand work, and the other working a straight-action tool somewhat in the manner of a horizontal traversing slotting machine. Both these machines had been successfully employed in regular work for a length of time at collieries in the neighbourhood of Leeds.

The coal-cutting machine of W. and S. Frith, shown in Figs. 1933 to 1935, is constructed for working a pick by means of a bell-crank lever, so as to give an action similar to that of the ordinary pick employed in hand work.

The pick A is fixed in a socket in one of the arms of the bell-crank lever B, the other arm of which is worked direct by the piston-rod of the horizontal cylinder C. The slide-valve D, Fig. 1936, for the admission and discharge of the compressed air by which the machine is driven, is an ordinary slide, worked by a tappet-roller E upon the piston-rod; the machine is thus self-acting as regards the strokes of the pick, which is started to work as soon as the compressed air is turned on by the stop-cock F in the supply-pipe G. The machine is mounted upon four wheels running upon the ordinary rails of the colliery, and is advanced the requisite distance between each blow of the pick by a hand-wheel H connected by gearing with the hind pair of carrying-wheels. The two pairs of wheels are coupled together, in order to render the full adhesion available for the forward motion of the machine; and by this means it is found that sufficient adhesion is obtained without the necessity of laying down a special rack-rail for the feed motion.

As the return of the pick after each blow is made by means of the self-acting tappet-motion working the slide-valve, it is necessary that the tool should go to the full extent of its stroke at each blow, before it can be withdrawn again. The amount of feed between each blow has therefore to be regulated by the attendant, according to the hardness of the seam of coal in which the machine is cutting, so that the pick shall complete an entire cut at each blow. In the event, however, of the pick being advanced too far at any blow, so as to put too much work upon it and stop it before the stroke is completed, it is only necessary to draw the machine back again by means of the hand-wheel H, until the pick is released from the cut; the unfinished stroke is then completed, and the pick goes on working again the same as before the stoppage. In order to allow of altering the height at which the pick performs the holing in the coal, the socket K carrying the pick is made to slide vertically upon the shaft of the bell-crank lever B, the height of the socket being adjusted by the forked arm J controlled by the screwed rod and handle L.

One of these pick machines worked the whole of the undercutting in the West Yorkshire Coal and Iron Co.'s Colliery at Tingley, near Leeds, holing a seam of coal 3 ft. 8 in. thick; and the compressed air for driving it was supplied by an air-compressing engine at the surface, with steam-cylinder of 20 in. diameter and 3 ft. stroke, working an air-cylinder of 18 in. diameter and the same stroke, and compressing the air to about 50 lbs. the square in. pressure. The depth of the pit is 170 yds., and the air is conveyed down the shaft and along the mine in 2½-in. cast-iron pipes, with a 1½-in. wrought-iron pipe laid up the bords to the working faces, and then a 1½-in. flexible tube to the coal-cutting machine. Small air-vessels are placed at intervals of 500 yds. along the air-main,

1933.

1934.

1935.

1936.

for the purpose of maintaining the pressure of the air at the machine when working at a considerable distance in the mine: the machine is worked at a distance of as much as a mile from the shaft.

In a trial of this machine, it was found that a pick of 75 lbs. weight, cutting a groove to a depth of 24 in. in from the face, gave about 74 blows a minute. At the colliery the coal was got by the long-wall system of working, as shown in Fig. 1937, in which the machine is indicated at M working along the straight face of 50 yds. at one of the banks. The time occupied by the machine in

1937.

undercutting a length of 56 ft. was twenty-five minutes, including all stoppages for clearing the rubbish out of the hole and for backing the machine when the pick occasionally made an incomplete stroke. The machine was then run back to the starting-point, and set to work again with a longer pick of 90 lbs. weight, completing the previous cut to the final depth of 3 ft. 9 in. from the face. With this pick the blows were about sixty a minute, and the half-length of 28 ft. was undercut in seventeen minutes, including all stoppages. The time occupied in running the machine back and changing the pick was sixteen minutes. The machine in this case was working at a distance of about a mile from the bottom of the shaft.

From this trial it appears that in undercutting to the depth of 24 in. in a single course, the work done by the machine was at the rate of about 30 square yds. an hour; and in undercutting in two courses to the total depth of 3 ft. 9 in., the work was done at the mean rate of about 15 square yds. an hour, including the time required for running the machine back and changing the pick.

The width or height of the groove cut out by the pick is 2 in. at the inner extremity, widening out slightly towards the face of the coal. It is necessary to stop the machine at intervals, in order to clear out the rubbish left in the hole; and the rails in front of the machine have also to be cleared of the material thrown out by each return stroke of the pick. Two men are required to attend to the machine, one working the hand-wheel for the advance of the machine, and the other clearing away the stuff.

A good criterion of the actual rate of working that may be safely reckoned upon with this machine in regular practice is afforded by its performance upon an occasion when it was kept continuously at work for twenty-four hours consecutively, on 21st and 22nd of May, 1868. During this time the machine was employed upon five different banks of coal successively, requiring accordingly to be shifted four times for the purpose. The average depth of holing was 3 ft. 6 in., and the total length of work completed to that depth during the twenty-four hours amounted to 257 yds. This gives the practical rate of holing by the machine at rather more than 12 square yds. an hour, including all stoppages for clearing the pick in working and for shifting the machine on the completion of each separate length of bank.

The other coal-cutting machine, before alluded to, shown in Figs. 1937 to 1939, is the invention of G. E. Donisthorpe, and may be described as a horizontal traversing slotting machine, the

1938.

1939.

work remaining stationary, while the machine traverses along the working face of the coal and cuts out a horizontal slot or groove along the bottom of the seam of coal or along a parting in the thickness of the seam itself.

The cutter-bar A carrying the cutting tools is fixed upon the upper side of the working cylinder C, which moves horizontally forwards and backwards at each stroke, the piston and piston-rod remaining stationary. This arrangement has the advantage of economizing space, and giving greater stiffness and a better attachment of the cutter-bar; and the whole is guided steadily between the guides B B by means of four sets of steel rollers D D attached to the cylinder and steadying it both vertically and laterally, as shown in the sectional plan of the cylinder, Fig. 1940. The piston-rod E is made hollow, as shown in Figs. 1940 and 1942, having two passages

communicating with the opposite sides of the piston; and the alternate admission and exhaustion of the compressed air is regulated by a cylindrical slide-valve F, Figs. 1937 and 1943, worked by the hand-lever G. The ports in the piston are circular, and at each end of the cylinder a projecting plug J is fixed on the inside of the cover, opposite to the port, as shown in Figs. 1940, 1941; this plug entering the port at the end of the stroke prevents the complete escape of the whole of the air in exhausting; and the air thus retained in the cylinder forms an air-cushion at the end of the stroke, whereby the piston is prevented from striking the cylinder-cover at either end. A subsidiary port I, Fig. 1841, alongside the main port, and provided with a valve opening outwards, affords a passage for the admission of the compressed air at the commencement of the next stroke, until the main port is unstoppered by the withdrawal of the plug J.

The working cylinder C is 6 in. diameter with 12 in. stroke; and the frame B in which it is carried is itself slung upon horizontal trunnions H, Fig. 1938, in another frame K sliding vertically upon the pillars L L, which are fixed on the base-plate M of the machine; and by means of a screw N and worm-wheel, Fig. 1937, the working cylinder can thus be raised or lowered bodily to any height at which the cutter is required to work. The trunnions and the curved slot H, Fig. 1938, also allow of the cutter being adjusted by means of the hand-wheel and screw X to work at an inclination to the horizontal, between the limits shown by the two dotted positions in Fig. 1938.

The cutter-bar A, Figs. 1938, 1939, is of cast steel, having six sockets for carrying the cutting tools. The tools are made of flat bar steel, with one-quarter twist in the shank, by which means the cuttings are thrown away from the face of the cut at each stroke of the bar A. The cutters are placed about 7 in. apart longitudinally along the length of the bar A, the average depth of the cut being about 3 ft. 4 in. in from the face of the coal; and the length of stroke being 12 in., the tool does no work during the first 5 inches of the stroke, but acquires a rapid motion whereby it strikes upon the coal with the percussive action of a blow, instead of cutting by a uniform steady pressure like an ordinary slotting tool. Previous to the adoption of this principle of working, the present pressure of air of 60 to 70 lbs. a square inch was found insufficient to work the machine; but with the percussive action now obtained this pressure is found completely effective, and the diameter of the working cylinder being 6 in., the blow is given with a total force of 1700 lbs. or $\frac{3}{4}$ ton upon the tool. The cutters are stepped $2\frac{1}{2}$ in. successively in advance of one another, as shown in the plan, Fig. 1939; and the bar is fixed upon the working cylinder by a centre pin O and set-screws P P, allowing it to be set obliquely in plan at an inclination to the line of the stroke, as shown by the dotted lines in Fig. 1939. By this arrangement the inclination of the cutters to the work can be slightly increased or diminished, according as may be required by the quality of the coal, so as to obtain under all circumstances the most effective action of the cutters. The width of their cutting edges ranges from $1\frac{3}{4}$ in. in the cutter at the outer extremity of the bar to 3 in. in the cutter nearest the working cylinder; and the slot cut out by the machine is therefore of the slightly tapered form shown in Fig. 1938.

The machine is mounted on four double-flanged wheels, Fig. 1939, running on rails laid for the purpose. The rail on one side is a plain wrought-iron bar Q placed on edge; and the other rail R is made of two bars placed 2 in. apart, with a series of cross-pins at $1\frac{1}{2}$ in. pitch, forming an open rack-rail, into which gears a pinion S worked by a hand-wheel T, whereby the machine is advanced for each cut, the ordinary amount of feed being $1\frac{1}{4}$ in. a cut. As the advance is given by hand by the man working the machine, any number of strokes can be given by the tool before the machine is moved forwards, in case the coal is too hard for the cutters to accomplish the full depth of cut at a single blow. The traversing pinion S gearing into the rack-rail is mounted in a slide on the base-plate M of the machine, whereby it can be raised out of gear with the rack when the machine has to be drawn away from one part of the mine to another.

The pressure of the air working the machine is also employed for steadying it against the

blows of the tool, so as to ensure the full effect of the blow being expended upon the coal at each stroke; otherwise the tool would be liable to be bent or broken, and the work would be irregular. This is accomplished by means of two vertical cylinders U U, each $8\frac{1}{2}$ in. diameter, the piston-rods of which stand up towards the roof of the mine, and are connected together at the top by a horizontal frame V carrying a grooved wheel at each end. A loose iron rail on a wood batten W is placed above the grooved wheels; and the compressed air being admitted on the under-side of the pistons in the cylinders U, the rail is pressed up against the roof of the mine, as shown in Figs. 1937, 1938. The total pressure exerted by the pair of cylinders U U amounts to 6800 lbs., or upwards of 3 tons, which is found amply sufficient to resist the blow of the tool. When the machine in its forward traverse has arrived at the end of the roof-rail W, the pressure is shut off from the cylinders U, and the air is let out from them through cocks opened by hand, thus lowering the frame V as shown by the dotted lines in Fig. 1937; the roof-rail is then shifted forwards to the extent of its length, and the pressure being readmitted to the cylinders U, the machine is again ready for continuing its forward traverse as before. The pressure exerted against the roof being elastic allows the top rail to accommodate itself to any irregularities in the level of the roof.

In working this coal-cutting machine at the West Riding Colliery of Pope and Pearson, at Normanton, it was observed that the number of strokes made by the tool was from 75 to 80 a minute, the pressure of air at the machine being from 65 to 70 lbs. a square inch at the time. The average depth of the cut during the time of observation was about 2 ft. 9 in., as there was a clearance space of more than 1 ft. left between the side of the machine and the face of the coal, the rails not having been laid close enough to the face of the coal. The width of the cut was about 2 in. at the inner end, widening to about 3 in. at the face of the coal; and as the cut was in this case being made in a parting of dirt of about the same thickness, no waste of coal was produced by cutting the groove. One man is required to work the machine, working the air-valve F by the hand-lever G, Fig. 1937, and also giving the feed of the tool by the hand-wheel T advancing the machine; and from three to five strokes were given by the tool between each advance of the machine, for completing the cut to the full depth of the groove; about three turns were then given to the traversing hand-wheel, advancing the machine about $1\frac{1}{4}$ in., after which the same number of strokes were again given with the tool. The cuttings are cleared out of the groove by a man following the machine with a narrow curved rake; and the height of the cutting tool in the machine is regulated occasionally, according to the slight variations in the level of the parting in which the groove is made, so as to keep the tool always working in the parting.

The width of the groove cut by this machine is shown in Fig. 1938, the width at the face of the coal being not more than about $3\frac{1}{4}$ in. in holing to the full depth to which the machine can work. In undergoing by hand to the same depth, the size of the cut is as shown in Fig. 1938, having a width of at least 13 in. at the face of the coal, making the whole size of the cut about three times that of the narrow groove excavated by the machine, which is shown by the dotted line in Fig. 1938. Supposing the machine to be holing in the solid coal, the waste produced by the undergoing in a seam of 5 ft. thickness, such as is being worked at the West Riding Colliery, would amount to only about 4 per cent., as compared with about 12 per cent. waste with hand work. An estimate of the absolute quantity of waste made by hand work in good seams of coal amounts to as much as 12 per cent., the whole of which is rendered nearly worthless; and taking the whole quantity of coal raised per annum in this country at 100,000,000 tons, the waste produced in undergoing by hand labour amounts consequently to as much as 14,000,000 tons a year.

The compressed air for working the machine is supplied by an air-compressing pump of 18 in. diameter and 2 ft. 10 in. stroke, worked by an engine that is employed for winding coals up an incline at the bottom of the pit. The compressed air is delivered by the pump into a large air-vessel, 3 ft. diameter and 30 ft. long, from which it is conveyed along the mine by a wrought-iron pipe $2\frac{1}{2}$ in. diameter and $\frac{1}{4}$ in. thick, put together with ordinary screwed sockets, and terminating in a portion of $1\frac{1}{4}$ -in. pipe and a long length of flexible tubing of the same size, which is coiled on the floor and drawn out by the machine as it advances along the face of the coal. Great difficulty was originally experienced in maintaining the pressure of the air at the machine when working at considerable distances from the compressing pump; but this has been completely obviated by the introduction of a second smaller air-vessel at the working face where the machine is in operation. This smaller air-vessel is 2 ft. diameter and 6 ft. long, and is mounted on wheels for the convenience of being quickly removed to any part of the mine. The air-compressing pump is capable of supplying air enough for working three of the coal-cutting machines.

By the adoption of compressed air as the medium for transmitting the power to work these coal-cutting machines, the important collateral advantage is obtained of improved ventilation at the working faces. The discharge of the exhaust air from the machines delivers a supply of fresh air, free from noxious gas, during the whole time that the machine is working; and the coldness of the discharged air, consequent upon its expansion at the moment of liberation, has a highly beneficial effect in reducing the temperature at the working faces. During the trial made by Fernie at the Tingley Colliery, a shot was fired at a short distance from the machine, for breaking down a mass of coal; and although the smoke at first completely obscured the working face and the machine, the whole of it was cleared away in so short a time as two minutes, having been carried off by the current of exhaust air discharged from the machine. In the case of any danger arising from accumulation of gas in the goaf or elsewhere, the means of safety is at hand, as it is only necessary to detach the india-rubber supply-pipe from the machine, and discharge a continuous jet of fresh air in the required direction, whereby the gas is speedily dispersed, and the dangerous place rendered safe. Also, as the undercutting of the coal is done so much quicker by the machines than by hand labour, the employment of the machines requires a smaller extent of working faces to be kept open for getting the same quantity of coal in the same time; the air has therefore a shorter distance to travel and becomes less loaded with gas, and is consequently safer and more wholesome for the colliers.

only will the traverse-motion come into action; thus the back of the baring is always parallel with the rail upon which the machine travels, thereby causing the coal to break off in one uniform line.

The cutting tools, Fig. 1946, are of a form easy of construction, and are very strong, and capable of penetrating hard material with little risk of breaking. The cutting edge is nearly a $\frac{1}{4}$ in. thick, and any or all of the cutters can be removed and replaced in a few moments.

The machine can be adapted to any gauge in use for the roads of the mine, and is easily moved from place to place on its four wheels. The supplementary wheels at each end are used only when in operation, in order to secure a greater base.

The water pressure by which the machine is actuated is produced, in this instance, by an engine placed at the bottom of the shaft.

The cylinder of this engine is 14 in. diameter; stroke, 2 ft. 3 in. Attached to the engine are two double-action pumps of $4\frac{1}{2}$ in. diameter, and 12 in. stroke. These are capable of maintaining a pressure of 360 lbs. a square inch.

When the machine is not working, the engine regulates its own speed accordingly, and is further used for forcing water out of the mine to the surface. When convenient, the water pressure may be obtained from any pumping engine on the mine, by connecting the supply-pipes with the ordinary pumps, thus obviating any special outlay of capital for the moving power. The machine when working makes 25 strokes per minute, and uses 40 gallons of water.

The water is conveyed from the engine to the machine chiefly by 2-in. wrought-iron pipes, the remainder being $1\frac{1}{2}$ -in. bore. The total length of these pipes is about 600 yds.

To allow the machine to traverse on the rails, it is connected to the $1\frac{1}{2}$ -in. pipes by means of an india-rubber tube of the same diameter. This tube will bear a pressure of 500 lbs. to the square inch. The wrought-iron pipes are the ordinary butt-welded steam-tubes, tested to a pressure of 500 lbs. to the square inch. They are used in preference to cast-iron pipes, because they occupy little space, are easily screwed together and bent, and will accommodate themselves readily to the varying floor of the mine, with no risk of breakage or leakage.

The exhausted or waste water is conveyed away from the machine by 2 $\frac{1}{2}$ -in. india-rubber hose, and by 2-in. ordinary gas-tubes, to the place whence it was forced, and thus a very small quantity of water is required to work the machine, namely, as much as is necessary to fill the circuit of the pipes. The water may be used over and over again as in the ordinary hydraulic press.

The pressure at the engine is 80 lbs. in excess of that at the machine when working at 20 strokes per minute. Whenever the cutting tools meet with any extra resistance, the retarded speed allows this pressure to equalize itself, and thus overcome any obstacle.

The amount of pressure used for working the machine varies from 150 lbs. to 300 lbs. an inch, according to the hardness of the material to be cut.

COAL MINING. FR., *Exploitation de houillère*; GER., *Bergbau*; ITAL., *Arte del cavatore di bitumace*; SPAN., *Extracción de carbon de piedra*.

Parkin Jeffcock, in a paper published in the 'Proceedings of the Inst. of M. E.' 1862, ably examined this subject, and applied his reasoning to the general features of the South Yorkshire district with reference to the circumstances affecting mining engineering.

The accompanying general plan, Fig. 1949, given by Jeffcock, represents that portion of the

1949.

Yorkshire coal-field which is more particularly called the South Yorkshire district; extending from Sheffield on the south to Wakefield on the north about 25 miles, and from west to east about 20 miles altogether, on either side of Barnsley. The plan shows the general extent of the coal-field, indicated by the shaded portion; the outcrops of two of the principal seams of coal, the Silkstone and the Parkgate seams; the positions of the principal faults; the localities of the more important collieries and iron-works; and the lines of railway and water conveyance.

The horizontal section, Fig. 1950, which is reduced from Thorpe's published section, is taken through Barnsley along the dotted line WE upon the plan, Fig. 1949, extending from the millstone grit on the borders of Derbyshire on the west to the eastern boundary of the coal-field at E.

The vertical section, Fig. 1951, represents the position and thickness of the principal beds of coal and mines of ironstone, as they were proved by borings at Wath Wood, near Lundhill Colliery, on the plan, Fig. 1949. Five beds of coal, between the Woodmoor seam and the Kent's Thin seam, do not occur at this place; a second vertical section, Fig. 1952, is therefore placed alongside, showing these beds in their corresponding position as they were proved in sinking at the Oaks Colliery, near Barnsley, Fig. 1949.

The South Yorkshire coal-field is a continuation northwards of the Derbyshire coal-field. On the east it is bounded by the overlying and unconformable magnesian limestone and Permian strata, and the extent of the coal-measures in this direction is yet unproved. On the west the millstone grit rocks crop out, forming the bleak moors of North Derbyshire; and the coal-measures extend northwards and constitute the North Yorkshire coal-field. The general dip of the coal strata is from west to east at an average angle of 1 in 9; this, however, is much modified in many localities by main faults, the principal of which are shown on the plan, Fig. 1949, by the strong black lines. The total number of coal seams is very great, as shown in the vertical section, Fig. 1951, and many of them have been worked in various localities.

The following are the principal seams of coal in their geological order, with their average thickness:-

1. Wath Wood or Muck seam	4 ft. 6 in. thick.
2. Coal, no name	3 8 "
3. Woodmoor seam	3 0 "
4. Winter seam	5 4 "
5. Upper Beamshaw seam	4 8 "
6. Lower Beamshaw seam	2 2 "
7. Kent's Thin seam	2 7 "
8. Kent's Thick or High Hazel seam	5 0 "
9. Barnsley Thick seam	8 ft. 6 in. to 9 0 "
10. Swallow Wood seam	5 0 "
11. Howard or Flockton seam	5 0 "
12. Fenton's Thin seam	2 3 "
13. Parkgate or Chapeltown seam	6 9 "
14. Thorncliffe Thin seam	2 6 "
15. Four-foot seam, variable	4 0 "
16. Silkstone or Sheffield seam	5 0 "
17. Charlton Brook or Mortomly seam	3 0 "

The most important seam of the series is the Barnsley Thick coal, which, under the name of the Main, or Top Hard coal, has been very extensively worked in Derbyshire. In the South Yorkshire district its average thickness is about 8 ft. 6 in., but the thickness varies exceedingly

at different places. It is most fully developed in the neighbourhood of Barnsley, but extends through the greater part of the district, and has been principally worked at Woolley, Gawber, The Oaks, Edmund's Main, Wombwell Main, Darley Main, Elsecar, Warren Vale, Rawmarsh, Hoyland, Lundhill, Mount Osborne, Thryburgh, Darfield, and Car House. The hard coal from this seam is in great repute for steam purposes, and stood high at the trials made at Woolwich in 1851 relative to the value of steam coals. North of Woolley the Barnsley seam is subdivided into two or three others, which are worked in the neighbourhood of Normanton under different names. In Derbyshire it appears to the best advantage at the large works of Mr. Barrow, at Staveley, where it is known as the Staveley Hard coal, which has been extensively used for steam purposes and in the manufacture of iron.

The Swallow Wood seam occurs about 60 yds. below the Barnsley Thick coal, its thickness varying from 3 ft. 4 in. to 6 ft. It has been worked only to a very limited extent, principally at Swallow Wood, and is known in Derbyshire as the Dunsil or Oldgreaves coal, lying there about 30 yds. below the Top Hard seam.

The Parkgate or Thorncliffe Thick seam occurs at an average depth of 219 yds. below the Swallow Wood, and has been chiefly worked at Parkgate, Thorncliffe, and Pilley. Its average thickness is 5 ft. 6 in., but the thickness varies considerably, from 4 ft. 10 in. to about 6 ft. It is known as the Bottom Soft coal in Derbyshire, where it has been very extensively worked.

The Thorncliffe Thin seam, called the Bottom Hard in Derbyshire, is found 24 yds. below the preceding; its thickness is from 2 ft. 6 in. to 3 ft., and it has been principally worked at Thorncliffe, Pilley, &c.

The Silkstone or Sheffield seam lies about 61 yds. below the Thorncliffe Thin, and has an average thick-

ness of about 5 ft. It is a very well defined seam, and may be taken as a sort of datum line in identifying the position of the other beds. It has been principally worked in the neighbourhood of Sheffield, and at Chapeltown, Thorncliffe, Pilley, Mortomly, and Silkstone, and is identical with the Black Shale or Clod coal of Derbyshire. The coal is of great value for house fire purposes, competing with the celebrated Hetton Wallsend.

By far the most important and valuable of the seams of coal are the Barnsley Thick and Silkstone seams. At the Woolwich trials, made by the Admiralty in 1851, relative to the strength

and value for steam purposes of the Barnsley Thick coal from Darley Main, West Hartley coal from Newcastle, and Welsh coal from Merthyr Tydvil, the total weight of water evaporated in each case was 24,960 lbs., and the evaporation a lb. of coal was 8.10 lbs. by the Barnsley Thick and West Hartley coals, and 8.25 lbs. by the Merthyr coal. Trials were also made of the Barnsley Thick coal in 1858 at Doncaster, on the Great Northern Railway, when the evaporation obtained was 7.64 lbs. of water a lb. of coal, the total weight of water evaporated being 448,281 lbs., and the coal used being a mixture of steam coal and house fire coal, consumed under Cornish boilers, working at a pressure of 45 lbs. The Barnsley Thick coal lights easily, burns freely, and raises steam rapidly. It produces only a very small quantity of white ashes and cinders, giving little trouble to the stokers, and the less it is disturbed the better; it does not clog or adhere to the bars, and makes no slag, maintaining a good clear fire with little sulphur. It is a most economical coal for marine engines, and in using it a light thin fire is particularly recommended.

The mines of ironstone occur between the Barnsley Thick coal and the Silkstone coal, as shown in the vertical section, Fig. 1951.

The first mine of importance is the Swallow Wood, about 60 yds. below the Barnsley Thick coal, which has been principally worked at Milton for the supply of the furnaces there. It consists of three measures of ironstone; and an analysis of a sample of the ore by Spiller, of the Geological Museum, gave 26.79 as the percentage of metallic iron.

The Lidgate mine, next below the Swallow Wood, has been extensively worked at Milton, Tankersley, and Thorncliffe.

The Tankersley mine is usually found about 50 yds. below the Lidgate, and is called also the Musselband ironstone, from the number of fossil shells it contains. It has been worked chiefly at Tankersley, and yields about 1500 tons of ironstone an acre.

The Thorncliffe Black mine lies about 70 yds. below the Tankersley; it is worked principally at Parkgate, and used in the furnaces at Milton and Elsecar; and an analysis by Spiller gave 34.16 per cent. of metallic iron.

The Thorncliffe White mine lies immediately below the Parkgate seam of coal, and consists of three measures, containing about 32 per cent. of metallic iron, and yielding about 1500 tons of ore to the acre. It has been worked principally at Parkgate and Thorncliffe, and was formerly worked extensively at the Holmes.

The lowest mine is the Clay Wood or Black mine, consisting of three measures, containing about 32 per cent. of iron and yielding about 1600 tons of ore the acre. It has been got to a great extent at Thorncliffe, and is identical with the Black Shale or Stripe Rake of Derbyshire, which is so much prized by the ironmasters of that county.

The principal iron-works of the South Yorkshire district are at Parkgate, Holmes, Milton, Elsecar, and Thorncliffe, in blast; and at Chapeltown and Worsborough, out of blast.

The modes of working the coal in the South Yorkshire district may be considered as modifications of the long-wall system, so extensively and successfully practised in the Midland counties. The pillar-and-stall mode of working adopted in the North of England has not been much used in South Yorkshire; and the long-wall system being principally confined to the Midland counties, the South Yorkshire system of working may be regarded as a combination of the two. Where the circumstances are favourable, the long-wall system is being extended in the Yorkshire coal-field; and wherever it can be adopted, it is to be recommended, on account of the simplicity of arrangement both for working and ventilation, and also as being the most economical method of getting the coal.

The principal modes of working the coal adopted in Yorkshire are the Narrow Work, Long Work, Bords and Long Work, Wide Work, and Bank Work. These are shown in the ideal diagrams, Figs. 1949 to 1968. They can be represented only by ideal plans, because none of them are carried out in their integrity at any collieries in the South Yorkshire district; and in some instances one mode is adopted in one part of the workings, and another elsewhere in the same colliery. These different systems of working, some of which, however, are falling into disuse, have been rendered necessary by the variable nature of the roofs and floors of the coal seams in the South Yorkshire district. The same reference letters are used throughout all the diagrams.

Fig. 1953 is a plan of the mode of working by Narrow Work, on the end of the coal. P is the downcast pit, and B the main bord (road cut transversely to the grain of the coal, against the face of the coal), from which pairs of headings or endings E E (roads cut against the end of the coal, lengthways of the grain) are driven at intervals of about 30 yds. When these endings have been carried to the requisite distance on either side of the main bord B, a communication is made between their extremities, and the coal is worked by short faces homewards, as shown at WW. The whole of the coal being thus got out, the roof is allowed to come down in the goaf as the working progresses, being temporarily kept up immediately behind the working faces by props or puncheons, which are afterwards withdrawn successively and shifted forwards. U is the upcast shaft, and F the ventilating furnace. The main current of fresh air from the downcast pit P is carried up the main bord B and along the farthest pairs of endings E, as shown by the arrows, and is then passed through the face of the workings W. The course of the air is determined by stoppings S built to block up the various crossgates between the bords and endings; and by doors D, through which the coal is brought down to the shaft from the workings W, and from the endings E that are in process of being driven. At C is an air-crossing, where the current of foul air proceeding from the workings to the upcast shaft U crosses over the current of fresh air entering the mine from the downcast pit P. At RR are regulators to control the quantity of air passing through each portion of the mine; when these are closed, the whole of the fresh air has to pass through the workings before reaching the upcast shaft; but when they are opened, a portion of the air finds a shorter course through the regulators direct to the upcast shaft, and a smaller quantity of air therefore passes through the workings. This mode of working is falling into disuse in Yorkshire, and is seldom adopted except under special circumstances, where the coal is of a soft

or friable nature and where the roof is not strong, the coal being therefore got in very short lengths, as shown at W W, with only a very narrow face in process of working at a time, whence the name of this mode of working.

1953.

There are two modes of Long Work, the first of which is shown in Fig. 1954. This and all the subsequent modes of working are on the face of the coal, the workings W being carried forwards transversely to the grain of the coal, against the face of the coal, instead of against the end of the coal as in the previous narrow work. In Fig. 1954 it will be seen that there is a long

1954.

face of work in progress at once in each portion of the mine: the workings are started from the main headings or endings E, and the coal from the working faces is brought down through the goaf by means of packed roads G, shown by the strong black lines, the walls of which are built up of rock and shale; the packed roads are carried forwards continuously as the working faces advance. The fresh air from the downcast shaft passes along the endings E and the packed roads G up to the working faces W, and thence by the bords B to the upcast shaft U, as shown by the arrows, the regulators R R controlling the ventilation in each portion of the workings. At H H are doors or stoppings with apertures to allow of passing some of the air through the packed roads G in the goaf, according as may be required to keep them clear of gas.

In the second mode of Long Work, shown in Fig. 1955, the workings are subdivided into separate lengths of face by the pillars L being left between them at first, about 30 yds. thick; but when the workings have been carried forwards as far as intended, the intervening pillars are then also worked, beginning from the farther end and working backwards, as seen at A, whereby

the current of air is always kept up against the pillar face A until the whole pillar is removed. The packed roads G are required for bringing out the coal through the goaf in this plan of

1955.

working, the same as in the first mode of long work; the strong dotted lines through the goaf in the neighbourhood of the pillar working A show packed roads that are no longer required to be maintained, and have been abandoned. The course of the air is shown by the arrows.

The mode of working by Bords and Long Work is shown in Fig. 1956. Here pairs of bords B B are driven from the main heading or ending E, at intervals of about 20 yards; and when they have reached the extreme distance intended, the whole of the intervening coal is worked homewards, downhill, and is brought out from the working face W through the bords B. In bords and long work, therefore, the bords form a marked feature in the system, being driven to the extreme extent in the first instance, as shown in the right-hand half of the plan, Fig. 1956, before the working of

1956.

the whole coal is commenced; and when this has been begun, as shown in the left-hand half of the plan, no packed roads are required in the goaf for bringing out the coal from the working face, but the coal is brought down through the bords themselves, which are thus not obliterated till all the coal is won, but remain of service to the last. In the previous modes of long work, on the contrary, shown in Figs. 1954, 1955, the progress of the work is in the opposite direction, uphill, and the face of work is opened without driving bords; and accordingly packed roads are required to be maintained through the goaf for bringing down the coal from the working face. The course of the air is shown by the arrows in Fig. 1956, and the air regulator is placed at R; but in bords and long work

there is no need of any arrangement for coursing part of the air through the goaf, as is required in long work.

In the Wide Work method, shown in Fig. 1957, the coal is got in banks W about 60 yds. long, each subdivided into bords 7 or 8 yds. wide, separated by pillars of an average thickness of 1 yd., as shown by the thick black lines in the goaf. Crossgates K are made to the main roads B at suitable intervals, according to the state of the atmosphere in the mine and the ventilation. For

1957.

ventilating the workings the current of air is passed up the farthest bord B, across the face of the work in the first bank W, and out at the other end of the bank; it is then carried forwards up the intervening pillar bord B to the next bank, and across the working face in the same manner, as shown by the arrows. This method of working is now being abandoned where possible for the long-wall system.

In the Bank Work, shown in Fig. 1958, the coal is got in banks W about 60 yds. long, as in the last mode, but each bank is worked all in one length without any intermediate pillars being left in each bank. The method of ventilation is the same as in wide work, as shown by the arrows. The mode of working by single bords B, as in both bank work and wide work, instead of by pairs of

1958.

bords, is, however, to be condemned on account of the difficulty and expense of maintaining packed roads through the goaf for the winning of the pillars B B at the last; or if they have not been maintained, of making new packed roads for ventilation: and again, these pillars being liable to a heavy pressure, the coal in the pillar working is rendered of little value.

The plan of the Long Wall system of working, Fig. 1959, shows the difference of this system from any of the ordinary Yorkshire methods of working described above. This is not an ideal plan, but a plan of the actual long-wall workings of the Parkgate seam at the Wharnciffe Silkstone Colliery near Barnsley, Fig. 1949. There is here no loss in getting out pillars, as all the coal is

excavated at one operation. The ventilation of the mine is at the same time considerably simplified, the current of air having altogether a shorter and less tortuous course to follow from the downcast shafts P to the upcast U, as shown by the arrows. The thick dotted line M M shows the position of a fault in one portion of the mine, and the workings are therefore laid out at that part conform-

1959.

ably with the course of the fault. By the long-wall system a working face of 430 yds. is here obtained in a single length without interruption, as shown at W; and in the lower portion of the workings along the fault M M another face has been opened of the same total length, but divided into two shorter faces by a pillar bord, for safety and convenience of working in the neighbourhood of the fault, the intervening pillar being removed before that portion of the mine is abandoned.

Various supports for the roof are used in the Yorkshire seams: wooden props or puncheons are adopted in some cases; in others, piles of wooden blocks called chocks or clogs; and in others, packs of rock and shale. Cast-iron puncheons also are now being extensively introduced, one of which is shown in Figs. 1965, 1966.

Two of the greatest difficulties that have to be contended with in mining are Water and Gas. With regard to Water, the mines in the South Yorkshire district are not in general heavily watered in comparison with other mining districts; the workings nearer the outcrops or bassets of the seams are generally more watered than the rest. Except in some special instances there are few collieries where large pumping engines are required: lift pumps are used exclusively, and even tubbing has

scarcely ever been resorted to. A remarkable inundation occurred in 1861 at the Woolley Colliery at Darton, near Barnsley, Fig. 1949, which is working the Barnsley Thick coal: the coal is drawn up a long inclined plane extending from the outcrop of the Barnsley Thick seam and following the dip of the seam; and the water is raised by means of flat pumps. On the 13th April, 1861, a sudden irruption of water into the workings took place, to such an extent that they were almost entirely filled. The water entered through a fissure in the overlying rock, which is of considerable thickness and is full of cracks and fissures towards its outcrop. It is probable that a large amount of head or drainage water had accumulated in these fissures while they remained closed, and that they afterwards became opened by subsidence of the strata in consequence of the working of the coal: the water was found to be drawn away from a well in the rock at the surface, 170 yds. above the coal. The accumulation of water must have been very great, as it continued rising in the day drift a fortnight after the inundation had occurred, at the rate of more than 1 ft. an hour, although a double 10-in. pump had been kept continuously at work; but its rise was subsequently stopped by additional pumping power.

In the amount of Gas generated by the different seams of coal there are great variations. The most terrible explosions have taken place in the Barnsley Thick coal, especially at the Darley Main Colliery, the Oaks, Warren Vale, and Lundhill; the Barnsley Thick and Silkstone seams being specially liable to sudden and powerful emissions of gas. The ventilation is produced by a furnace, shown in Figs. 1960 to 1963, situated at F in the diagrams, Figs. 1954 to 1958, at the bottom of the upcast shaft U, by which a fresh current of air is kept continuously flowing through the mine, so that any gas issuing from the coal is speedily diluted and rendered harmless. For distributing the air through the workings, the stoppings S, doors D, and regulators R are arranged in proper places. The division of the air into separate splits, each of which ventilates a distinct portion of the workings by means of the crossings or overcasts C, and the "scale doors" or regulators R, may be considered, if properly carried out, one of the best preventives of explosions in these very fiery South Yorkshire mines. All the return air should be conducted into the upcast shaft by a dumb drift N, Figs. 1960 to 1963, so as not to pass through the fire of the furnace; and the underground furnaces, whether closed or otherwise, should be fed with nothing but fresh air direct from the downcast shaft.

At some of the mines in the district, belonging to Fitzwilliam, large fans driven by steam power have been substituted for the furnace generally used elsewhere; they are a simple and efficient means of mechanical ventilation, well worth the consideration of all interested in mining, and have now been continuously working with complete success for several years. In the early periods of mining the only ventilation was the natural ventilation, the current of air through the workings being produced simply by the colder and denser air from the downcast shaft displacing the hotter and rarer atmosphere of the mine. Sometimes rarefaction was increased by putting a pan of coals in the upcast shaft; but the consequence of such imperfect ventilation was that the workings were sometimes stopped for many days together. Natural ventilation could, of course, be adopted only when the shafts were of moderate depth and the workings on a limited scale.

In the South Yorkshire district, safety-lamps were first used exclusively at the Oaks Colliery, in the workings of the Barnsley Thick coal, where Stephenson lamps are used in preference to Davy's; and the use of safety-lamps has since extended to many other collieries. At the Wharfedale Silkstone Colliery, near Barnsley, working the Silkstone seam, Stephenson and Davy lamps are used exclusively; and as the coal-field is very much cut up with faults, the gas cannot be bled away, but as each fault is cut through the greatest caution is required in dealing with the gas in the solid coal beyond, *in bye*. In addition to the use of safety-lamps, an abundance of air should be taken into the working places of fiery mines. Since the explosion at Lundhill in 1857, safety-lamps have been exclusively adopted there. The importance of their use in fiery workings was strongly shown at the Oaks Colliery in 1857, when an outburst of gas took place in the workings down the engine plane, so violent that it was compared to the roar of a draught in the furnace. All the Stephenson lamps were put out, and the Davy lamps were ignited internally, the gauze becoming red hot. As the outburst of gas occurred within a hundred yards of the main intake to the upcast shaft, and a large quantity of air was passing this part at the time, the gas was soon diluted and carried away; and in less than an hour the only traces that remained were found at one or two places where the floor had been upheaved. Thus no doubt a terrible explosion had been averted by the use of safety-lamps; but if any one of the lamps had been out of order, or the gauze smeared with oil or coal dust, or if any naked light had been in this part of the workings, an explosion would inevitably have occurred.

COAL-WASHING MACHINE. FR., *Machine à laver les houilles*; GER., *Kohlenwaschmaschine*; ITAL., *Macchina da lavar litantrace*; SPAN., *Máquina para limpiar carbon de piedra*.

We give, Figs. 1969 to 1973, a set of coal-washing apparatus and coke ovens at one of the establishments of the Wigan Coal and Iron Company. The washing machinery, which is contained in a building 48 ft. long by 24 ft. wide, consists of four iron chambers, each of which is in free communication with a cylinder placed at one end of it, as shown in the plan, Figs. 1970 to 1972. These cylinders are each 3 ft. in diameter, and the pistons working in them have a stroke of $3\frac{1}{2}$ in., and are driven at 150 strokes a minute, so as to keep the water within the chambers in a state of constant agitation.

The coal to be washed is discharged from the railway wagons into a large hopper outside the building, and it is lifted from this hopper, Figs. 1969, 1970, by the elevator shown in the section, Fig. 1970, this elevator delivering it to the crushing rollers, by which it is reduced to a uniform size. After passing the crushing rollers, it is taken up by a second set of elevators, and delivered to the washing chambers, or bashes, down a trough laid at an easy gradient, this trough having four compartments, down which the coal is washed by a small stream of water. The coal, during the process of washing, is placed on perforated copper screens or sieves slightly submerged in the water contained in the bashes, and the pulsation of the water, occasioned by the action of the pistons, causes the good coal, which is the lightest, to be washed over into the shoots with which

the chambers are provided. The pyrites, on the other hand, being heavier, fall down and lie on the perforated sieves; and at regular intervals the sluices are opened, and the pyrites allowed to fall into the chamber below. At the bottom of each chamber there is another sluice, which is opened occasionally to allow the refuse to be discharged into wagons placed to receive it. The good coal from the shoots of the bashes is also delivered directly into wagons.

The washing machinery, elevations, and so on, are driven by a beam engine, with 14-in. cylinder and 2 ft. 6 in. stroke, arranged as shown in Figs. 1969, 1970. The loss by washing is about 10 per

1969.

1970.

cent., by weight, of the gross quantity of coal passed through the machine. Several machines of the kind we have described are in use at the Wigan Coal and Iron Company's works; and they turn out from 300 to 350 tons of small coal a day.

The general arrangement of the coal-washing machinery and coke ovens will be understood from the general plan and section, Figs. 1971 to 1973. From this it may be observed that the ovens, which are each 11 ft. in diameter and 8 ft. 6 in. high, are arranged in two parallel double rows, a chimney being provided for every eight ovens. The charging is performed by the aid of a tramway laid over the tops of the ovens, Fig. 1973, the coal dust being brought from the washing apparatus in 25-cwt. hopper wagons along this tramway, and dropped through holes left in the crown of the ovens for this purpose. The charge of each oven is 8 tons, and this charge is allowed to burn five days or 120 hours. This, when burnt, is cooled by the aid of a water-pipe inserted in the oven, and is afterwards drawn out by rakes.

One of the most successful of recent coal-washing machines is that constructed by M. Evrard for

the mines of La Chazotte, in France, Figs. 1974 to 1976. Figs. 1974 and 1976 are vertical sections through the machine in two directions at right angles to each other, and Fig. 1975 is a plan of the whole. The special object in view in this construction is the washing of very large quantities of coal of comparatively unequal size, and the separation of these different sizes by the aid of the washing process. This large washing machine is thereby enabled to combine the advantages of machine labour with the superior quality of work performed by hand-washing. The coals are

1971.

1972.

1974.

thrown into a hopper A, Fig. 1974, with a revolving base upon a larger revolving screen, where the largest pieces are freed from stones by hand, two workmen being placed upon the screen B, and carried round by the latter in its revolution. There are two screens with narrow openings below this first, and they deliver the smaller coal by means of two elevators C, to the top of the washing machine. Each kind of coal is brought up separately, and thrown upon a circular table D, which revolves slowly round a large fixed cylinder E, containing the floating piston F. The two elevators

bring the coal up to the circular table, and it is levelled there by two scrapers fixed in different heights (*m n* in plan, Fig. 1975), so that a stratum of small coal is spread over a layer of larger coal below. The central part of the machine is filled with water, and the floating piston *F* is moved up and down in the water by means of a lever *L*, Fig. 1975, worked by a cam. The lever

is counterbalanced by a float *G*, immersed in water, and its movement causes an alternating up and down current of water through the screens in the revolving table *D*, by which the different materials mixed together in the unwashed coal slack separate themselves in parallel horizontal layers, according to their difference of specific gravity, and also according to their size of grain. There is, however, one thing of great importance required for a successful operation, namely, the agitation of the water must commence with great power, and must successively diminish in force as the washing proceeds, since the first action effects the settlement of the very largest pieces of stone at the bottom, and of the large-sized coal in a stratum immediately above that. This being done, it requires a more gentle agitation, so as to leave the lowest layers undisturbed, while operating through these upon the superposed strata of small-grained materials, so as to give the small pieces of stone and other heavy matters an opportunity to pass through the coarse-grained coal down to the lowest stratum of stones. With a uniform action of the machine, *M. Evrard* obtains this important result, by inclining the table against the water lever, as shown in Fig. 1976. He thereby obtains a greater immersion of the table, and, consequently, a more powerful rush of water through its sieves at the one part of each revolution, and a less powerful action at the opposite side where the coal is partly raised above the water-level.

The body of this machine is constructed in masonry, in the shape of an inverted cone, with a diameter of 33 ft. 6 in., and a height of 32 ft. 10 in. Its bottom opens into a drain-pipe for removing the mud collected there. The floating piston is 17 ft. 4½ in. in diameter. The table *D* is 32 ft.

10 in. in diameter, and 6 ft. 6 $\frac{3}{4}$ in. wide. It is perforated with holes of $\frac{1}{8}$ in. in diameter. The inclination of this table amounts to one foot for the whole length of the diameter of the table; the depth of layer of coal is 6 in., and the water-level 8 in. over the lowest point of the revolving table. The coal is removed from the table after having passed through one entire revolution by means of four scrapers placed at different heights, so as to remove each another of the superposed strata of coal ranged according to the size, the smallest coal being raked off from the top, while the lower layers give coarser-sized coal in proportion to the depth. The lowest stratum is formed by the stones and other heavy impurities of the coal, and this is removed whenever it has reached a certain height. The washing process, as carried on with this machine at Chazotte, reduces the contents of ashes of the coal slack from 15 to 17 per cent. on the unwashed slack down to 8 or 9 per cent. The production of one of these machines is 138 bushels for each revolution, and, taking the speed at the average adopted at Chazotte, namely, one revolution in five minutes, with 100 strokes of the piston during that time, the total production is 1650 bushels an hour. The total power required for the complete machine, with its revolving screen and elevator, is 10 horse-power.

A very simple mode of washing the impurities out of small coal has been at work at South Tyne Colliery, Haltwhistle. The machinery employed consists of an arrangement of boxes or troughs, into the upper series of which, A 1, A 2, A 3, Fig. 1977, the water for washing is conducted by a pipe P. At the end of A 3 is a small screen, formed of $\frac{3}{8}$ -in. round iron rods, placed about $\frac{1}{2}$ of an inch apart; immediately below this screen another series of troughs, B 1, B 2, B 3, is similarly arranged, terminating with a perforated zinc plate placed in a sloping position like the screen in the upper series. The upper troughs are 2 ft. 4 in. wide and 13 in. deep; the lower ones are 2 ft. 5 in. wide and 6 in. deep.

At c, d, and e, Fig. 1977, grooves are placed, into which slips of wood are inserted, one above another, at different stages of the washing; these partially check the current of water, and assist in collecting the stones, pyrites, and so on. W, Fig. 1978, is the wagon-way, by which the coal is brought to the washer.

It will be observed that the pipe P is bent so that the water pours *against* the end of the trough; this has been found to act better than when the water is poured in the contrary direction. The mode of working is apparent; an operator shovels the coal into the trough, and another with a rake spreads it and keeps it under the action of the current. The water that passes through the screen carries much of the smaller coal with it; to obviate this the lower series of troughs were erected, along which the water is conducted, and finally passed over the perforated zinc plate. The velocity of the current is regulated, when required, by raising or lowering the troughs, their arrangement being such that this is easily effected. With this apparatus two operators can wash three wagons of coal an hour.

COAST DEFENCE. FR., *Fortification Maritime*; GER., *Küstenbefestigung*; ITAL., *Difesa delle coste*; SPAN., *Defensa de la costa*.

Coast Defences.—The defences of coasts and harbours, especially those of an island like England, where if attacked the assault must be delivered more or less immediately from the sea, forms an important branch of the general technical art of fortification; with this considerable difference, however, that while the works of an inland fortress or strong place are generally constructed with a strict regard to certain rules laid down for the different systems of celebrated engineers, the acknowledged heads of their profession, the defences of a coast must in a great degree depend on local circumstances, and, if secure from an attack on the land side, do not require to be furnished with the appliances for a protracted siege. The struggle with an enemy afloat and unsupported with land forces would then be short, sharp, and decisive, the victory remaining to the hardest

hitter, the biggest gun, or, perhaps, to the craftiest-laid torpedo. In like manner, the proper placing and construction of coast defences emancipates, as it were, the officer of engineers from the more mechanical operations of permanent fortification, and, if he possesses genius, enables him to take advantage of every natural feature, both above and below the water-level, either for defence or offence, and make the most of them.

Their History.—Although in the very dawn of Jewish, Greek, and Roman history we read of the walls and other fortifications of towns, we do not find any mention made of impediments to prevent invaders landing on their coasts, except occasionally a free fight on the beach, such as the Greeks appear to have experienced when they reached the shores of Troy. When Julius Cæsar landed on the Kentish strand, he had, it is true, to break through a bulwark of half-naked blue-stained Britons, which his heavy-armed legionaries soon proved too strong for. William of Normandy met with considerable opposition when he disembarked as an invader; but he eventually conquered. In most cases we find the invaders securing themselves a safe haven or tête-de-pont for return in case the fortune of war should declare against them. Thus the Greeks fortified their ships on the shores of Troy, and the Romans created the germs of the future fortifications and defences of Dover and Portsmouth, and perhaps the Thames. But in the first few centuries after the Conquest the constant wars between England and France exposed both nations to the visits of hostile fleets, and subjected the unfortunate inhabitants of our sea-board to much misery, especially on the south and east coasts. We can yet see in the Isle of Wight the existing outline of a town (Newtown) burned by the French fleet in the time of the second Edward, and which remains, with its houseless streets and market-places, a desolation to the present day. Even localities so remote as the Welsh coasts were not safe, as we read that in 1405 the French landed at Milford Haven and plundered Carmarthen and other towns, safely regaining their ships; while as late as 1758 we retaliated by sacking the now impregnable Cherbourg, and levying a tribute on its *Monts du Piété* and other public institutions.

As the invention of artillery, however, grew in importance, the attention of our rulers seemed turned to the necessity, on certain points of our coasts at least, of securing the cities and towns situated near them from being burnt or plundered with impunity; and the sequestrations of the rich monasteries in Hampshire and the Isle of Wight furnished the eighth Henry with funds sufficient to erect the castles of Southsea, Hurst, Sandown, Yarmouth, and Calshot, as well as to fortify the narrow entrances into the harbour of Portsmouth, which was then, as now, considered the first naval arsenal of England. Besides these, we owe to Henry VIII. the defences of Falmouth, Plymouth, Pembroke, Deal, and other important points on the coast. In Queen Elizabeth's time the defences of Milford Haven, the Thames, and Plymouth, as well as minor works on the Kentish and eastern shores, were not neglected by her shrewd and far-seeing ministers, and the many existing traces of the reign of the Stuarts in the old fortifications of Portsmouth, Devonport, Sheerness, Gravesend, and other places along the coasts, although erected more probably from dread of a Dutch than a French invasion, show that neither Charles nor James neglected the defence of England on its then weakest and most accessible points. During the reign of Anne and the first two Georges the constant dread of descents from the partisans of the Pretender, or his French and Spanish allies, caused further extensions of our coast defences; and when the French fleet rode triumphant in the Mediterranean, after the fall of Minorea and execution of Byng, we deemed it necessary to strengthen the land defences of Portsmouth by the first fortifying of the old Hilsea lines. It is a curious thing that one of our ancient northern coast defences, namely, the Old Fort on the Bass Rock, was the last spot in Great Britain that held out for the Stuarts. The long wars of the French Revolution, although our fleets finally swept the seas of our enemies, still demanded constant attention to various exposed and unprotected points of our coast; but it was not till France again had a navy, and the defences of Cherbourg, Cronstadt, and Sebastopol created, as it were, a new era, and the due progress of things produced the Crimean and American wars, that the subject was really taken up in a comprehensive and extended manner; our eyes seemed suddenly opened to the utter worthlessness of many of our existing works, and an honest effort made to effect all the improved modes of fortification now absolutely necessary by the monstrous strides that modern science has made in the weapons both of offence and defence. The Report of the Commissioners appointed to consider the defences of the United Kingdom, dated the 7th February, 1860, entered fully into the details of their existing state, and gave their recommendations for their augmentation or renewal; and until the present time immense works, costing an aggregate sum of at least nine millions both in coast and inland defences to our harbours and arsenals, have been carried on, subject however to the disadvantage of the ever-changing increase in the weapons of attack and a corresponding increase ever forced on them in those of defence, causing works which might have been deemed perfect a few years ago to be now nearly useless or obsolete.

Reconnaissance of a Sea Frontier.—In addition to the general descriptions necessary in making a reconnaissance, that of a sea-board line should clearly describe the nature of the coast; whether it is bordered by dunes or sand hills, or edged with flat rocks in shallow water which would render access to it more or less dangerous, or by cliffs which would render it altogether inaccessible; the points on which descents could be easily made, the reentrant angles affording sheltered creeks and anchorages; the high lands and capes affording eligible sites for the erection of forts and batteries should be clearly pointed out, with the height of each above the ordinary high-water level, also all islets and rocks capable of being made available for advanced works, such as towers, and so on; the shoals, creeks, roads, and ports, with their soundings, the nature of the winds necessary for entering and sailing out of these ports, of which it will be requisite to note the local peculiarities; the state, garrison, and armament of the different batteries established for the defence of the anchoring grounds; the field-works, if any, formed on points where descents might be practicable; the camps, fortified towns, and other strong places which cover or protect the principal maritime establishments or military arsenals; finally, to analyse

carefully the existing system of defence, and to consider the best mode of forcing it. If rivers have their mouths on these coasts it is necessary to consider very carefully the influence of the tides on their entrances. It is not less essential to indicate the hours of high water at all the principal points and ports, and the period of tide more or less favourable to the approach to the different points of disembarkation. To these general remarks, taken from the French '*Aide Mémoire*,' we may add that in modern warfare it will be very necessary to take into consideration the various lines of railway by which forces from the interior may be suddenly concentrated so as to crush any inferior or isolated body of men who may seek a hostile landing on a coast, and also the facilities which may exist for the placing of obstructions either floating or hidden.

General Principles of Coast Defence.—Before entering into this subject it must be premised that, while we write, some of the most important points of coast defence are involved in much doubt, and must be considered as subject to important changes, according as the experiments on our guns, our ammunition, our armour, and our obstructions, floating or otherwise, present from day to day new phases. We can therefore only offer a few useful general principles on the subject from the best modern authorities, simply reminding our readers that the great question of ships *versus* forts and iron *versus* earth yet remains to be solved, when the giants of the earth again do battle.

Von Wurmbs, in his '*Lehrbuch der Kriegs Baukunst*,' remarks that the defence of a sea-surrounded country, or an extended line of coast, requires in the first instance movable bodies of troops cantoned near the most important points, and acting in co-operation with divisions of the fleet, flotillas of gunboats, and war steamers. Well-arranged lines of railway and telegraph will be here of great importance. Fortresses are, however, necessary at the principal arsenals, dock-yards, and other sources of supply, as well as at those points where the landing of a large body of an enemy's troops might take place, and so enable them to attack us on the land side.

The fortification of the principal important points of a coast line, such as our war havens of Portsmouth, Sheerness, Plymouth, Milford Haven, and Cork Harbour, also demand an enceinte on the land side capable of withstanding a sudden assault, and outworks which are strong enough to defy a regular attack, to resist the operations of a hostile fleet, and finally to keep the enemy at such a distance as to prevent a bombardment of the place and its establishments. This has been the principle adopted in the modern land defences of our naval arsenals, which are now surrounded with substantial forts as well towards the land as the sea, so as to hold an enemy at bay until our forces could be hurried up from all sides. On other points, coast batteries or forts of a minor magnitude become necessary to defend roads, havens, or anchorages, to protect the interests of commerce, or to hinder the landing of an enemy; due precautions should in all cases be taken to secure the rear of these batteries from surprise by proper gorge walls, and so on.

As, nevertheless, fortresses cannot defend every point, or be placed close enough to hinder the passage of a powerful fleet, we must therefore in such cases take advantage of floating and hidden obstacles of every kind, such as torpedoes, floating batteries, booms, chains, rope nets, and so on.

Coast fortifications, it must always be considered, are opposed against the power of a most formidable enemy. In the present day we must consider the enormous and still increasing armaments, both in number and weight, of modern ships, and their armour creeping up from 4 in. to 15 in. in thickness. Even frigates which a few years ago were seldom equipped with anything heavier than an 18-pounder, now carry 12-ton guns, discharging a 300-lb. bolt. Also, in a proper depth of water, ships can change their position easily and quickly, and by the help of steam can tack in the face of contrary winds and lay their broadsides full on against the opposing forts, unless these are situated high enough above the water-level.

But, on the other hand, many circumstances favour the defence of fortresses against ships when unsupported by land forces. The most formidable position of ships in attacking a coast defence is no doubt with broadside on, and, theoretically at least, as close as possible; but in taking up this position, if the ship, not of course a turret, allow itself to be raked by the fire of the fort, it is in the first place quite powerless to return a gun, and its sudden destruction may in many cases take place. If the wind suddenly changes, the keel touches a shoal, or a shot knocks the machinery out of gear so as to hinder its withdrawal from an enemy's fire, then it may be destroyed by the guns of the fortress, if they are heavy enough to penetrate her iron plating; for in modern warfare we must consider all fighting ships as thus protected. This fate very nearly met our fine 90-gun line-of-battle ship the '*Albion*' and 50-gun frigate '*Arethusa*,' by the fire of two or three guns only of the little Wasp and Telegraph batteries, on the heights of Sebastopol Harbour, on the 17th October, 1854. In modern times, many brilliant examples of this have been given. One large shot striking a line-of-battle ship near the water-line may sink her, or a shell bursting through her decks explode her magazines.

Fig. 1979 shows the defences of the entrance to Sebastopol Harbour, and position of the cliff batteries and attacking ships. The figures show the height in feet above high-water mark.

We may here remark the circumstance that coast batteries have generally a very large object to aim at,—a line-of-battle ship, for instance, from 200 to 300 ft. in length, and, with her sails and rigging, 60 to 80 ft. in height; while the ship may have no target to fire at but an open coast battery, covered with a strong earthen shield, and with the muzzles of its guns not rising more than 1½ ft. above the crest.

It is desirable to have the guns of a small battery as much as possible of the same calibre, if not of the same nature. It must be also considered that a ship changing its position at the rate of 8 knots an hour moves 600 yds. in 2½ minutes; therefore to meet this, not a single gun, but a number on each battery, will be found necessary and most efficient to injure a passing fleet.

Previous to 1861 not less than twenty-three varieties of guns were mounted on our coast batteries, after which period the number was restricted to five varieties, namely, the 10-in. gun of 86 cwt., 68-pounder of 95 cwt., 8-in. of 65 cwt., 32-pounder of 56 cwt., and 13-in. mortars; but with

the late imagined improvements in artillery our batteries will be soon generally armed with the 12-ton 300-pounder, and on important points with 25-ton 600-pounders.

Batteries for mortars, flanked, however, by a few heavy guns, are requisite on certain important points. That of Puckpool, commanding one of the eastern entrances to Spithead, is a formidable battery of this artillery arm, mounting thirty 13-in. mortars.

Each description of gun should have a separate expense magazine for its ammunition.

Low barbette batteries should never be used when the work is at less elevation than 100 ft. above the sea-level, and then only they are safe from enfilade.

Barbette batteries have the advantage of a more extended range of fire than those with embrasures.

If a battery be less elevated, the parapet must be heightened, and the gun then fires through an embrasure, or it must be raised, when great range is required, to fire over a parapet of 7 ft. protected by bonnettes.

In earthen batteries the distance between the guns must not be less than 35 ft. when mounted on traversing platforms, and traverses should be provided for every two guns. In casemated and iron-plated batteries the guns are generally spaced 24 ft. from centre to centre, = to a 12-ft. pier and a 12-ft. shield.

Casemated batteries are necessary when it is required to place a work close to deep water, and more than one tier of guns is necessary to defend the position.

All coast batteries, whether casemated or not, should be retired as much as possible from deep water, unless by doing so the object of the battery might not be attained.

We in many cases utilize our casemates both in coast and land batteries by using them as barracks for the garrison, but all partitions and rear walls should be made movable and as slight as possible. Continental coast batteries, when casemated, are generally open in the rear; in double-tier casemated batteries the magazines and stores are usually placed in the basement story, which is faced with solid walls of great strength, and covered with bomb-proof arches.

It is almost useless to discuss here the question of embrasures. Modern science, however, plainly points to the adoption of wrought-iron shields both for casemated and earthen batteries when the Moncrieff system of gun-carriage is not used. The thickness of the shields may vary according to exposure from 9 to 15 in., with the aperture for the gun's mouth as small as practicable.

Red-hot shot or shells filled with molten iron requiring a supply of furnaces and fuel to heat same, were until lately part of the equipment of every coast battery of importance. The universal adoption of iron-clad vessels has however diminished very much the importance of this mode of defence, and our best modern coast forts have no appliances of any kind for heating shot or melting iron except in very peculiar circumstances; an enemy, however, attempting a landing with a flotilla of wooden boats, might suffer severely from the use of heated shot.

The following additional observations are principally founded on Sir J. Burgoyne's 'Notes on the Coast Defences of Great Britain.'

In all arched vaults, such as casemates liable to be battered, the covering arches should be brought endways to the front, so as to form a revetment en décharge.

Batteries or brigades of guns to be brought up with troops to parts of a coast threatened, will be worthy of being organized in time of war in central secure stations.

The most effective fire against ships is doubtless from guns placed but little above the level of the water, but so placed they would be subjected to an overwhelming fire from ships in return.

In proportion as batteries are elevated they lose in the best effect of their own fire, but become far less exposed to suffer from that of ships.

There is also from elevated batteries, if close to the water, a certain space near them which they cannot command at all, and where vessels and boats would be consequently safe from them.

Sir J. Burgoyne considers an elevation of not less than 50 ft. as a good medium elevation: at that height the shot may be made to strike the water at a distance of 200 yds., and will ricochet well, and at the same time the guns would be but little exposed to direct fire from shipping.

Rockets may be of great service in close quarters with ships. With reference to the exposure of guns and gunners, he remarks that in military operations the first aim is to obtain success;

to save life is a secondary consideration, excepting so far as may not impede the first, when of course it becomes an anxious and imperative duty.

He recommends the construction of packets and mercantile steamboats to carry guns in case of need, and the organization of the population of the coast, the coastguard and dockyard men to man our batteries.

The experiences taught in the last American war have thrown quite a new light on what we, a few years ago, learned in the Baltic and the Black Seas. Von Scheliha, in his work on 'Coast Defences,' lays down some general rules, which we here give, being worthy of consideration, and supporting his propositions by examples of different conflicts on the coasts and rivers of America, premising that he considers the Confederates in the first place committed a great mistake in attempting to fortify so many points as they did both on their coasts and rivers.

a. That railway communication with different points is preferable to fortifying places of secondary importance.

b. That exposed masonry or brickwork is not capable of withstanding the effect of modern artillery.

c. That earth, especially sand works properly constructed constitute a better protection against modern artillery than permanent fortifications built on the old plan.

d. That guns mounted en barbette, even when protected by properly-built traverses, may be silenced by a concentrated fire from ships.

e. No fort now built can keep out a large fleet unless the channel be obstructed.

f. A mere partial obstruction of a channel not sufficient to keep out a large fleet.

g. No fleet can force a passage if kept under the fire of heavy batteries by properly-placed obstructions.

These views of Von Scheliha are on the whole satisfactory to us with a few exceptions, when we consider the vast outlay we have made within the last few years on our coast defences. With torpedoes and other hidden obstructions, backed by the fire of our modern forts, no fleet could possibly pass narrow channels like that between Hurst Castle and Scone Point, or the winding sinuosities of deep water between the Spithead Forts, the Thames, Medway, entrance to Plymouth Sound, and other similar localities leading to our principal arsenals and dockyards, as well as the river entrances to our great commercial emporiums, as Liverpool, Hull, Bristol, &c.

The vast alterations in the armaments even of our older defences have rendered a great number of additions to our magazine and store accommodation necessary; increased provision must be made for shells, apparatus for large guns, and so on. In the larger earthen coast batteries the magazines are generally in the rear of the work (which should have its gorge closed by a defensible loop-holed wall), and constructed with bomb-proof arched brickwork, with a covering of earth varying from 4 to 6 ft.; smaller expense magazines are formed in the various traverses, and other secure places in the earth-works. There is considerable difficulty in this climate in preserving these magazines free from damp, principally arising from condensation of saturated air on the walls. If deeply seated in or covered with earth, the ventilation is often defective, and where wooden floors are used considerable ravages have been made by dry rot, the warm and damp air within the magazines appearing to favour the growth of fungi in the timber. Floors of asphalt laid pure without grit are now used in magazines with advantage, and the application of steam in drying the internal air of magazines is a subject worthy of consideration.

The views of Rear-Admiral Porter, U.S.N., on coast and river defences, as enumerated in his report, 1865, are these, namely:—

a. Too much importance cannot be attached to the employment of torpedoes and other hidden obstacles.

b. Considers that no forts can withstand the united fire of monitors and iron-clad vessels.

c. Recommends the combination of military with naval attacks. These formed an important feature too much overlooked, perhaps, in the attack and defence of coast forts during the American war, as at Charlestown Harbour, Vicksburg, &c.

d. Little difficulty occurs in running past the strongest forts if no obstructions natural or artificial exist, but on forts only no safe reliance can be placed.

e. He knows no instance in which troops and ships properly combined have attacked a fort but they have taken it.

f. One gun on shore being considered equal to ten afloat is a principle not at all to be depended on.

g. Even if guns in a land battery are protected by traverses they are not safe from vertical fire.

h. It must, however, be allowed that there are certain points on every coast where forts can be built unassailable by ships, and that Federal Point, Wilmington River, where Fort Fisher stands, is one of them; also if the engineer who built the latter had placed it one mile inside of where it now stands it would have been inaccessible both by sea and land.

i. Guns placed in a land battery should not be less than from 60 to 100 ft. apart.

j. Our frowning stone walls with their guns standing en barbette, or looking through small ports in the casemates, look strong, while both arrangements are serious defects.

k. Latterly the rebels revetted the stone walls of their forts, external as well as internal, with sand bags.

l. Fort Fisher was the key to all the immense system of defences to Wilmington Harbour, and will furnish food for study to our military engineers for years to come; and in many cases the system inaugurated by the rebels will be adopted by us.

m. Never erect a fort without consulting the hydrography of its approaches. In Wilmington River a chain of the strongest works ever erected was lost because Fort Fisher, the key to them all, was placed within reach of ships.

n. The shells of navy guns most effective against land batteries.

o. He recommends that all our works shall be of earthwork, or that those now built should be covered with earth; the guns to be mounted on monitor turrets; iron to any thickness and guns of any measure may be thus used, and so far have an advantage against a floating enemy, in which the use must be limited.

p. The value of land fortifications is, he considers, not in the least diminished by the late results; their importance is greater than ever, but they must be properly built.

Fig. 1980 shows the position of Fort Fisher at entrance to Wilmington River.

Fig. 1981, plan of the defences of Fort Fisher.

Classification of Coast Defences.—The sea defences of our naval arsenals, commercial harbours, and most accessible landing points on our coasts, may be classified as follows:—

1. Existing old castles erected originally in the times of the Tudors and Stuarts, many of them still forming the nuclei of our present works.

2. Coast towers, martello towers, &c., of more modern construction, dating principally from the period of the earlier wars of the French Revolution.

3. Simple earthen batteries firing through embrasures or en barbette, in many cases open or undefended at gorge.

4. Earthen batteries of improved formation, with closed defensible gorge, provided with iron shields to embrasures, and permanent accommodation for gunners, magazines, &c.

5. Double or single tier casemated composite batteries, with granite facings, iron shields, and defensible keeps and other works at rear.

6. Iron-plated sea forts, in many cases isolated, but covered with iron wherever exposed to shot from direct fire of floating armaments.

In this classification we have not included numerous coast forts similar to class No. 5, constructed on the old principles of unprotected embrasures, with walls of brick or similar materials, in some cases faced insufficiently with stone. Such is Fort Victoria and Cliffe End Fort, on the right-hand side of the Solent passage, the batteries at the entrance to Portsmouth Harbour, and numerous other old though costly forts of the same construction, which must be considered to all intents and purposes obsolete, and should be reconstructed sooner or later, in one of the classes we have given above. This applies to defences constructed by Russia, France, America, Spain,

Holland, and other Powers, as well as by our own Government, during the last couple of centuries, when the principles of Vauban and Coehorn were perhaps more considered in theory than the advantages of site, local marine difficulties, &c., which to-day afford room for the display of the peculiar talents in coast defence by our modern officers of engineers.

Class 1.—Previous to Henry VIII's time we had, on many points of our coast, castles in the feudal style, such as at Dover, Scarborough, Bamborough in Northumberland, and many others, erected, however, before the invention of artillery. Many of them were allowed to fall to decay when that important element began to come into operation, and the earliest improved form of coast defence appears in the many castles erected by Henry VIII. in dread of an invasion by the Catholic Powers of Europe after his quarrel with the Pope. They consisted generally of a central keep, with curved casemated batteries at a lower elevation, and were constructed of strong and substantial masonry or brickwork, available for store and barrack purposes to the present day. The castles of Southsea, Hurst, Yarmouth, and those of Falmouth and Dartmouth Harbours, Deal, and Walmer, are of this period.

Fig. 1982 shows Southsea Castle as originally built.

Scale, $12\frac{1}{2}$ " to a mile.

A, Keep. B, B, Batteries. D, D, Ditch.

Fig. 1983 shows Hurst Castle, once the prison of the first Charles. It is now a place of much strength, large casemated granite batteries, same as class No. 5, mounting sixty-one heavy guns, being erected in front and on each flank of the original castle, and showing that the engineers of Henry VIII. had a good eye for a site for defence. Besides these heavy guns, it will probably be eventually equipped with an armament of three turrets on the upper platform, mounting six additional guns, certainly not less than 600-pounders each.

Fig. 1984 shows the modern extensions to the old Hurst Castle.

A, Original work. B, B, Modern extensions. C, C, Defensible wall in rear.

Scale, 300 ft. to an in.

Scale, 48 ft. to an in.

Fig. 1985 shows the old castle of Yarmouth, still mounting half a dozen light guns, and affording accommodation for a few stores and gunners. This is a curious relic of mediæval times, although as a work of defence it is now obsolete and rendered useless by the more modern works in its immediate neighbourhood at Fort Victoria and Cliffe End.

The old works at Dover and Sheerness of this period are quite absorbed by the modern works of defence surrounding them. The still-existing important coast work at Landguard Point, mounting twenty heavy guns, has been a good deal modernized, but dates from the time of

James I. The old defences of the sea entrance to Portsmouth and Plymouth Harbours are principally of the Stuart period.

Fig. 1986 shows a bird's-eye view of the defences of Plymouth, land and sea, anno 1643.

Scale, $\frac{3}{4}$ " to a mile.

Class 2.—In the early part of the revolutionary war the damage inflicted on one of our ships of the line and a frigate by a single-gun tower in Martello Bay, in Corsica, caused rather an exaggerated idea to be formed of its power of defence, and numbers of them were erected on our southern and eastern coasts, as well as on the weakest points of the Channel Islands, on the coast of Ireland, in the vicinity of Dublin, Cork, and Lough Swilly, &c. Rear-Admiral Porter, in 'Von Scheliha,' reports a similar case where a one-gun, 24-pounder tower, cut up and repulsed a 20-gun frigate that he served in.

Sir J. Burgoyne considers towers may be usefully applied in detached positions, and no doubt, if properly covered by an earthen envelope, would still be found of advantage in defending our coasts in minor operations, or in groups of four to six opposing the landing of an enemy during a period of war, on many points of the 300 miles of shore accessible for landing troops of the 800 miles extending from the Humber to Penzance.

Martello towers were nearly all built on the same model, in England of brick, and in Ireland and the Channel Islands of granite. They generally mount a 24-pounder gun on top, are loop-holed more or less, and accommodate a garrison of from six to twelve gunners. In some cases they are surrounded by a ditch with small bridge, and covered by a glacis; in other cases are merely accessible by a ladder, movable and defended by a machicoulis. Few of those towers are now equipped, and they are generally occupied by a few coastguard men.

Figs. 1987 to 1989, from 'Von Wurmb's,' show the plans and section of a martello tower, the stores and ammunition being kept in the basement. The outer walls are generally from 6 to 8 ft. in thickness.

Figs. 1990 to 1992 show one of the series of towers of the same nature approved by the first Napoleon for coast defence purposes. They are generally square instead of round, and accommodate a larger garrison and mount more guns. They were intended for the same purposes as our smaller towers. On many land frontiers where a small garrison has to hold out against numerous assailants unprovided with heavy guns, such as those of New Zealand and the Cape, these towers would be found very useful, and on the frontiers of the latter colony several of them have been erected. They should, however, be carefully furnished in this case with tanks or wells.

Class 3.—*Earthen Batteries undefended at Rear or open at Gorge.*—On many points of the coast elevated from 100 to 300 ft. above high-water mark these batteries will be found economical in construction, and effective. Our experience in the Crimea, which we have already alluded to, where, on the 17th October, 1854, the Allied fleets attacked the outer defences of Sebastopol,

Harbour, and the warm reception our heavy-armed ships met from the guns of the little Wasp and Telegraph cliff batteries, which inflicted more damage on them than all the guns of the granite casemated forts put together, will render even iron-clads cautious how they approach those elevated batteries, capable as they are now of being armed with guns of the heaviest calibre. Batteries of this nature in time of war would be supported and supplied by magazines and depôts situated inland, and easily accessible by tram-roads or otherwise.

Earthen batteries may, at an emergency, be easily thrown up, and by the use of strong timber-framing and earth even mount a second tier of guns. Many of the Confederate batteries during the late American war were of this construction; but the materials they are composed of should be always at hand, and therefore they are inapplicable on rocky cliffs, shingly beaches, and similar sites.

Fig. 1993 shows a cheap earthen battery open at rear for seven guns of any calibre up to 300 lbs., the cost of which with bomb-proof magazines, traverses, &c., will not exceed 800*l.* a gun. It is similar to a very excellent battery lately constructed on Hatherwood Cliff, near the Needles, in the Isle of Wight.

Figs. 1994, 1995, show sections of an earthen battery covering a strong wood framing, forming a casemate below, similar to many erected by the Confederates during the American war.

Figs. 1996, 1997, plan and section of Fort Powell, in Mobile Harbour, a combination of earth-work and timber.

Class 4.—*Earthen Batteries, with Accommodation in Rear for Troops and Stores, &c., with closed Loop-holed Gorge and enfiladed Ditches in Front and on Flanks.*—Mounted with heavy guns, batteries of this nature are a most useful element of defence for our commercial harbours, and the rivers leading to our principal maritime emporiums, &c. They are constructed generally on the most commanding positions, and have ample accommodation, in low flat-roofed buildings, for their garrison

in the rear, and well-protected bomb-proofs for magazines and stores, wells and water-tanks, so as to be enabled to resist a *coup-de-main*, if the enemy should land a force in their neighbourhood. The guns, which may be of the heaviest calibre, fire either en barbette or through earthen embrasures protected with iron shields. The ditch in front and on flanks is often further defended by a loop-holed Carnot-wall and flanking caponnière chambers. Of this class are batteries lately erected to protect the channel of the Humber, the entrance to the Orwell and Stour rivers near Harwich, the new batteries on each flank of Southsea Castle, and various other points on the coast. Moncrieff gun-pits will be equally applicable to batteries of this construction as the last; ample shelter for gunners is provided in the interior of traverses, passages to magazines, &c. These batteries in connection with floating or hidden obstructions would make the approach to our principal maritime towns, situated a few miles inland, nearly impossible; the gunners also enjoying good quarters, not subject to the inconvenience or dangers of casemated batteries.

In the construction of batteries of this description the immensely increased penetrating power of modern artillery on earth-works must be taken into consideration. The penetration of a 600-lb. shot fired from a 13-in. gun at 200 yards is estimated at 50 ft., and a 150-lb. 9-in. shot at the same distance, 30 ft.

Fig. 1998 shows Southsea Castle, with auxiliary earthen batteries and defensible gorge-wall in rear.

Figs. 1999 to 2001 show a 2-gun battery similar to those on the Humber and near Harwich, with Carnot-wall in ditch, soldiers' quarters, and stores in rear. The unit for such batteries may be considered the distance from centre to centre of each gun mounted, or generally from 35 to 40 ft. American engineers consider this distance ought to be enlarged.

Earthen batteries are sometimes armed with mortars which will make, where they are mounted, a different arrangement necessary.

Figs. 2002, 2003, show a unit of a mortar battery containing platforms of from four to six mortars in a group. These may be placed in the most eligible positions for vertical fire, and the remainder of the battery armed with heavy guns.

Class 5.—*Single or Double Tier Casemated Batteries, faced with Granite and provided with Iron Shields to Embrasures.*—When the Defence Commission of 1860 made their report, granite-faced casemated batteries, from the experience the then unarmoured ships had received in the Baltic and the Crimea, were in high favour; it was then a question of granite *versus* oak, not as now granite *versus* iron; and in the representations in the pictorial papers of the day, the granite forts

of Cronstadt and Sebastopol presented a most threatening and formidable appearance. Those of Cronstadt had defied our attacks, because, as military critics say, they were never made; and in the little tussle between the Allied fleets and the Sebastopol batteries it must be confessed that we stood in considerable awe of them, and kept, with one or two exceptions, at a most respectful distance, and when we did approach nearer got the worst of it. The destruction of the Bomarsund defences would naturally be attributed to their unfinished state, as well as to the co-operation of a land attack; therefore the Defence Commission were rather inclined to look with favour on granite walls and embrasures, even when unprovided with iron shields or platings; and we find our most important and expensive works were proposed to be executed in that material, and,

with the (in the course of time) necessary alterations and additions for iron shields to embrasures, have been so constructed. We may instance—the Garrison Point and Isle of Grain defences, near Sheerness; the Thames and Medway forts; the important position of Gillkicker and Hurst Castle in the Spithead and Solent defences of Portsmouth Harbour; many works also in the Plymouth and Milford Haven defences. But more recent experience has shown us, in batteries at the water-level, or only moderately elevated above the same, even when furnished with iron shields to embrasures, that solid stone piers offer but a poor resistance to the heavy guns of modern warfare. Unfortunately, many of our forts were already thus built before the experience of the late American war was acquired; and to plate them with iron now would cost nearly as much as their original construction; and, indeed, in many cases when they are retired from the water's edge would not be necessary. It is, however, probable that for the future granite will enter much less into our coast defences as an element of resistance than it has hitherto done. An inspection of the diagram we give, of a granite-faced iron-embasured coast battery, Figs. 2014, 2015, shows a rather defective construction, for if the intermediate piers be battered down, the abutments of the groined arches necessary for the movement of the guns within will be destroyed, and the whole of the bomb-proof masonry and guns on terre-plein above will become a heap of ruins. The attention of our engineers is now directed to a simpler mode of construction, in which wrought-iron girders and iron-buckled plates covered with concrete and earth will probably supersede brick arches altogether, unless in cases where the end of the arch itself goes through the external walls, and direct fire will not affect its stability. Batteries of this nature are composed of units, the unit being a casemate for one gun; a battery of any number of guns therefore consists of as many units arranged in as many tiers as may seem desirable. The store and magazine accommodation is generally in the basement, where the external walls are solid, and of great thickness, and it will be necessary to provide for at least 200 rounds of shot and shell for each gun, besides all necessary tramways, lifts, &c., for the easy conveyance of the heavy missiles we now use, and the fall of one of which might endanger the safety of the whole battery. These magazines are lighted by oil lamps, with thick plate-glass fronts and reflectors, and fixed through apertures in the external walls. In many cases during the late American war it was found necessary torevet stone-faced batteries with sand-bags.

Figs. 2004 to 2006 are a plan and sections of Fort Sumter, which after a long resistance was finally destroyed by the Federal American fleet. It is not a favourable example of a casemated battery, as the casemates are small and confined, and the thickness of the walls appears insufficient.

Figs. 2007, 2008, show plan and sections of the unit of a single-tier casemated battery. Turret guns or heavy guns on barbette may be mounted on top. In this case the magazines are detached and not in basement.

Figs. 2009 to 2011 are a coast battery, with a small keep in rear, mounting thirteen guns in casemates and eight heavy rifled guns on terre-plein, from Von Wurmbs' 'Lehrbuch der Kriegs Baukunst.'

Figs. 2012, 2013, show two casemates of the old Blockhouse Battery at the entrance to Portsmouth Harbour, and section through same. The limited dimensions of the casemates are a great contrast to those of the present day, although with the old guns this battery was considered a most efficient one.

Figs. 2014, 2015, show an example of one of the most approved single or double tier casemated battery, with magazine and stores beneath, and casemates fitted to accommodate troops, with verandah behind. Before the adoption of iron external plating, these batteries were probably the strongest construction used. Their cost, including the shields, buildings, and wall in rear, would be about 3500*l.* a gun. This construction is applicable to any portion of a curved surface, or to the entire circle.

Many of the batteries of the Russian arsenals, and those of France and the United States, are formed on this principle, which we are beginning reluctantly to consider obsolete. Russia and other countries have already commenced plating their granite batteries with iron. We fear,

however, that total reconstruction will be in many cases found necessary, as it was with our men-of-war a few years ago.

Class 6.—Iron-clad isolated Forts plated on Stone Walls, or independent Iron Constructions.—There are in progress now the stone bases of four marine forts, 200 ft. diameter, at Spithead, and one of an elliptical shape, but nearly of the same mean dimensions, on the Shovel Rock, behind the Plymouth Breakwater. Recent experiments at Shoeburyness would seem to point out that the resisting face or iron construction of these forts should be quite unconnected with, and independent of, the internal arrangements of masonry or brickwork, forming, as it were, an external shell round same. The plating of granite walls with iron plates, connected by heavy bolts and screws, we have always considered to be a mistake, as the elasticity and continuity of material which might permit it on the wooden sides of ships are much wanting either on walls of granite or brick. The Russians are attempting a sort of plating on their Cronstadt forts; but practical men doubt of its ever being effective, and the expense of plating walls with railway iron and such small material in the American war led to no satisfactory results when opposed to heavy guns. The internal arrangements of forts of this nature will differ little from those of the casemated granite forts shown in Figs. 2014, 2015.

Plan. Scale, 80 ft. to an in.

Sir J. F. Burgoyne, in his letters to the Secretary of State with reference to the defence works, dated 20th February, 1867, observes:—"The circumstances under which it is most requisite to apply iron defences on the fullest scale are where batteries are necessarily placed in very exposed and isolated situations, and where the area of the site on which guns can be placed is unavoidably restricted; such as in the sea or in a very few analogous positions on shore, where foundations are costly and where the works are subject to a concentrated fire from a large number of powerful iron-plated men-of-war.

"On the shore where the space is not limited and where guns are more or less dispersed, or in channels where there is no probability of ships being able to engage batteries for a lengthened period, it is only requisite to apply iron in the form of shields for strengthening that part of the work about the embrasures, which in batteries of an earthen or granite construction would otherwise be very weak. In cases where batteries are at a considerable height above the sea, no embrasures are necessary, and iron shields are not required."

General Notes on the Practical Construction of Coast Batteries.—When stone is used in the facing of batteries it should be of the hardest and most compact nature, in as large blocks as possible, and set on its natural bed; even in granites this should be regarded, although they are often erroneously supposed to have none. If intended to be afterwards iron-plated, all the necessary holes for bolts, chases, sinkings, &c., should be previously made. Granite or other stone facing may be backed with brickwork, and the same may be used in all revetments, walls of magazines, &c., not exposed to direct fire.

The greatest care should be taken to ensure ventilation to all floors and other woodwork in earth-covered buildings.

Section on line A B. Scale, 32 ft. to an in.

In throwing up earthen batteries of any size, the engineer should study the geological peculiarities of the site, nature of the formations, &c. Many serious failures in our earth-works have occurred by the neglect of this precaution, especially near the junction of the chalk and tertiary formations, and in the various drift deposits on our southern coasts.

When earth-works are to be thrown up, the proper drainage of the natural surface beneath them should be considered, so as to prevent the accumulation of water in the earth formed as a rampart. This should be a preliminary step, and is too often overlooked, causing constant slips in the slopes formed.

Earth-works should be formed in layers not more than 15 in. in thickness, and well rammed. Occasional thin beds of burnt ballast or shingle should be used, and agricultural drain-pipes so laid as to conduct off all superfluous water as quickly as possible.

Slopes steeper than 45° can hardly be formed without the employment of built sodwork, which experience proves is very liable to decay. Flat slopes may be either covered with flat sods or soiled with fine mould and sown with selected grass seeds, with roots calculated to form a fibrous network.

Conduct all rainfall off your works as rapidly as possible, by means of surface, pipe, or other drainage.

Give your guns plenty of room, and let their platforms or *racer-blocks* be firmly bedded.

If iron plating be used, let its form be simple and with as few bolts as possible, and let all ironwork of embrasures be painted the same tint as the surrounding material, whether grasswork or granite, so as not to present a distinguishing mark at a distance.

Earth-works should be formed as free from shingle or loose stone on the external covering as possible, although in some cases a core of such material may be found convenient to use; one of chalk forms an excellent nucleus for a battery.

The comparative cost of earth, concrete, granite, and iron, in relation to their comparative strength, may be estimated, taking earth as the unit, as 1, 3, 10, 50. Concrete costs 10 times as much as earth, but offers 3 times the resistance; granite 100 times as much, but 10 times the resistance; and iron 40 times as much, but from 2000 to 3000 times the resistance.

Every battery, no matter how small, should be provided with a well or tank for the supply of water.

The position of the flag-staff of a coast battery should be such as to draw off the fire of an enemy to a point where it will do as little harm as possible, as it is often the only target for an enemy to fire at.

Let all artificial lights in magazines, &c., be so placed that no concussion can displace them.

No ventilating shaft or passage should be made which could admit of the direct entrance of any missile into a magazine or passage of same.

And finally, gunners should be made to feel perfect confidence in the stability of the batteries they are appointed to defend, and in the sufficiency of shelter and means of supplying ammunition to the guns, and cover for the wounded.

The following statements will show the financial position of our defence works from the period of the first report of the committee until 1869.

TABLE A.—ORIGINAL ESTIMATE OF THE DEFENCE COMMISSION OF 1860.

Place.	Recommendation of Royal Commission.		Already authorized, but not voted.	Total.
	Purchase of Land.	Erection of Works.		
	£.	£.	£.	£.
Portsmouth	330,000	2,070,000	400,000	2,800,000
Plymouth	755,000	1,915,000	350,000	3,020,000
Pembroke	150,000	450,000	165,000	765,000
Portland	100,000	150,000	380,000	630,000
Thames	50,000	180,000	..	180,000
Medway and Sheerness ..	..	400,000	..	450,000
Chatham	180,000	1,170,000	..	1,350,000
Woolwich	300,000	400,000	..	700,000
Dover	20,000	150,000	165,000	335,000
Cork	..	120,000	..	120,000
Armament of works	..	..	..	500,000
Floating defences	..	..	..	1,000,000
Totals	1,885,000	7,005,000	1,460,000	11,850,000

When the report of the commission was considered by Government, it was determined to raise the money for works and lands by loan, and to provide for the armaments and floating defences in the annual estimates.

Omitting, therefore, these last two sums (1,500,000*l.*), the commissioners' estimate may be divided thus:—

For completion of works authorized previous to 1860	<i>£.</i> 1,610,000
For new works recommended by the commission, including 1,885,000 <i>l.</i> for land	8,740,000
Total	<i>£</i>10,350,000

This amount was, however, in the first instance reduced by Government, by the omission of several important items, namely:—

Portsmouth ..	{Two Spithead forts and two advanced forts, Gosport position}	460,000
Plymouth ..	{Inner line, N.E. defences, omitted, and reduc- tion in Breakwater Fort}	400,000
Pembroke ..	Reduction in number of land-works	150,000
Medway ..	Grain Spit Fort	100,000
Woolwich ..	Total amount	700,000
		8,540,000

Government added, however,

Dover, additional	<i>£.</i> 30,000
Central Arsenal (afterwards omitted)	150,000
	180,000

First reduced estimate *£*8,720,000

In proposing, however, the first vote to Parliament, further works were omitted, namely:—

Amount proposed by Government	£.	8,720,000
Portsmouth ..	Connecting lines	20,000
Plymouth ..	{Part of N.E. defences and the whole of the Saltash}	1,800,000
Chatham ..	W. defences	700,000
Pembroke ..	{Further reduction in number of land-works}	250,000
		2,150,000
And a further reduction for works provided for in)		390,000
A Estimates, 1860-61		2,540,000

Remaining to be provided by loan .. *£*6,180,000

TABLE B.—ESTIMATED EXPENDITURE FOR COMPLETION.

		<i>£.</i>	<i>£.</i>
Portsmouth ..	{Land defences {outer line	550,000	
	{inner line	320,000	
	{Spithead defences	1,387,000	
	{Isle of Wight defences	163,000	
	{Needles defences, including Hurst Castle}	261,000

Electro-magnetic Induction.—An induction coil has an influence by which an electric or galvanic current produces magnetic polarity in certain bodies near or round which it passes.

Magneto-electric Induction is the influence by which a magnet excites electric currents in closed circuits.

The *Induction Coil* of J. Kidder, Fig. 2022, consists in arranging the fine insulated wire which composes the helix or helices, U, O, used upon a magnet S, G, for obtaining an induced current or currents, either wholly or in greater quantity at or near the centre of the length of the magnet, or what is termed its neutral portion, in combination with the arrangement of the inner or primary coil S, and its core of soft iron G. The said helix or helices are made adjustable upon the magnet between the poles of S, D, and the so-called neutral portion thereof, for the purpose of varying the power of the induced current. S, G, D, is securely fixed to the base T. See BORING AND BLASTING, p. 573. TELEGRAPHY.

COMPASS. FR., *Boussole*; GER., *Compass*; ITAL., *Bussola*; SPAN., *Brújula*.

A compass is an instrument consisting essentially of a magnetized needle turning freely on a point, used to determine horizontal directions, in reference to the north and other cardinal points.

An *Azimuth compass* is one constructed like the *Mariner's*, except that the card is accurately divided into 360°, and the instrument is furnished with two sights, and has a motion in azimuth. It is chiefly used to note the actual magnetic azimuth, from which is determined the variation or declination of the magnetic needle.

The *Mariner's compass* is one which has its needle permanently attached to a card so that both move together. The card is divided into thirty-two parts or points, called also rhumbs, and the glass-covered box containing it is suspended in gimbals, in order to preserve its horizontal position.

A *Surveyor's compass* is one having the needle suspended by itself, and with a graduated circle of 360°, on which the needle indicates the angle between a given direction and the magnetic north. It is also furnished with two sights.

Variation compass, one of delicate construction employed in observations on the variations of the needle. See COMPASSES.

COMPASSES. FR., *Compas*; GER., *Zirkel*; ITAL., *Compassi*; SPAN., *Compas*.

A compass is a simple instrument for describing circles, measuring figures, and so on. It consists of two, or rarely more, pointed branches or legs, usually joined at the top by a rivet, on which they move.

Compasses used for drawing purposes admit of many refinements, and vary in construction in many ways. With draughtsmen the first consideration is a perfect joint, of the making of which there are two distinct methods, one adopted pretty generally on the Continent and sometimes in England, called the *long joint*, and the other the *sector joint*. In the long joints, the head extends some distance down the body, as shown in Fig. 2023; consequently, with the closing of the compasses, a larger amount of surface comes continually into action, producing much greater friction and stiffness when the instrument is nearly closed than when it is wide open. This is the fault of the joint; its only merit is that it requires little skill in making, as it admits of fitting up if the work has been commenced improperly. It is universally used for common instruments, for which it answers very well if properly made. The other form of joint in use, technically called the *sector joint*, Fig. 2024, is now made to all compasses with any pretence to good quality of workman-

2022.

ship. In this joint the working surfaces are of circular form, equally distributed around the centre; consequently, the compasses move with equal pressure whether nearly closed or wide open. It is not necessary to screw the centres of sector-jointed compasses tightly, as the surfaces are not required to come in perfect contact—for this reason, that after the sector joint is made, the workman lubricates between the joint with hot beeswax, which aids in producing that peculiar deadness in movement so much esteemed in the sector joint. If the joint be made true the wax will never leave it. The writer has parted sector joints which have had twenty years of constant wear; the wax appeared the same in quantity as when first introduced, although it was blackened; the amount of wear on the plates not having been sufficient to take out the fine file-marks which were left in making the joint. This is a peculiarity of the sector joint which no other joint possesses.

The sector joint, to attain perfect movement, should be tightened and loosened as little as possible, thus allowing it to form its own surface. Care should be taken that no oil gets upon the joint, as it speedily dissolves the wax and spoils the joint.

The method of trying if a joint is perfect is to open the compasses until they are in line, and then to close them again very slowly, noticing if equal pressure is required at all openings; this will test the evenness of the joint. Another important consideration is, that the centre should fit perfectly; to examine this it will be necessary to take the compasses about half open, and close and open them alternately and quickly for as small a distance as possible, as it were to feel the joint. In doing this, if the centre should not fit, a slight jerk will be felt immediately after commencing to open or close them. Improperly-made sector joints are worse to work with than improperly-made long joints.

With regard to compasses with changeable points, there are two ways of fixing the points to the compasses: in one manner by an angular pin which fits into a socket and is secured by a screw, and the other very much better plan of a cylindrical socket opened on one side, so that it forms a spring. In the first plan the screw is always slipping its thread or getting lost. The opening legs of Drawing compasses are occasionally made of tubes; these are termed Tubular compasses. These have inner tubes, or, what is better, solid bars, fitted telescopically, which extend the legs to take higher radii if required. With tubular compasses, the points turn on an axis, so that there are no loose pieces; these kind of compasses are preferred by many mechanical draughtsmen. A smaller kind of compasses, termed bows, have a handle above the head joint. In the common English construction of this instrument the opening joint is placed very near to the centre of the instrument. This is obviously wrong; the opening joint should be placed as near to the top of the instrument as is consistent with allowing just sufficient length to form a handle. The hollows are better placed sloping inwards than outwards. In compasses, Figs. 2025, 2026, of a superior class, the points of which are made to carry needles, Stanley, of Great Turnstile, Holborn, has made improvements which are said to obviate the general shakiness of these points. Instead of splitting the point down in the English fashion, or boring a cylindrical hole up the point, in the Continental fashion, to contain the needle, in the new plan a conical hole is bored from the back of the point, so that when the needle is pressed into the hole it is wedged sufficiently to hold it firm. The back of the needle is secured by a cross-bolt, which holds the needle more firmly than it is held in any other plan in use. Stanley also makes another point, especially for tracings. In this point the needle is pressed forward by a soft spring, so that it merely bites the surface of the paper sufficient to make a circle without entering it in a perceptible degree. This is a very useful point for tracing from old drawings with large centre-holes, or in a general way for a draughtsman with a heavy hand.

Section. Front of Point.

Enlarged Section of Stanley's Spring Point.

New Adjusting Beam Compasses.

Beam Compasses, Fig. 2027.—These are distinct from those described above, in having no joint; the distance between the points being obtained by a pair of heads sliding on a lath or beam. The points are made plain, or for ink and pencil, as in the ordinary drawing compasses. The general method of fine adjustment is by a screw at the end of the beam which is made to carry one of

the heads with its motion. A. Strange has introduced a new adjustment in these beam compasses, now being used in plotting the survey of India. This is shown in Fig. 2027. It consists of a point with a socket joint fitted into the end of the beam compasses. The point, after being properly ground to its socket and fitted with a milled head above, is bent below the socket, so that the point is made an eccentric. In taking a distance off with this beam, after clamping the movable head as nearly as possible to the distance required, the milled head is slightly turned either way, and the point brought exactly to the position with great precision and ease.

Reconnoitring Compass, for the use of military men, travellers, geologists, and so on.—Every traveller, when exploring a new country, should be provided with a portable compass, to find his way when the sun or the stars are not visible. Such an instrument, to be complete, should be capable of being used in the hand, as well as of being placed on a stand, for the purpose of observing horizontal angles. We ought also to be able to place it upon a board M, Figs. 2028, 2029, for the purpose of setting it, by means of notches *d* in the centres of the squares of the plane.

The compass which we give appears to satisfy all these conditions. As usual for this kind of instrument, it is in the form of a watch; it has a small pendulum P for observing vertical angles. The following are the additions which have been made to it:—

1. A small flat piece *bb* has been fixed to one side; the use of this part is to observe horizontal or vertical angles. For these latter angles it offers special advantages when the observer wishes to take inclines which do not reach the eye, as in the case of the profile of a distant mountain.

2. The bottom of the compass has been provided with a female screw C, Fig. 2028, for the purpose of fixing it to a table by means of the screw *d*, or to a stand by means of the movable rest T', Fig. 2030, similar to the one described for Burel's level. They are affixed to the compass in the same way as a key to a watch.

3. A small reflector A, quicksilvered half upon one face, half upon the other, and turning upon a hinge F, Figs. 2028, 2029, is fixed to the ring of the compass. This reflector serves as a limb when the instrument is placed upon a stand, or even when held in the hand. When on a stand, dipping or descending angles are observed on the upper side of the reflector, and ascending angles on the lower side.

When held in the hand, the eye, being situated above the limb to observe descending angles, may at the same time read the degree marked by the needle; but in the case of ascending angles, the eye, being situated below the compass to see the opposite side of the reflector A, cannot see the degrees. To remedy this, Captain Hossard quicksilvered a portion A' of the glass of the compass. By this means we may see the image of the eye in the reflector A', and make it coincide, in the same vertical plane, with the image of the object observed reflected by the reflector A. When the planes perpendicular to A and A' coincide, they form a plane perpendicular to the hinge F, and consequently a new reflecting limb, which is such that, the point observed being situated above the eye, the eye may at the same time be situated above the compass, and thus read the degrees marked by the needle. A small flat piece of mica *g*, adapted to the extremity of the compass-needle, enables the observer, by inclining it a little, to apply friction to the limb, and so arrest its oscillations.

The reflector A, being quicksilvered on both sides like those of Burel's level, the compass may, in a case of need, be transformed into a level. For this purpose it is sufficient to apply a screw to the reflector to regulate its verticality when the instrument is suspended by the cord H H, Figs. 2028, 2029. This cord, passing through in H to the opposite side of the compass, allows it to be suspended for the purpose of taking directions in mines. This compass costs 55 francs.

Field-glass with Support and a Micrometer for determining distances.—Having procured a level and a compass, a third instrument not less useful is requisite: this is the field-glass, not merely for distinguishing distant objects, but for determining distances by the addition of a micrometer at its focus. Those are most portable and clear which reverse the objects; this is a small inconvenience for those who are accustomed to such glasses. A small micrometer, engraved upon gelatine, in which the millimètre is divided into 8 or 10, is sufficient to determine distances with tolerable

accuracy by means of the formula $X = \frac{H}{h} \phi \times 100$, in which X is the distance from the object to the object-glass; H the size of the object; *h* the number of divisions which it intercepts upon the micrometer; ϕ a constant coefficient, determined by experiment when X, H, and *h* are known. It is the focal distance of the object-glass, measured in parts of the micrometer. The formula $X = \frac{H}{h} \phi \times 100$ is engraved upon the cover of the field-glass with the value of ϕ , which varies from 11 to 12.

We find also upon the cover another formula $X = \frac{ac \cdot h'}{h' - h}$ relative to the case in which, H being unknown, two successive observations, *h* and *h'*, are made at a distance *a* from the object. The divisions of the micrometer are marked in fives by a small bar, for ease in reading; Fig. 2031 represents the appearance of this micrometer. There is a horizontal and a vertical one, enabling the observer to draw upon paper divided into squares the portion of the landscape comprised in the field of vision.

In order to make a careful observation with the field-glass, we must be able to fix it. This is easily effected by means of a gimlet fixed to the rim by a hinge movement like that of compass-heads, Fig. 2032.

Burel's Reflecting Level.—The advantages possessed by this instrument are:—

1. The simplicity of its construction and rectification.
2. The length of its line of sight.
3. The readiness with which it may be used, even in the hand without a stand to rest it upon.
4. The smallness of its size.

Description of the Instrument.—The principle upon which this level is constructed is this, namely, that the line A A, Fig. 2033, which joins the centre of the eye and the centre of its reflection, is horizontal when the reflector is vertical.

The instrument consists of a reflector B fixed in a small pendulum C, which naturally retains the vertical position by turning about the horizontal axis D, by means of a single piece of ribbon. A lid E, Fig. 2034, fitted to the tube F, shuts in the instrument and protects it from the wind. An aperture K K in the tube F allows the reflector to be seen; this aperture is closed by turning a second tube G. A stopper H closes the tube F at the bottom.

To use the instrument, withdraw the stopper H, open the aperture K K, and looking into the reflector, bring the image of the eye-ball upon its edge, so as to make it coincide with the object towards which the operator is looking.

When great accuracy is required the instrument must be placed on a stand. The results thus obtained have been equal in point of accuracy to those given by the spirit-level. [A result established from experiments made at Lyons by order of Lieutenant-General Rohault de Fleury, who was the first to conceive the idea of applying the principle of reflection to levels.]

When an approximative value is sufficient, the tube may be held in the hand.

These levels were first constructed with a double suspension; it has since been discovered that one is sufficient. They also bore in the middle of the reflector a horizontal line; this line was found to be embarrassing, especially when the instrument was used in the hand; it necessitated the holding of the image of the eye upon it, which was always a difficult operation; many forgot it, looked only upon this horizontal, and thus obtained an inclined line of sight.

Rectification of the Instrument.—The reflector B, Figs. 2033, 2035, is quicksilvered, half upon one side, half upon the other. It follows from this arrangement that the instrument is reversible, and that, if it is properly set, we ought to obtain the same result by using either face of the reflector. This arrangement renders the rectification of the instrument very easy, and enables us at any moment to verify its adjustment. When its adjustment is not correct, it may be rectified by means of the screw L which presses upon the reflector and changes its inclination.

This mode of rectification supposes the two faces of the reflector parallel.

Measuring and Tracing Inclines.—To render the instrument capable of measuring or tracing inclines, a rod J furnished with a heavy head I is introduced into the hole M in the pendulum C, Fig. 2033. The reflector thus assumes an inclined position, and the trigonometrical tangent of the angle of inclination sought, is proportional to the distance from the centre of gravity of the weighted rod to the reflector.

The division of the tube J is founded upon the following demonstration, due to Goulier.

A heavy rod O P, Fig. 2036, is suspended at the point O. Its centre of gravity is at A. Under the action of weight, this rod is vertically in equilibrium.

Suppose at the point A, at right angles with O P, another rod A B fixed to it in any manner; suppose the centre of gravity of this second rod at the point B, what will be the position of equilibrium of the system?

Let $p p'$ be the weights of the two rods applied at the points A and B; their resultant $p + p'$ passes to the point G of the line A B determined by the relation $\frac{G B}{A G} = \frac{p}{p'}$.

The system, under the action of the force $p + p'$, will turn about the point O, until G has arrived at G' upon the vertical passing through the point O.

Let us now determine the angle ϕ .

We deduce from the relation $\frac{G B + A G}{A G} = \frac{p + p'}{p'}$, or $\frac{A B}{A G} = \frac{p + p'}{p'}$.

Now A G is the trigonometrical tangent of the angle ϕ , therefore $A G = R \tan. \phi$, whence $\tan. \phi = \frac{A B}{R} \times \frac{p'}{p + p'}$.

But $\frac{p'}{R(p + p')}$ is a constant quantity K, therefore $\tan. \phi = A B \times K$; $\tan. \phi$ is, therefore, proportional to A B.

If the rod A B be divided into equal parts, we shall have the measure of $\tan. \phi$.

To effect the division of the rod, the tangent of the angle ϕ must be determined directly, and this value introduced into the equation; from this we may deduce the number of divisions corresponding to this particular value of the angle. We shall then have merely to continue the division upon the rod.

If now we wish to take the angle of a plane with the horizon, the rod must be thrust in to a greater or less degree; this will cause the mirror to incline, and when the eye sees its image coincide with the object looked at upon the line of inclination, the reflector is perpendicular to the incline. The angle of the reflector with the vertical (the angle ϕ) equals, therefore, and serves to measure the angle of the inclined plane with the horizon.

As the reflecting pendulum is inclined during the observation, the tube F should also be held inclined. If the tube be mounted on a stand, the stand should be provided with a movable rest T, of wood, Fig. 2037, fitted to the tube F; or of copper, T', Fig. 2030, fitted to the stopper H.

When we have to measure an incline the tangent of which exceeds the length of the rod J, the solid cylinder I must be drawn out, and the second numbering of the tube J used. The division upon the end of the tube M' may be adapted at pleasure to the pendulum. Care must be taken to screw it on the side of the screw L, and to introduce the tube J into the tube M' on the same side. Ascending inclines are always observed on the face of the reflector corresponding to the screw L, and descending slopes on the opposite face. If, therefore, after having observed an ascending incline, it be required to observe a descending one, M' must be unscrewed, the opposite face of the reflector brought forward, and M' re-screwed on the side of the screw L.

It is obvious that the axis D must be horizontal to enable the ribbon to which the reflector is suspended, and, consequently, the whole system, to turn freely under the action of the rod. It has been found, however, that on holding the instrument in the hand, its weight is sufficient to move the apparatus in a vertical plane. Thus we have the required condition of exactness.

Level reduced to the Reflecting Pendulum and its Axis, Fig. 2035.—The instrument has been reduced to its simplest expression by retaining only the pendulum C, with its reflector B, and its axis. In this condition it is still very convenient to use in the hand, even in taking inclines; but it is more exposed to the wind, and it can be placed upon a stand only by means of a screw-ring fixed on one side of the stand and passing, on the other, through a little cylinder placed for this purpose on the upper portion of the level. This little cylinder is not represented in the Fig. 2035.

Level serving as a Goniometer.—The base of the tube F, Figs. 2033, 2034, may be easily divided at every five degrees, and a corresponding portion of the rest T, Fig. 2037, inlaid with copper, serves as a vernier.

Figs. 2038 to 2040 represent front, back, and side elevations respectively of a mariner's or ship's compass invented by A. Albini; Fig. 2041 is a plan of the same; Fig. 2042 is a plan of the under-side of the compass card, and Figs. 2043, 2044, are sections of the said card; Figs. 2045 to 2047 are front elevations of the mechanism by which the sliding bar hereafter referred to is raised and lowered; Figs. 2048, 2049, are a side elevation and a plan respectively of the said mechanism; Figs. 2500, 2051, are detached parts of the same. The same letters of reference indicate the same parts in each figure.

turns on a central pointed support in the usual manner, as represented in the figures. The construction of the compass card and its metallic printing ring will be readily understood by an examination of Figs. 2042 to 2044, Fig. 2042 representing a plan of the under-side of the compass card and ring, and Figs. 2043, 2044, cross-sections of the same taken at right angles to one another. Underneath the printing ring o^2 of the compass card O is a bar R provided with set screws r, r , which screws r, r , by being adjusted as required under the ring o^2 , prevent the excessive vibration of the said ring and card. d^2 is a drum on the axis of the fusee hereafter described. Over this drum and the pulleys d^4, d^4 , an inking ribbon d^3 passes, which ribbon is kept in a state of tension by the said pulleys d^4, d^4 . One of the axes d^5, d^5 , upon which the pulleys d, d , are mounted is fixed to one of the bars d^6 , and the other of the said axes is fixed in an arm d^7 which is jointed to the other bar, the said arm d^7 being pressed outwards by a spring d^8 , Figs. 2038, 2039. The required tension in the inking ribbon d^3 is thus maintained. The

drum d^2 is hollow, and constitutes a reservoir for the ink, which ink passes through perforations in the periphery of the drum to a strip of cloth with which it is covered. The inking ribbon d^3 is by this means kept properly charged with ink. H^1, H^2 , are drums situated within the inking ribbon d^3 , Fig. 2038, around which drums a slip of paper h^3 is coiled. These drums turn on the axes h^1, h^2 , and are steadied by springs h^3, h^4 . I, is a horizontal cushion situated a little below the printing ring o^2 of the compass card O. On this cushion the strip of paper h^3 is printed. By an examination of Figs. 2038, 2039, the manner in which the strip of paper h^3 passes over the cushion I and between it and the inking ribbon d^3 will be readily seen. J is a sliding bar having guide-slots j^1, j^1 , working on fixed guide-pins j^2, j^2 , Fig. 2039. The bar J has a rising and falling motion communicated to it by means of mechanism actuated by the clock-work combined with the compass. To the top of the sliding bar J a small presser ring o^2 is affixed. The said presser bar j^2 is situated over the edge of the type or printing ring o^2 of the compass card, and at each descent of the said bar J presses down the said ring o^2 upon the inking ribbon d^3 and prints upon the strip of paper h^3 the course followed by the ship. Parallel

with the presser bar j^7 is a rod j^8 , which on each descent of the bar J presses upon the inking ribbon d^3 , and thereby leaves on the paper h^3 a dot indicating the exact direction of the ship's head, the pressure exerted by the said rod j^8 being moderated by a coiled spring j^{10} . The rising and falling motion of the sliding bar J and the feeding forward of the inking ribbon d^3 and strip of paper h^3 are effected at the proper times by mechanism constructed and actuated by clockwork in the following manner:— B is a clock dial for indicating the time, the said dial being fixed to the plate A^2 ; C is the spring or going barrel of the clock; D is the fusee, which is wound up by a handle d^1 on its axis. On the axis of the fusee is the drum d^2 over which the inking ribbon d^3 is passed. By the motion of the said fusee the ribbon d^3 is moved slowly over the drum, and a fresh portion of it is successively brought over a blank portion of the strip of paper h^3 for the next impression of the type or printing ring and rod. Motion is communicated from the fusee D by means of toothed wheels d^3 , E^1 , E^2 , F^1 , F^2 , and G to an axis g^1 , on which are fixed a counter-balance g^2 and snail-shaped cam g^3 . The speed of the axis g^1 is retarded by a fly-wheel S on a shaft s^1 , on which is fixed a pinion s^2 which is driven by a toothed wheel g^{10} . To the axis g^1 a lever g^8 , Fig. 2050, is fixed, the end g^4 of which lever constitutes a detent. To the free end of the said lever g^8 is a segmental bar g^5 , which is furnished with detents g^6 , g^7 . The detents g^4 , g^6 , and g^7 , operate in conjunction with the cam L , as hereafter described. The said cam L is shown separately in Fig. 2051. Above the lever g^8 is another lever K turning on an axis k^1 and pressed down by the spring represented. The said lever K is supported by an arm k^2 and cam g^3 . The lower end of the arm k^2 of the lever K is turned at right angles, and upon this bent part the cam g^3 acts. The lower end of the sliding bar J , by which the descent of the printing ring c^2 upon the strip of paper h^3 is effected, is joined to the free end of the lever K . The sliding bar J is raised, supported, and allowed to descend at the proper times by the operation of the cam g^3 upon the arm k^2 of the lever K , to which the said sliding bar J is jointed combined with the operation of the cam L upon the lever g^8 . The cam L is double-acting, the portions marked l^1 , l^2 , having flat faces,

2040.

Fig. 2051. The said cam L is fixed on an axis l^2 , which carries the seconds' hand of the clock, and gives motion by means of a toothed wheel l^1 to a pinion M, which is connected to a chronometer escapement N, by which the motion of the apparatus is regulated. The toothed wheel l^1 , connected with the said escapement N, carries a movable pin l^3 , which once a minute acts on a

2041.

pin l^3 on the periphery of a wind-up barrel l^0 , so that in case the "going" or spring barrel C is run down, the motion of the works is stopped. The action of the parts for giving the rising and falling motion to the bar J is as follows:—When the parts are in the respective positions represented in Figs. 2038 and 2045, the sliding bar J is supported in its raised position by the arm h^2 resting on the cam g^3 . At every half minute the detent g^4 of the lever g^5 escapes from the part l^2 of the cam L by the rotation of the axis l^2 of the seconds' hand, and the said lever g^5 falls from the position represented in Figs. 2038 and 2045 to that represented in Fig. 2046 by the partial rotation of the axis g^1 , upon which the said lever g^5 is fixed, the cam g^3 partaking of the same motion. On the completion of the minute the detent g^6 of the lever g^5 escapes by the further rotation of the cam L from the part l^1 , and the cam g^3 releases the arm h^2 and allows the lever K and bar J to fall, the said parts assuming the positions represented in Figs. 2047 to 2049. By the descent of

the bar J the printing of the ship's course upon the strip of paper h^3 is effected, the ring o^2 of the compass O being depressed by the presser bar j^7 , and the rod j^8 at the same time being caused to make a dot on the paper. The detent g^6 of the lever g^5 having thus escaped from the cam L and caused the descent of the bar J and the printing of the ship's course, the detent g^7 of the said lever,

2042.

which is of slightly greater length than the detent g^6 , rests on the said cam L for two seconds, in order to defer for that space of time the revolution of the cam g^3 , and thus prevent the undue

vibration of the compass card, which would result from the too sudden rise of the presser bar j^7 from the ring o^2 of the said compass card. On the expiration of the two seconds the rotation of the

cam L permits the escape of the detent g^7 therefrom and allows of the further rotation of the cam g^2 , whereby the said cam is brought round to the position represented in Figs. 2038 to 2040, and 2045, and by acting on the arm k^2 of the lever K raises the bar J and lifts the pressure bar j^7 and rod j^8 .

The lever g^8 having been brought round with the cam g^2 to the position Figs. 2038 and 2045, the said lever g^8 is again ready to be released at the proper times by the cam L and cause by its action the descent of the cam g^3 and the consequent fall of the bar J and the printing of the ship's course as hereinbefore described. In Fig. 2041 the printing of the ship's course and the centre of the ship's course at intervals of a minute upon the strip of paper h^3 is indicated in dotted lines. The strip of paper h^3 is shifted on the raising of the bar J so as to bring a blank part in position for the next impression in the following manner:—On the face of one of the drums H^2 , upon which the strip of paper h^3 is coiled, is a series of pins h^5 , h^5 , one of which pins is acted upon at each ascent of the bar J by the pawl j^3 jointed to the lower end of the said bar J; an intermittent rotatory motion is thereby given to the drum H^2 , the return motion of the said drum being prevented by the pawl j^4 , which turns on one of the guide-pins j^2 of the bar J, Fig. 2038. Attached to the pawl j^3 is an elbow lever j^5 , by means of which the said pawl j^3 can be thrown into or out of gear with the drum H^2 , as may be required. The said pawl j^3 is furnished with a catch j^6 which, when the said pawl is out of gear, as indicated by dotted lines in Fig. 2038, rests on the bearing b^5 in which the axis i^3 turns and thus prevents the descent of the sliding bar J. By means of a milled button T fixed on an axis t connected by toothed wheels to the motion work of the hands of the clock, the said hands may be set as required. The parts of the mechanism of the clock which I have not described are of the ordinary kind. The whole of the compass is suspended on gimbals P P, to allow for the motion of the ship. Instead of causing the descent of the sliding rod J and the printing of the ship's course at intervals of a minute, the clockwork may be so arranged as to cause the descent of the said rod J at other short intervals. In England, this compass is constructed only by Elliott Brothers, London.

Hedley's Mining-Compass, or Dial, Figs. 2052, 2053, invented by the late John Hedley, and manufactured extensively by John Davis of Derby. This dial possesses many advantages over the

2052.

2053.

1. The Dial as an ordinary rigid one.
2. Inclined to suit the declivity of a pit.

3. Arc attached at pleasure, for ascertaining the angle or dip.
4. Screw for moving the vernier.

ordinary dial, inasmuch as it gives an operator all the advantages of the ordinary one, and in addition, by its construction, allows longer sights to be taken in pits of any declivity, by means of

a ring moving on centres. This ring, Fig. 2053, carries the sights, and can be moved to any angle, the centres remaining in all cases horizontal. To the ring is attached, when required for use, a graduated arc, which gives the vertical angle and difference for hypotenuse and base. A vernier is fixed to the horizontal circle for dialling with the fast needle. See GEODESY. HAND-TOOLS. SURVEYING.

This article, placed under what we consider an appropriate term, is designed more for artisans engaged in ordinary building operations, than for civil and military engineers.

Foundations.—The foundation of a building is the horizontal platform, either natural or artificial, prepared for carrying the walls and superstructure. It must not be confounded with *footings*, which are the bases of walls made broader to distribute the weight more equally over the foundation; nor with piers, although it is not always easy to define where a foundation ends and where a pier begins: in general, all those parts of a structure which are sunk in the natural soil, the conditions of which are therefore different from those parts above ground, are foundations.

There are three important points which should be considered in all foundations:—

1st. That the weight to a unit of area imposed upon it should not be more than it and the sub-soil below it can bear.

2nd. That it should be as nearly as possible homogeneous and equally strong throughout.

3rd. That the upper surface should be horizontal: if not in one, then in several planes.

Foundations particularized.

Rock.—It is generally supposed that rock is a dangerous substratum to make a foundation platform from; for it is rarely that rock is found so homogeneous as to provide a large horizontal surface without artificial filling in; and it is difficult to make the filling in as hard as the rock itself, which it should be, that the settlement, if any, may be uniform. Also in many cases of inclined strata there is the danger of one part of the strata slipping over the other from the additional pressure of the building.

Renaud, from experience, recommends that a foundation in rock should never be less than 0m·3 in depth, for security against slipping and detrusion.

Hughes gives an example of a pier of an aqueduct 50 ft. high, which being founded partly on rock and partly on gravel, was split, owing to unequal settlement.

Gravel.—Many consider a sound thick stratum of gravel to be the most secure foundation possible. In such cases it is only necessary to sink a little into the stratum, rather more than into rock, and to take care that the area of foundation is proportional to the weight a square unit the gravel is calculated to bear. When the gravel is not sound, besides the latter precaution, it is advisable to sink deeper and fill in with an artificial foundation of concrete or large stones or hard durable timber.

Sand.—When in thick strata, and not liable to be moved by water or other disturbing cause, sand forms a very good foundation; it is desirable to sink deeper into sand than into gravel, and to fill in with an artificial foundation to counteract any irregular settlement of the sand. When exposed to the action of water or any other moving action, however slight, sand is a dangerous foundation to trust to, on account of its great mobility.

Clay appears to be considered an uncertain and troublesome substratum for a foundation, on account of the irregularity of its strata, and its action on being disturbed; for there is a tide in the land as well as in the sea. In consequence of clay's plasticity and its retention of water, it is liable to yield unequally to the pressure of a building, and to move irregularly when exposed or cut into; consequently, care must be taken both to spread the structure over a large area of foundation and to load the foundation uniformly in the course of the construction. *Dobson* gives examples of the expansion of clay on exposure to air by cutting and also on saturation with water. In the Box-hill Tunnel 6 in. was allowed for the expansion; and in the Metropolitan Railway the expansion of the clay on cutting had to be provided for in the centering and staging. A bed of clay can be sometimes made firmer by piling or by making holes in it and filling them with stones or gravel: the elasticity of clay is sometimes so great that *Renaud* states that piles are often forced up again by the action of driving the neighbouring piles.

It frequently happens, especially in the alluvial banks of rivers, that below the soft ground of the immediate surface lies a hard stratum, and when the thickness of the soft superstratum is not great (30 ft. may be considered a maximum for ordinary cases), a secure foundation may be obtained by carrying piles or piers down to the hard ground below and supporting a horizontal platform on their tops. These may be wooden or iron piles driven till they enter the hard bottom; or piers formed by sinking well-holes through the soft ground and filling them up with masonry, loose stones, or, *Renaud* says, even sand, though this last should only be used when the superstratum is sufficiently firm to resist the lateral pressure of the sand. The tops of these, if piles, may be connected by beams and planks forming a horizontal platform; or if piers, by arches filled in at the spandrels to a horizontal surface. These piles or piers must be considered as columns fixed at the bottom and calculated accordingly, without trusting to the lateral support of the intermediate strata.

Firm Ground overlying Soft Ground.—In some cases of alluvial foundations, a stratum comparatively firm of gravel or clay is found at the surface or near it, the substrata below that being much softer. In such cases, if the weight of the structure is not very great, it is frequently desirable to leave the hard crust unbroken; but then the area of foundation should be enlarged, beyond what would be used for the same stratum, if of considerable thickness; and special care should be taken to distribute the pressure equally. Also in these cases the hard crust should be cut into as little as possible for any purpose; if it is clay there is danger of it yielding by exposure to air and wet; if the substratum is sand there is danger of its being moved by the action caused by drainage or any operations of that kind, consequent on the building.

Soft Ground of Indefinite Thickness.—When the soft superstratum is of indefinite or very great thickness, and not hard enough to float the building upon it, by extending the area of the foundation, it must be supported upon piles or piers, carried sufficiently deep that the friction on their sides will be enough to carry the weight. In the case of piling, they should be closer together than in the former case, and the heads of the piles, besides being connected together with timber framework, should be surrounded with a mass of masonry or concrete, to distribute the weight and add to the resistance. If piers are employed they may be of masonry, sunk in the manner that wells are formed, and which are used as foundations by the natives in India, or they may be hollow cylinders of iron.

When the ground is exceedingly soft, there is considerable danger of the pressure on that part underneath the building causing that part surrounding it to rise above its original level; to counteract this, as far as possible, the piling or piers should be extended beyond the area of the foundation, and the ground in the immediate neighbourhood should be consolidated or weighted with stones or concrete, and as few excavations as possible should be made in the natural soil. It is also necessary in these cases to equalize the pressure all over the area of the foundation, because there is sure to be a settlement, however small, and the smallest irregular settlement will cause a break in the structure. Equalization of the pressure on the foundation will not, however, prevent an absolute settlement, nor a rising in the neighbouring ground, which latter can only be counteracted by piling and counterbalancing the pressure by weighting the surrounding parts.

Concrete.—The nature of concrete that should be used for a foundation depends on the nature of the soil it is to be laid in; the object in all cases being to get as nearly as possible a homogeneous bed under the structure. If the soil is dry, a concrete of sand, gravel, and as much ordinary lime as is necessary to produce a coherence of it altogether is sufficient; as it is little more than a bed of coherent gravel; but then it must be spread over such an area that it might be sloped at an angle of 45° from the outside of the footings of the walls, down to the bottom of the foundation; and of such a thickness that it will not be liable to crack under the pressure. For ordinary buildings probably from 2 to 3 ft. is sufficient. If the soil is wet, or the building is of great weight or special character, the concrete should be made of hydraulic lime and sand and broken stones, in about the same proportions as would be used in rubble masonry; that is to say, the lime should be about $\frac{1}{4}$, the sand about $\frac{2}{3}$, and the broken stones about $\frac{1}{4}$. These, however, must be considered only as average proportions for medium hydraulic lime and ordinary wet soils; the proportion of lime must be varied inversely as its quality is better or worse, or as the circumstances are more or less important. In such cases the concrete, if properly constituted and laid, may be considered as a solid coherent mass, capable of bearing without crushing the weight the square foot mentioned in recognized tables as the crushing resistance of different kinds of concrete, a proper coefficient of safety being used. The bed of concrete must also be thick enough not to break by transverse strain, but so as to settle in one mass if the subsoil yields. These two considerations will determine the area of the bed for the foundation.

With moderate hydraulic limes and common limes there will be an expansion of the mixed concrete, consequent on the slaking; in some cases the lime increases to double its original bulk; this may be almost entirely provided for by allowing time for the lime to be thoroughly slaked before laying the concrete; in some cases, however, the lime, or parts of it at least, will take so long to slake, that the process is completed after the concrete is laid, and it is therefore generally desirable to consider this expansion in preparing the site for the concrete.

As the principal object in laying a bed of concrete is to form a solid cohesive mass when it hardens, it has been sometimes recommended that it should be thrown in from a height to consolidate it; this practice, however, has the disadvantage of separating the fine from the coarse particles: it is better to lay the concrete from barrows or boxes on the level of the site, and to consolidate it afterwards by ramming; in ordinary foundations, to effect this properly and to allow the lime to set, the concrete should be laid in strata of not more than 1 ft. thick each; it is very desirable to bond these strata into each other in the process of laying, as the joint between two days' work is always a weak part in the mass. In large foundations, or with strong hydraulic lime, it is better to make the strata 2 or 3 ft. thick; on that account, for the same reason, the whole of one strata should be laid as quickly as possible.

In large foundations in water, a slight coffer-dam is generally made round the area required; if there is rock underneath, the coffer-dam is made of framework filled in with sheeting; the soft ground is then dredged out from the inside of the coffer-dam, and the space is filled with concrete to the height at which the regular masonry begins, which would be generally at 3 or 4 ft. below the lowest water-line. In this method the concrete is generally lowered into the water within the coffer-dam, in a box with a movable bottom, which is made to open when the box is near the place required, and so allow the concrete to fall gently into its position; of course, a strong hydraulic lime must be used, and therefore the concrete should be laid as quickly as possible in a mass.

Fascines.—In soft marshy ground of great depth, a foundation of fascines is frequently employed in places where suitable brushwood is plentiful, in Holland for instance; and in such places it is highly approved of. Its recommendations appear to be that when carefully made it is elastic, durable, and uniform.

Authorities differ as to the best size of fascine for foundations; Pasley recommends 6 in. diameter Lewis used them 12 in. diameter successfully, as a foundation for a 3-gun martello tower at Hollesley Bay on the coast of Suffolk, built in 1812. Hughes, U.S., says that on the Dutch railway from Amsterdam to Utrecht, they used two kinds, a saucisson of 0^m·4 circumference and a fascine of 0^m·5 circumference. But all agree that they should be compactly made of carefully-selected wood.

When the sward of a site of the town was removed, preparatory to laying the foundation, speaking of the operations in Holland, the ground was found so soft, that a 10-ft. rod was easily thrust down the whole length of the rod with the hand.

Extract from Paper by Hughes, U.S.—Description of the Fascine Foundation of the Embankment of the Amsterdam and Utrecht Railway.—The fascine foundation is to be formed by an under and upper framework of hurdles (*saucissons*) 0^m·4 thick, with a backing of fascines between them. Including the second layer of *saucissons* of the under frame, and the first layer of the upper frame, the mean depth of the backing ought to be 0^m·5. The *saucissons* to be of a uniform texture of straight sticks, strongly connected together by not less than eight twig bindings for every metre in length. Those of the first layer of the under frame to be placed lengthways, in the direction of the road, at 1 metre central interval; those of the second layer at right angles to the first, also at 1 metre central interval. The longitudinal *saucissons* to break joint; the two layers to be tied together at every crossing with strong twig bindings. Upon this under frame, which must be well filled up with sand to the level of its upper surface, are to be laid the first course of fascines; then two transverse layers crossing the first at right angles; and on this a fourth layer, like the first, at right angles across the axis of the way, but having the larger ends of the fascines turned to the other side: they are to be well rammed together. The packing must have a depth in the centre of 0^m·6, and at the side 0^m·4. The upper frame, of the same construction as the lower frame, to be placed over it, so that the upper layer of *saucissons* comes parallel to the axis of the road. Through each crossing, stakes are to be driven, passing through the hurdles of the under frame.

The fascines to be made of sound and clean willow wood of not less than three years' growth, or of oak brushwood of not less than five or six years' growth; the wood to be straight and cut green last season, to be firmly bound with two bindings and well tightened. The length to be 3½ to 4½ metres.

Piling.—There are two modes in which piles may be used to form a foundation:

1st. *When the soil is soft for a considerable depth*; in which case a large area should be covered with piles connected together by framework at the top, and so forming one united body, which would resist settlement chiefly by the friction of the subsoil against the sides of the piles.

2nd. *When there is a stratum of hard ground below the soft*; in which case the piles should be driven into the hard stratum and each pile would act as an independent column bearing a certain proportion of the whole weight, and resisting settlement both by friction and by its own transverse strength.

1st. *Soft ground throughout.*—M. Renaud says the piles should be from 0^m·8 to 1^m·2 central interval, which agrees with the general practice in England; they should be at that interval both ways, that is, the area should be studded with piles 1 yd. apart both ways; in England the size of piles is generally determined by the size of the logs or barks in which pine timber is sold in the market, and which are about 12 in. square on the average; a pile made of one such piece is commonly called a *whole pile*; when one such balk is cut into two piles they are called *half piles*. M. Renaud says the diameter should be $\frac{1}{3}$ of the length, and never less than 0^m·18. Mr. Dobson recommends the area to be enclosed with sheet piling before the main piles are driven, in order to consolidate the ground better; he says soft clay is too compressible to be well consolidated by piling; it is so elastic that sometimes a pile is forced out of the ground by the driving of a neighbouring pile.

When the tops of the piles are connected by timber, Dobson says the first pieces should be those across the breadth of foundation, and the longitudinal pieces running parallel to the length of foundation should be over them: on these latter, planking should be laid to carry the masonry; it distributes the weight better to lay the planking diagonally. When the upper stratum of the ground is very soft, or when the timber framing at the top is fixed at considerable intervals, the upper part of the ground should be taken out and filled in with stones, or concrete or regular masonry, to increase the resistance of the piles and to form a more uniform platform for the superstructure; when of concrete, this top filling-in should be about 3 ft. thick for large buildings not excessively heavy.

2nd. *Hard ground below.*—In this case, as each pile resists partly by its resistance to deflection, the diameter or cross-section should be greater in proportion to the length: when the depth is considerable, say above 25 ft., and the weight of the structure is considerable, two or more piles should be driven close together and well connected together at top; the piles should come immediately under the weight to be borne, and their number should be determined from that weight, and the timber framework at top should be strong and well tied together. It is advantageous in this case to arrange the superstructure of the building so that it may be ultimately carried on piers at intervals, and consequently that piling will only be required underneath those piers. It is evidently of great consequence that the piles should be quite vertical.

Various kinds have been used when the piling was of uniform character in straight lines, and when labour was expensive. Nasmyth's steam pile-driver has been used in England; it is an ingenious adaptation of his steam-hammer; the steam-cylinder rests on the head of the pile, so that the action of raising the ram tends to drive the pile down, as well as the fall of the ram itself. Another and more common mode of applying steam is by making the steam work an endless chain, which passes over a pulley at the top of the driving machine and round an axle at the bottom; the chain is made so that it lays hold of the catch of the ram by a self-acting apparatus. It is released at any height required in a similar manner to that of the crab-engine, and immediately on coming to rest on the pile is caught by the endless chain again.

The upright part of the pile-engine must be truly vertical when the pile is to be vertical, because the ram is guided in its fall by the two uprights; when the pile is to be driven in an inclined position, if the framing of the engine admits of it, the guiding pieces should be inclined accordingly. but if (as is usually the case) the framing does not admit of it, temporary guiding pieces must be laid against the uprights to the slope required, and the ram must work in them.

The statical weight which any given pile will support, without sinking, may be theoretically calculated from knowing the effect upon it of a known ram falling a known height. If the weight of the ram be w , and the weight of the pile p , and the fall of the ram be AB , Fig. 2054, and the distance through which it has driven the pile be BC ; then the velocity of impact is $v = \sqrt{2g AB}$, and the velocity with

which the pile and ram move on together is $v_1 = \frac{w}{w+p} v$.

Then the weights $w + p$ have passed through the space BC with a velocity commencing with v_1 and decreasing to 0; therefore

the accelerative velocity of the motion is $\left(\frac{(2 BC) w}{w+p} v \right)^2$, and as forces are proportional to the velocities, they generate in a unit

of time; then $g : w + p :: \left(\frac{(2 BC) w}{w+p} v \right)^2 : P$ being the pressure which would generate the accelerative velocity, and, consequently, the statical pressure which the pile will bear without moving farther.

This calculation is more applicable to piles which resist by the friction on their sides; it is applicable to those which are driven through very soft ground into a hard substratum, but in this case, in addition to this calculation, a further one should be made, considering the pile as a column fixed at its lower end, and liable to break by deflection.

M. Renaud has given an empirical rule which will serve as a guide. He says, first of all, that piles of a diameter of $\frac{1}{32}$ of their length will carry 0.5 a millimetre square; this must mean resistance to deflection, or crushing the wood. He also says, if a ram of 600 kilogrammes falling from a height of 3.6 drives a pile 0.03 in ten blows; or if the same ram falling from a height of 1.2 drives it 0.01 in thirty blows; then in either case the pile will bear 25,000 kilogrammes permanent statical weight. By which it is apparently supposed that the statical resistance varies directly as the square of the fall and weight of ram, and inversely as the depth driven in by a blow. He does not, however, place much dependence on his formula, for he recommends a practical experiment to be made in each case.

Pasley points out that if a scarp revetment 30 ft. high is built on piles 3 ft. apart each way, each pile will carry about 10 cub. yds. of masonry and about 3 cub. yds. of earth; and taking the former at 160 lbs. and the earth at 100 lbs. the cubic foot, the total weight on one pile will be 51,300 lbs.

He also says that at Neuilly Bridge, the arches of which are 128 ft. span, the weight of masonry on each pier is 15,417,648 lbs., which is borne by 135 piles. Therefore the weight on each pile is 114,200 lbs. They are of oak, 12½ in. diameter and 13 ft. long.

Also, that Perronet considered that oak piles 9 in. diameter should not be loaded with more than 50,000 lbs.; and if 12 in. diameter, with 100,000 lbs.

Also, at the Bridge of Tours, one pier which gave way was on sixty-five piles of oak 8 ft. long, 9¾ diameter, and carrying each 166,212 lbs., the toe of the pile being in firm soil.

The tops or heads of wooden piles are generally protected from the action of the ram by an iron hoop, the head being cut round for the purpose. The foot or toe of the pile is generally shod with an iron-pointed shoe to save the wood. Cast-iron shoes are recommended in preference to wrought iron by some engineers, because it is more difficult to make the wrought iron to fit the toe of the pile exactly, which it should do to save the wood fully. The fastenings of the cast-iron shoe should be of wrought iron.

Wrought-iron piles have been generally used in the form of hollow tubes, and the mode in which they have been driven in England has been by attaching a broad-bladed screw at the end, and weighting the pile when vertical, and turning it by an apparatus at top, and thus screwing it into the ground. This method is only applicable in sand or soft soil. The chief difficulty appears to be to keep the pile vertical. In the 'Minutes of Proceedings of the Institution of Civil Engineers' for 1848, is a description of Mitchell's wrought-iron screw-piles, as used at the Southend Pier.

Hollow Cylinders.—As before mentioned, in soft soil of indefinite thickness, or sometimes when it is desired to reach a hard substratum, the superstructure of the building may be supported on piers at intervals, the foundation of which consists of hollow cylinders of masonry or iron, extending to the depth required, and sustained chiefly by the friction on their sides. The mode of sinking these cylinders is by excavating the soil from the inside, and allowing them to sink by their own weight, in the manner in which the *steining* of masonry wells are formed. The practice appears to have been long in use in India, where it is the custom to sink many of these masonry wells over the area of the foundation required, and connect them at the top by arches or flat stones. Owing to the use of iron, the English engineers have been able to enlarge upon this method, and it has become a common method of obtaining foundations for piers of bridges and such structures

2054.

in water. When they are applicable, they are economical and expeditious, and they can be carried to great depths. They are generally made of cast iron, but the largest cylinders are of wrought iron. They are generally made of from 5 to 10 ft. diameter, and in lengths of from 6 to 10 ft.: probably 3 ft. diameter is the smallest size that could be used, and sometimes they are of much larger diameter. The soil inside is excavated by hand labour; therefore in passing through watery soil it is necessary to keep the water out, which is done by forcing into it a pressure of air sufficient for the purpose. There must in such cases be an arrangement of air-tight partitions across the interior of the cylinders with trap-doors in them for the passage of men and materials, for the men are working, like in a diving-bell, under a heavy pressure of air. M. Renaud mentions a cylinder foundation at Bordeaux, on the Gironde, a gravelly bottom movable by floods; the cylinders were 3m·6 diameter. There were 13m·35 of water, and 7m·5 of foundation below that, making a total pressure of 20m·85. The thickness of the cast iron was 0m·04. The joints were planed, and had a ring of india-rubber between them, laid in a groove in the joint. In this case the cylinders were forced down by hydraulic pressure. He also mentions a foundation in the Rhine at Strasburg, consisting of a cylinder of wrought iron, 7 mètres diameter and 0m·008 thickness of metal, the depth of water being 11 mètres and total depth of cylinder 17 mètres. It was filled with concrete.

The centre pier of Saltash Bridge, near Plymouth, rests on a wrought-iron cylinder, 37 ft. diameter and 70 ft. deep from the surface of the water. The cylinder rests on trap rock, and is filled with granite masonry.

It is the general practice to fill the interior of the cylinder with cement or masonry, so that when the iron is destroyed by rust the masonry column will resist by its own strength.

Foundations in Water.—The difficulties in making foundations under water, which are added to the ordinary difficulties on land, are, 1st. The presence of water, impeding all operations; 2nd. The stratum of mud or gravel generally found on all beds of streams; 3rd. The danger of the foundation being undermined by the current. There are five different methods used for making foundations in water, so as to meet these difficulties.

1st. By piling or cylinders.

2nd. By throwing in loose stones to form an artificial bank up to the surface of the water.

3rd. By using a diving apparatus, and building regular masonry under the water.

4th. By sinking a box or caisson of the size of the foundation required, and building inside it.

5th. By enclosing the area of the foundation in a coffer-dam, and pumping the water out of it.

Before the introduction of iron cylinders and of the use of concrete so extensively, the ordinary method of obtaining a foundation for the piers of a bridge was by piling under the area of the pier, and cutting off the piles as low as the water admitted, and planking over the tops of them to form the platform. To prevent the current, increased by the obstruction of the piers, from carrying away the soil about the piles, a mass of loose stones was generally laid round the upper part of the piling; but this was not always efficacious in strong streams with soft bottoms. In such cases M. Renaud recommends that the area of the pier should be enclosed with sheet piling and filled in with concrete. He mentions an example of a difficult case of foundations in a stream with a bed of moving gravel, at Moulins, on the Allier. Three bridges had been carried away by the undermining of the foundations. A flat bed of masonry, 1m·65 thick, and 1 metre below low water, was laid on the gravel from bank to bank for a length on the stream of 34 mètres, and protected above and below stream with a wall. Several of the bridges over the Thames at London have given way in consequence of the undermining of their pile foundations by the increased current caused by the improvements in the river. Therefore piling is not used now generally, except for long sea-walls and in special cases.

Loose Stones.—By this method masses of loose stone, just as taken from the quarry, are thrown into the water from a stage built on piles over the area of the foundation required, and are left to find their own position of equilibrium. It is therefore a method chiefly applicable to breakwaters, moles, and such extensive sea-works. The principal point for consideration is the size of the stones to be used in the different parts of the work. As the action of waves is greatest near the surface, and, according to experiments made in the Gulf of Lyons, does not extend below 24 to 30 ft. even during hurricanes, the smallest stones should be placed at the bottom and the largest at the top. In forming the foundations for the walls of the Basin Napoleon at Marseilles, the French engineers laid down precise rules for these sizes. The stone was a limestone, and they divided all that came from the quarry into the following four classes:—

1st. Rubble, in pieces weighing from	5 to 100 kilogrammes each.		
2nd. Blocks	" "	100 to 1300	" "
3rd. Blocks	" "	1300 to 3900	" "
4th. Blocks	" "	3900	" upwards.

And the following proportions of each class were used:—

1st.	..	..	..	..	..	..	..	..	..	3
2nd.	..	..	..	..	..	..	..	..	..	3
3rd.	..	..	..	..	..	..	..	..	..	3
4th.	..	..	..	..	..	..	..	..	..	3

Dobson quotes from Poirer's account of a mole constructed at Algiers in 1841, of loose stones, of which the minimum size was from 18 to 27 cub. ft., and the general size under 100 cub. ft. It was found that up to a level of from 13 to 16 ft. below low water the stones preserved a slope of 1 to 1, or 1 height to 1½ base, and above that level they preserved a general slope of 1 to 6 and 1 to 10, becoming flatter nearer the surface; but that nearer the surface the stones never rested long in one position, but were altered by every storm.

In building a superstructure of regular masonry on the top of a foundation of loose stones, it is

desirable that the junction of the regular masonry with the loose stones should be well covered on the exposed side to allow for the subsequent movement of the stones.

The breakwaters of the harbours of refuge at Portland and Holyhead are excellent, and remarkable examples of foundations of loose stones in water.

Regular Masonry.—In places where squared masonry is not expensive, or where, from circumstances, it is necessary to have a vertical face to the foundations and walls, the foundation is sometimes built up from the bottom in regular masonry, with the help of a diving-bell or other diving apparatus. It is advantageous, when practicable, that sea-walls should have vertical faces (or nearly vertical) to a depth of 20 or 30 ft. below low water, because the waves will not break generally in that depth, and the wall would in that case have to resist only the oscillating action of the waves, and not the progressive action. With the assistance of a diving apparatus, the process of construction is carried on in much the same manner as on dry land. The bottom is levelled, and any superficial strata removed, and the stones are lowered and placed singly; of course a strong hydraulic lime must be used for the mortar.

Caissons.—In this method a large case or box (called a *caisson* in France, which name, from the more frequent use in that country of this method, has also been adopted in England), is floated over the area of the foundation, and sunk by building the foundation inside it; as it sinks, the sides of the caisson are also carried up sufficiently high to keep out the water, and thus the great box containing the masonry gradually sinks to the bottom; the bottom must be levelled and prepared for it beforehand, with the help of a diving apparatus. The caisson has been generally made of wood, but wrought iron has been used. Renaud calls it a great flat-bottomed boat, and says the method is applicable to deep water. Both he and Dobson agree that the great difficulty is in obtaining a hard level surface for the bottom of the caisson to rest upon. Any soft strata should be dredged away; and if the surface is irregular, a bed of hydraulic concrete should be laid over it; if the natural bed is too soft to carry the caisson, piles must driven over the area, and a platform of concrete or planks formed on the top of them for the caisson to rest on.

Coffer-dams.—When circumstances require that a perpendicular wall should be built in not very deep water—say 20 ft.—and when there is good holding ground for piles, and the area of the foundation is not very large, then it is a very efficacious method of obtaining a foundation, to enclose the area with a temporary water-tight wall, and pump out the water from the interior, and proceed to form the foundation, as if it was on dry land. This temporary water-tight wall is commonly called a *coffer-dam*, and is generally made by driving two rows of piling, about 4 ft. apart, the piles in each row touching each other, and the space between being filled up with clay. In constructing the coffer-dam, a row of what are called *guide-piles* are driven along the line of the coffer-dam; they are generally made of *whole timbers*, and are at, about, 10 ft. intervals; on the inner (or coffer-dam) side of these, two longitudinal timbers are fixed, called *wale-pieces*, one as low down as the water will permit, and the other near the top, thus connecting the guide-piles together: inside of and close against the wale-pieces are driven what are called *sheet-piles*, about 3 in. thick and of the breadth of whole timbers, driven as close together as possible. At about 4 ft. distance, another row of guide-piles, wales, and sheet-piles is formed, the sheet-piles being on the inner side, so that the two rows of sheet-piles form a long narrow deep trough; from this trough the natural mud or sand must be excavated by dredging down to some impervious stratum, and must then be filled up to above the highest water-line with an impervious clay, well worked and kneaded into its place, which working is generally done by men's feet: the clay so worked is commonly called *puddle*. This is a general description of a good-sized coffer-dam, but the dimensions of its part must vary with the size and circumstances of the whole; and it may be made sometimes without piling, and sometimes the rows of piles may require additional piles, and braces, and struts, to resist the pressure of the water. For when the water within the area of the foundation is removed, the piles of the coffer-dam will be in the condition of beams fixed at the lower end, and subject to a transverse strain arising from the pressure of the water acting at its centre of pressure. The principal points to be considered in using coffer-dams are:—

In soft ground there is danger that before there is any weight put on the area of foundation, it may be forced up by the pressure round the outside of the coffer-dam.

It is very necessary that the piles should have good hold into a sound substratum. There is always great danger of leakage between the bottom of the puddle wall and the natural bed of the water: leakage through the puddle is also to be guarded against; sometimes gravel is mixed with the puddle to lessen its tendency to crack, and so leak. Springs of water arising from the ground inside the foundation area should be provided for by draining to a suitable spot and pumping. It is probable that after the water inside has been removed, a pump will have to be kept constantly at work to keep down leakage and springs. The clay for the puddle wall should be cut small and well rammed or *punned*, as it is called, in layers.

Coffer-dams have been much used in England for foundation work in water, because it enables the bottom to be well examined and carefully prepared for the superstructure. It is an expensive and laborious method, because a part of the piling has to be driven from barges, and because of the puddling.

Sheet-piles must be shod and capped similarly to other piles; their toes are generally cut with a bevel or incline, forming a point, which in driving is placed next the last driven pile, so that the pressure against the bevelled part in driving forces the toe close to the last pile.

Sometimes coffer-dams are only used to form *shores* or revetments to the sides of the area of foundations, and the water is not removed; then the soft strata required to be removed is dredged out, generally by hand dredging; and the foundation is formed by putting in hydraulic concrete in mass between the rows of piling of the coffer-dam.

Walls.—A wall of a house has two duties to perform: *First*, to support the floors and roof; *second*, to screen the interior from the weather. These two duties should be always clearly distinguished in considering the construction of every wall. For the first duty, it will generally be

sufficient that the wall should consist of piers or columns at intervals, extending in an unbroken perpendicular line from roof to foundation. For the second duty, the spaces between these piers may be filled in a slighter manner, and even with different material, because the utmost pressure this part of the wall has to carry is that of its own weight, and part of that may be frequently thrown upon the piers. In ordinary dwellings these two parts are generally united into one common thickness of wall, in which apertures are left for the doors and windows; but it is not less necessary to keep them distinct in the mind, and to ensure that the solid blocks between the apertures, which are the real piers carrying the whole weight of the structure, extend in an unbroken line from roof to foundation, and that the spaces above and below the apertures have as little weight to carry as practicable.

Squared Masonry.—Stone walls are built sometimes of regularly *squared masonry* laid in uniform horizontal courses; sometimes of masonry only roughly squared and laid in courses, horizontal, but not regular, and which is technically called *Random rubble*; sometimes of rough masonry without any courses, but roughly shaped to fit into each other, and which is technically called *Uncoursed rubble*; and sometimes of rubble faced with squared masonry, and which is technically called *Ashlar*. The choice of either of these modes of building must depend on the material available, and the object of the work. For walls of dwellings the first method is the strongest and most certain. With such masonry the mortar or cement should be of a fine description, and only sufficient of it used to make a layer between one stone and another, as the main strength of the wall depends on the bonding and mutual pressures of the stones, and the chief object of the mortar is to ensure the pressures being distributed over the surface.

The danger to be apprehended in stone walls of square blocks is that the blocks will not press evenly on the beds of their courses, and so cause fracture of a stone; therefore stones should not be too long, compared with their breadth. Of whatever the quality of stone, the wall should consist of as much stone and as little mortar as possible.

The courses of such masonry should be horizontal and of equal or nearly equal heights: the horizontal joints in a wall may extend through it, as the pressures are generally vertical, but the vertical joints should be broken both transversely and longitudinally, otherwise the wall approximates more or less to the condition of an assemblage of thin columns. Subject to this condition, it is immaterial, as far as construction is concerned, where the vertical joints occur. *Bonding* is the technical name for breaking joint so as to connect the parts of the wall into one mass as much as possible, and where it occurs regularly the stones are called *headers* and *stretchers*; occasionally a *through bond stone* should occur extending through or nearly through the wall. Renaud recommends that the length of stones in squared masonry should not be more than four or five times the height: and Hosking recommends that the *through bond stones* should not be very long, but extend only about $\frac{2}{3}$ through the wall, laid alternately from each face. Tredgold recommends that even through bond stones should not be more than three times their thickness in length. As a general rule, the stones should be cut with the natural quarry-bed horizontal.

Rubble masonry, if coursed, is subject to the same general conditions as squared masonry as respects bond and joints. More mortar is necessary, on account of the greater irregularity of the surfaces; for the stone is only roughly dressed with the hammer and chisel, and the stones being of irregular sizes, the horizontal joints are broken; therefore the bonding is not so regular nor so good, and more through bond stones are required. This description of walling is, therefore, more suited for thicker walls than the squared masonry; it is very effective when the stone is of a highly-stratified character and capable of being roughly squared without much difficulty. It was much used by the Gothic builders, who had a difficulty in obtaining large blocks of squared stone. Squared masonry is the exception in Gothic buildings, and is used for columns, groins, and such like principal parts, the main body of the walls and arches being filled in with rubble in random courses.

Uncoursed Rubble Masonry is the term applied to masonry of unsquared stones, roughly dressed to fit into each other, and therefore without regular horizontal or vertical joints. It requires higher skill to build such a wall well, than one of horizontal courses, to fit the stones properly into each other, and so make the wall as much as possible one mass of tightly-wedged stones; therefore, it shows a skilful builder to build a dry rubble wall without mortar; but uncoursed rubble requires more mortar than coursed and of a better quality, for as there is a greater liability in the wall to slip over its joints from the vertical pressures, a greater part of its strength depends on the resistance of the mortar to shearing. It is a method most suitable with unstratified stones having irregular planes of cleavage, and it should be the object in fitting the stones together to make use of those natural planes of cleavage.

This method was first used in what is called cyclopean or polygonal walling, which, in the Mediterranean, was of large blocks dressed to the form of the natural cleavage, sometimes with care, and so fitting closely without mortar, and forming a very strong wall, though expensive in labour. Many of the old Venetian walls in the Mediterranean and also Gothic walls in many places are built of small stones in this manner. The stones should be of uniform size, with bond stones to tie the two faces of the wall together. But the most usual and efficacious mode of bonding a wall of this masonry is by horizontal bands of a few courses of squared masonry or of brickwork extending through the thickness of the wall and all round the building. Such a method was commonly employed by the Romans; walls of rubble-work, sometimes very rough, sometimes no better than coarse concrete, and alternated with bands of the thin Roman brick, constitute a general type of Roman masonry. M. Renaud says the intervals of the courses of bricks were from 1 mètre to 1^m.4.

But the most advantageous employment of this description of masonry is in revetments and such like walls of fortifications. Such walls are generally of considerable thickness, and have generally only one fair face—two favourable circumstances for its use. If well built with stones of nearly equal size and with good mortar well filled in, it offers a better resistance to artillery fire than

squared masonry, unless of very superior description. It is necessary in such cases to put a facing to the wall of rather larger and more regular stones, and to make the exterior face perpendicular, in order to avoid the growth of vegetation on it. Renaud says truly that in all masonry of small pieces the bond is not so important as the mortar and the care of execution.

Brickwork.—If the stones of a wall of squared masonry were obliged to be all of one size, then, in order to ensure the effective bonding in the horizontal courses, the length of the stones should be double the width; then the stones in one horizontal course would be laid lengthways and in the next course crossways, or, as it is technically called, *stretchers and headers*. See BOND.

Mortar.—The mortar and the workmanship are of more consequence in brickwork than the bricks themselves. If the pressures on a wall were always exactly vertical, then all that is required in the building would be to distribute those pressures over the parts intended to carry them; but there is almost always a liability of inclined pressures on all walls, and a certain inclined pressure on many: hence the mortar is subject to a shearing strain, and much of the efficiency of the wall depends on its strength and adhesion to the bricks. This is particularly the case in walls of fortifications exposed to artillery fire. It is invariably found in cases of breaching brick walls by artillery that the brickwork is shaken for considerable distances beyond the actual rupture, and that the line of shake almost always follows the joints. The line of pressure in this case being nearly horizontal, the only resistance to motion besides the weight of the portion of the wall is the resistance to shearing of one or more joints of brickwork. Hence it is especially important in walls of brickwork and squared masonry so exposed to arrange them in large masses.

The proper thickness of the joint of mortar in brickwork must depend somewhat on the nature of the lime used. If the mortar is equal in strength to the bricks, the joints may be as large as the bricks, as was the case in the old Roman brickwork, the joints of which were from 0^m·02 to 0^m·03. This was partly on account of the thinness of the Roman brick compared with its area. When the mortar is inferior in strength to the bricks, as is generally the case, the less there is of it the better. Hosking recommends that with bricks 2½ in. high no four courses should reach 11½ in., which allows less than $\frac{1}{10}$ in. for a joint. He also points out that thick joints of mortar (unless of superior description) are more liable to injury by wet and frost, and to cause a greater amount of settlement in the wall. The minimum size for a joint is simply that no two bricks should touch each other.

The necessity of using clean and moist bricks will be pointed out in our article on Limes and Mortars, and also the advantage of using stiff mortar, as compared with the more common practice of *Grouting*, which is the term used for a very liquid mortar poured over the wall at every one or two courses, with the object of filling up the joints thoroughly. Besides the evils of drowning the lime, and saturating the brickwork, and tempting the bricklayer to use wet mortar and dry bricks, it is evident from the foregoing considerations that a wall so built would not have as much resistance to shearing in its joints as one well filled up with stiff mortar.

Secondary Parts.—By the *secondary parts of walls* are meant cornices, string courses, window-sills, chimneys, and so on.

These are frequently made of stone, although all the remainder of the building may be of brick. The object of a cornice or coping, as far as construction is concerned, is to prevent wet from entering in the top of the wall. It should therefore project over the exposed face of the wall, and be sloped on the top, and hollowed out on the under-side, to prevent the water from running on to the wall; and it should be itself impervious to water. Stones, when used for such purposes, are generally connected together by metal *cramps* or stone *dowels*. A cornice or coping of brickwork should be made of bricks, specially moulded and burnt for the purpose, and set in hydraulic lime. The formation of a cornice by projecting courses (or corbelling) is subject to the same considerations as in footings; the pressures are exerted on the projections in a similar manner, but in the reverse direction. String courses are now seldom used, except for purely ornamental purposes, and for these it is only necessary to bed and bond the stones or bricks sufficiently into the wall to give them stable support. For constructive purposes, string courses are bonding courses in the wall itself, and should therefore go through the wall.

Window-sills are more frequently made of stone than any other of these parts, on account of the transverse strain they are subject to: in order to preserve the horizontal line, the sill is generally made in one piece, resting on the piers of the wall at each side, and not on the filling-in part between; otherwise there would be danger of fracture, owing to the unequal settlement of the piers and the intervening part. A window-sill is the coping of that part of the wall it covers, and should therefore be shaped similarly to a coping or cornice.

If there is no danger of irregular settlement the sill need not be made in one piece.

To provide a place for the fire and its flue in each room in climates where they are necessary, part of the wall is made thicker from the foundation; consequently, it is desirable to arrange the fire-places in the successive stories so as to come over each other. The space required for a grate for an ordinary room varies from 3 to 5 ft. wide, and about 1½ ft. deep, and 3 ft. high, according to the size of room and grate; the wall at the back of the grate should be at least one brick thick. The sizes of the piers or *jamb*s, as they are called, depend on the number of flues to be inserted in them; for the flue of each fire, after being *gathered* into a throat immediately above the fire, is diverted on one side to allow space for the fire-place of the next story above it. A flue, if built in brickwork, cannot easily be less than 9 by 4½ in., and as there should be at least half a brick between each flue, and one brick on the outside of the outermost flue, the size of the jamb for a given number of flues is thereby determined. It is difficult to give precise rules for the arrangement of fire-places, because so much depends on the grate. The problem is to provide as easy an exit as possible for the products of combustion, and yet not more than they require. This is met theoretically by inclining the sides of the fire-place gradually to an opening close above the fire and calculated to be just large enough for the products of combustion; this part of the problem is generally provided for in the grate; it is like the sluice-gate of a water-mill, excepting that air,

being so much more delicate a substance than water, requires much more careful provision for its flow. After passing through the grate, it should be allowed to flow into the open air as regularly as possible: there is, therefore, an advantage in having very smooth sides to the flues; this is generally effected by plastering the inside of them with a special plaster to resist heat; it is common hair mortar mixed with cow-dung. A much better mode has been lately employed, by inserting glazed earthenware pipes in the wall, which gets rid of the objectionable corners of the brick flue, and of its unnecessarily large size. The large size of the flue both decreases the velocity of the stream of hot air, and allows cold air to descend and check the flow of it; the flue should decrease in size slightly as it ascends.

Carrying all the flues up together in one stack, or *chimney-breast*, as it is called, is both economical, and tends to preserve an equal temperature in them; for the latter reason, which is a most important one, brickwork is better for chimneys than stonework. But for the last few feet above the roof, each flue should be in a separate stack of its own, and as small as possible, for everything that obstructs the wind tends to produce a counter-current in the flue. No two fires should lead into one flue, unless they are always alight together, or a down-draught will occur probably in the one not lighted. No woodwork should be built into the chimney-breast or any part of the chimney for any purpose whatever.

Thickness of Walls.—The thickness of the walls of ordinary buildings, Fig. 2055, is more a practical than a theoretical question. As M. Renaud points out, the theoretical thickness to meet the vertical pressure only would be very small in any case. The rupture of the wall by separation of the joints would almost always take place before the crushing of the stone itself, and that force should, therefore, be provided for, or at least the two must be taken into consideration together. With squared stones the crushing would be the most probable, and in this case generally the safe weight is taken at $\frac{1}{10}$ the breaking weight. In rubble-work the tendency is to rupture of the joints, owing to the irregular pressures; the proportion of the safe weight to the breaking weight should therefore be less.

M. Renaud quotes the following theoretical rules from Rondelet for the thickness of walls of ordinary buildings:—

For Isolated Walls,

$$b = 12 \sqrt{\frac{h}{s}} \quad \left. \begin{array}{l} \text{where } b = \text{breadth} \\ h = \text{height} \\ s = \text{weight of cub. mètre of masonry.} \end{array} \right\} \text{ of wall in mètres;}$$

This rule is evidently based on the assumption that the force acting on the wall is similar to that of the wind, in which case the equation for overturning the wall would be $s \cdot h \cdot b \cdot \frac{b}{n} = p \cdot h \cdot \frac{h}{m}$, where p = force per unit of area of wind, and n and m are coefficients depending on the circumstances in each case.

For Walls of Houses, Fig. 2056,

$$\frac{l \cdot h}{\sqrt{l^2 + h^2}} \quad \left. \begin{array}{l} \text{where } l = \text{span or distance between opposite sides in mètres.} \end{array} \right\}$$

Which appears to be based on the assumption that the pressure on the walls varies as the span of the roof. The height h in this case is to be taken between the floors or points of support supposing them to be of strong construction.

He states the following to be the usual thicknesses of walls in Paris; they are of squared masonry of limestone:—

	Exterior Walls. Mètres.	Interior Walls. Mètres.
Houses 18 mètres high	0·5	0·4
Walls tolerably close	0·45	0·4
Floors 4 to 5 mètres apart	0·6 to 0·8	0·43 to 0·5
" at top		
Large houses		

The interior faces of the walls are always made perpendicular, and the *batter* or increase is always on the outside.

In London the minimum dimensions for walls of houses in streets is fixed by Act of Parliament, in order to provide for the strength and security from fire of rows of houses with common party walls. But these dimensions must not be taken as guides for military buildings of a permanent character; in such buildings it is not safe with the ordinary description of brickwork to make any wall less than $1\frac{1}{2}$ brick thick; and, in accordance with the principle of the Act, an additional half brick should be added to the thickness for every two stories of height. This addition is generally made in England on the inner face of the wall, for the convenience of resting the beams of the floors on them. This is perhaps a better constructive arrangement than the French one, but it must depend upon the circumstances of each case which is adopted.

Footings.—In the process of constructing a wall, the mason or bricklayer first lays the *footings* on the foundation platform. The footing is an enlarged portion of the wall for the purpose of distributing the weight over the foundation: it is properly a portion of the wall and not of the

foundation, although it is not always easy to draw the line between them. When the pressures pass down through the centre of the wall, the footings may project equally on each side; when otherwise, the footings should be so arranged that the line of pressure shall pass nearly through the centre of them into the foundation. The size of footings and the mode of forming the increase to the thickness of the wall must depend on the circumstances and the material. For ordinary buildings Tredgold recommends that the extreme breadth of the footing, when the subsoil is clay or sand, be double the thickness of the wall; if on gravel or chalk subsoil, that its breadth to be that of the wall as 3 to 2.

Supposing the whole pressure per lineal foot on the wall to be equally distributed over the breadth of footing ab , Fig. 2057, then the reaction of the subsoil on the part bc will be equivalent to that proportion of the whole pressure, acting upwards and tending to break the projecting part bc about the section cd , which section must be strong enough to resist that transverse strain; in brickwork it is usual to make the projection of a footing for light buildings $\frac{1}{4}$ of a brick in every course, and for heavy buildings $\frac{1}{2}$ of a brick in every two courses. In stonework the proportional projection for a given height of course may be greater, according to the relative transverse length of the stone. The footings should always be made of large stones or of picked bricks, laid in very good mortar, and well bonded, with the object of distributing the pressure as uniformly as possible over the foundations. The foundation platform should, if possible, be in one horizontal plane, and the footings should be equal in height throughout the main walls of a building, in order to avoid, as much as possible, irregularity of settlement from unequal heights of wall.

The *Damp Course*, as it is commonly called, a course of some impervious material to prevent the damp rising from the ground through the masonry into the body of the wall. It is generally placed immediately above the footings, if these project above ground; but the damp course should be, if possible, 1 ft. above the ground. It generally consists of two or three courses of hard-burnt bricks laid in hydraulic mortar. A highly-burnt glazed hollow brick is made for the purpose, the perforations being horizontal, so that a current of air passes through the wall at that point. Perforated bricks are liable to crack under pressure.

TABLE OF THE PRESSURES ON THE FOOTINGS OF WALLS.

From Tredgold, *Encyclopædia Britannica*, and Renaud.

Tredgold's Rule for breadth of walls $W = \frac{1}{4} f b d$, when $b d$ = area of cross-section of part of wall under consideration, W = safe weights in lbs. f = tabular number = $\frac{1}{4}$ th the splitting or $\frac{1}{4}$ th the crushing force, in lbs. per square foot.

General Principles of Wooden Roofs.—Under the head of roofs are included all kinds of coverings of a permanent character to buildings; both the covering itself, which has to keep out the weather, and the framework which has to carry it.

If the covering is quite impervious, it may be nearly flat; but a horizontal beam, or framed girder, is not the most economical mode of spanning a large opening, especially in wood. As far as the framework is concerned, it is more economical to arrange it in one or more inclined planes or in a curve; and as few descriptions of covering are quite impervious or can be conveniently built in curves, the inclined planes are the most suitable mode of forming roofs in general. The inclination of the planes and the number of them must depend on the climate, the nature of the covering, and the circumstances of the case. With the same description of covering, supposing it to be only partially impervious, the inclination should vary according to the rainfall and snow of the locality; speaking very generally, it may be said to vary according to latitude; but this would be too uncertain a guide for an architect. There must be a certain inclination for each country, at which a particular kind of covering will keep out the rain and snow. These inclinations for the English climate, for different kinds of coverings, will be given hereafter.

Garbet has stated a very proper general principle to be observed in all roof-frames, of whatever inclination, that the *numbers of orders of bearers should be as few as possible*. This will be best illustrated by describing the arrangement of ordinary roofs. When covered with slates or tiles, or any similar covering in small flat pieces, the bearers immediately under them must consist either of boards extending continuously underneath, or of battens placed horizontally at the interval of two courses of the slates or tiles. These again must be carried by beams called *rafters*, placed down the slope of the roof at right angles to the others. This arrangement Garbet would call two orders of bearers; it is the mode generally adopted in roofs not exceeding 20 ft. span: each pair of opposite rafters are generally tied together, either by a *tie-beam* at their feet or by a *collar-beam* about half-way up; from which this has got the name of the collar-beam roof.

When the span exceeds 20 ft., the bearers would become so large that it would be economical to introduce an additional order of bearers. The ordinary method is to support the *common rafters* by one or more beams extending horizontally beneath them, called *purlins*, which themselves are supported on other rafters below them, which latter being placed at considerable intervals, are much stronger, and are called the *principal rafters*. The common rafters rest against a horizontal beam standing on the foot of the principal rafters, and called a *pole-plate*, and abut against a horizontal *ridge-piece* at the top; thus they have little strain on them beyond the transverse strain between the purlins. The purlins are subject to a transverse strain between the principal rafters. The principal rafters are supported by a framework of which they themselves form a part, and which varies according to the span of the roof. This framework is called a *roof-truss* or a *trussed principal*, and forms the final and most important bearer of the roof. For spans between 20 and 30 ft., this truss generally consists of two *struts* supporting the principal rafters half-way down, and meeting in the centre, where their combined vertical force is suspended by a vertical rod or post called a *king-post*, to the vertex of the roof. The horizontal force at the foot of each principal rafter is carried by a *tie-beam*, which also supports the ceiling, if there is one, and is itself supported by the king-post.

When the span is above 30 ft., in order to provide intermediate points of support for the principal rafters, two vertical posts, in such case called *queen-posts*, are introduced each with its struts, the heads of the posts being connected by a horizontal beam, called a *straining-beam*, which carries the horizontal strains arising from them.

The general principle of such trusses is to carry the strains of the roofs in such a way as to relieve the walls from any but vertical strains.

Garbet would call the above arrangement one of *four orders of bearers*, namely:—1. Boards. 2. Common Rafters. 3. Purlins. 4. Principal Rafters. The usual interval for such "*trussed principals*" in ordinary roofs is 10 ft., and the interval of such purlins is about 6 ft.: with those fixed intervals this form of roof-frame is applicable to a considerable range of spans. It is evident, however, that as the span increases, it will at last be more economical to increase the interval of the principals, and to strengthen the purlins accordingly by framing or "trussing" them: and that for small spans it will be economical to combine the principal and common rafters in one, and to dispense with the purlins. The span at which it is desirable to introduce an additional order of bearers, in any such system of framework for constructions, is determined by considerations both of economy and stiffness; for, besides the calculations for the comparative cost with or without the additional bearer, it is necessary to consider the deflection; and as that varies directly as the cube of the length between the points of support, it may be desirable in some cases, where it is necessary to limit the absolute deflection, to introduce an additional order of bearers before the economical limit has been reached.

The examination of the strains exerted in a queen-post roof will sufficiently explain them for all this class of roofs. The *boards* or *battens* are subject to a transverse strain between the points of support afforded by the common rafters, which is made up of the weight of the roof covering and the allowance for pressure of wind (reduced to the vertical direction); they should never have a long bearing, as stiffness is very essential in the bearers of the roof-covering. Each *common rafter* is subject to a transverse strain between its point of support, and to a longitudinal compression from the reaction from the opposite rafter; the force causing both these strains is that of the weight of roof-covering and boards, and pressure of wind bearing on the area supported by the rafter. The *purlins* and *pole-plates* and *ridge-pieces* are subject to transverse strains arising from the pressure of the common rafters they carry, divided proportionally between them; the pole-plate also carries the longitudinal compressible pressure of the rafters, and transmits it to the principal rafters. The *principal rafters* are not generally subject to transverse strain, except from their own weight, but chiefly to longitudinal compression, because the purlins are generally placed immediately over the points of support of the rafter. Thus, at the junction of the lower strut with the rafter, the pressure of all that part of the purlin and its superincumbent weight that is carried at that point, is resolved into a compressible strain down the principal rafter, and another down the strut; and at the junction of the queen-post, principal rafter, and straining-beam, the pressure of that purlin, together with the vertical strain from the queen-post, are resolved into a compressible strain down the principal rafter, and another along the straining-beam: and at the upper strut a similar compressible strain results; and at the vertex, the pressure of the ridge-piece and vertical strain from the king-post are resolved into compressible strains down the principal rafters. Thus, the principal rafter is subject to accessions of compressible strains at these points from the vertex to the foot; and each part of it must be calculated accordingly to resist those strains. The *struts* are subject to compressible strains arising as above mentioned. The *king-post* and *queen-posts* are subject to tensile strains arising from the vertical components of the compressible strains.

The *tie-beam* is subject to the tensile strain which is the horizontal component of the compressible strain down the principal rafter; the vertical component of the same being carried by the walls. Tie-beams are generally made much larger than necessary to resist this strain only, even after allowing for the usual coefficient of safety, because they have generally to carry the transverse strain arising from the ceiling of the rooms below. The beams of that ceiling are generally fixed

to the tie-beams, each of which has therefore to carry all those beams and ceilings between two of the main trusses of the roof. For this reason the depth of the tie-beam is generally made much greater than its breadth. Each of these frames, or *trusses*, or *framed principals*, as they are called, are generally put together on the ground and hoisted into their places in one piece. The effect of putting the weight of the roof on this framework will be to deflect it a little out of its original form; some of the beams will become shortened and some lengthened; this should be taken into consideration in the design of the roof, as it not only throws the strains in different directions to those in the original form, but it alters the slope of the roof and may affect the junction of the eaves with the gutters.

The ends of the tie-beams generally rest on *wall-plates* or *templates*, and are sometimes *notched* on to them. The best position for the wall-plate is in the centre of the thickness of the wall, and the junction of the rafter and tie-beam should come immediately over it; and the most effectual mode of finishing the lower part of the roof is to allow the common rafter to project over the wall, and so carry the rain clear of the building. As the ends of the common rafters rest on the wall-plate, the whole pressure from the roof thus falls on the centre of the wall. When a roof is so finished, the lower part of it projecting over the wall is called the *eaves*: there is therefore an open space between every common rafter, which must be filled up to prevent the wind from entering the space between the roof and the ceiling. This is generally done with woodwork, which is called the *eaves' boarding*. In any method of finishing the eaves of a roof, the ends of the tie-beams should not be imbedded in masonry, or they will be liable to decay before the remainder of the roof. When there is a parapet or *blocking course* above the eaves of a roof, then either the parapet must rest upon projecting courses corbelled out from the outer face of the wall, or the wall-plate must be placed nearer the inner edge of the wall; in which latter case the pressure of the roof will not coincide with the axis of the wall. The wall-plate is not unfrequently placed close to the inner edge of the wall, and the junction of the tie-beam and rafter placed on the inner side of the edge; a practice which not only has the disadvantage of directing the line of pressure out of the axis, but subjects that short part of the tie-beam to transverse strain, thereby also causing a tendency to draw the wall-plate off the wall.

The ordinary method of framing these beams together, so as to send the strains in the directions required, will be considered presently; and Tredgold's rules for calculating their dimensions will be given hereafter.

Flat roofs are used in countries where there is little rainfall, as in the southern and eastern coasts of the Mediterranean, probably both from their usefulness and economy. The flat roof is not only the most simple mode of covering the house—a mere repetition of a floor—but adds another story and a garden to it. The following extract from a paper by Sir H. Jones on Maltese houses shows the mode of constructing a flat roof in that island: Beams of red pine from the Adriatic, about 10 by 12 in., are placed horizontally across the walls, at central intervals of about 4 ft. Sometimes a series of arched ribs of stone are built across from wall to wall instead of the beams. On these flat stones of the soft Maltese sandstone, about 4 ft. long, 10 or 12 in. wide, and 3 in. thick, are placed, butting close together without mortar; on these a concrete of red argillaceous earth and small stones, and called "*Forba*," is laid, with a slight slope on the upper surface to carry off the rain that falls: this forba is kept moist and beaten with rammers. When dry, there is spread over it a layer of cement $\frac{3}{4}$ in. thick, composed of four parts lime, three parts puzzolana, or of five parts lime and three parts pounded earthenware. This is spread in a liquid state, and then beaten with rammers and worked with trowels, and kept moist until it has set. The beating is done by women kneeling, with hand boards.

In countries where stone suitable for this purpose cannot be procured, timber is used instead, or a combination of wood beams and flat tiles, or wood beams and concrete of a quick-setting cement is used. Asphalt is sometimes substituted instead of cement for the exterior coating in this country when flat roofs are made; there is some danger in using it, on account of the expansion and contraction of the framework below. It is necessary in all flat roofs to make the framework very stiff—that is, to avoid any considerable amount of deflection, which would break the impervious coating of cement or asphalt; consequently, it would be desirable to introduce an additional order of bearers, or to provide in some other way for stiffening the structure at a smaller span than in an ordinary wooden floor. For the same object of stiffening the framework, it should be connected with the walls as firmly as practicable; the ends of the beams should be framed into the wall-plates or templates, which should rest on the wall as near the centre of its breadth as practicable. When a masonry parapet is made round the walls, great care should be taken in the construction of the open gutters at the sides to carry off the roof-water, and prevent it getting into the walls; frequent outlets through the parapet should be provided. Solid stone forms the most effectual gutter; and next to that, perhaps, a concrete of hydraulic cement.

Gothic and Arched Roofs.—In England roofs are generally made in one plane from the ridge to the eaves; but in France and some other countries, it is common to make them in two planes; this is partly for the architectural effect, but chiefly for the economy of gaining an additional story in the roof. The general method of arranging the roof is the same in almost all cases; there are the principal trusses at intervals, the purlins, the common rafters and boards: it is only the framing of the truss that varies. In the principal truss of the *Mansard* roof (as that of two planes is called, from the architect who first employed it extensively in Paris), besides the main rafters, which might be made to balance each other without ties, there are tie-beams from each angle to the next but one, and connected together at the crossing; these ties do not carry the whole horizontal strain of the roof, like that of the English truss, but leave a portion of it to be carried either by the walls, or by the strength of the bolt and beams at the crossing of two such ties.

In some of the old Gothic wooden roofs, the frame of the principal truss was made without any direct ties, chiefly for the sake of the effect when the timbers of the roof were visible, but also because the high pitch of the roof caused the horizontal strains to be less. The principal rafters

were generally supported by a collar-beam high up, and at one or two points lower down by vertical posts resting on the ends of horizontal pieces projecting from the point of support next below, the projecting points of junction of these vertical and horizontal pieces being connected by curved struts: the series of these curved pieces being carried from the walls on each side up to the collar-beam in the centre, they formed an imperfect tie to the roof—imperfect because it depended on so many joints, and because, if perfectly jointed, it resisted deflection by the strength of the joint, and not by the beam itself. The lowest of these curved pieces, being carried to a point considerably lower in the walls than the eaves, brought the general line of pressure of the roof to a lower point on the wall, and thus reduced the necessary thickness of the wall to meet it. Hampton Court Palace contains a good specimen of these roofs; those at the old palace at Eltham, and at Westminster Hall, are also remarkable examples.

When the span of a roof exceeds 50 ft., the queen-post roof-truss becomes heavy, and uses a large proportion of timber in the dead weight of the bearers: the polygonal or curved truss is one of the forms which has been proposed to avoid this ineffective use of timber in very large spans. In it a polygonal or curved rib of wood is formed, to which the tie-beam is suspended, and from which the purlins are supported: the curve of this rib should be such that a line of pressure will pass through it, thus putting it entirely in compression throughout its length; the tie-beam and suspension-bars will then be in tension. Dobson states that Philibert de Lorme was one of the first architects who proposed a polygonal rib of wood, which he constructed of two or more thicknesses of plank, the pieces of which were in equal lengths, and their ends abutted against each other; each thickness of plank thus forming a polygonal rib; the two thicknesses were bolted together.

Walls of Framed Work.—Walls of wooden buildings generally consist of vertical pieces, placed close enough together to support the boarding or plastering with which they are covered, and resting on a horizontal piece at bottom, commonly called a *ground-plate*, and connected at the top by a *wall-plate*. When the ground-plate is supported continuously by a wall, it only performs the part of an ordinary plate—that of distributing the pressures equally; and the uprights, or posts or studs, as they are sometimes called, are so many wooden columns, carrying each its proportion of the vertical pressure. No piece of quadrilateral framing can be put together so firmly as to resist completely some small distortion of shape from lateral pressure; therefore, it is most desirable in every wooden wall, as in every piece of framework, to have some inclined pieces framed into the structure, by which the pressures can be resolvable into triangles. These inclined pieces, which are called *struts* or *braces*, are sometimes only battens fastened across the studs. The corner-posts are generally larger, as they have to withstand a double lateral pressure. It would make a stiffer, though a more expensive wall, if the studs were placed farther apart, and, consequently, made of large cross-section, and an intermediate order of bearers for the boards was introduced. In America a wall is sometimes made entirely of boards in two or more thicknesses, placed at right angles or diagonally to each other. When a wooden wall has to span an opening, as is frequently the case in the interiors of houses, in partition walls covered with lath and plaster, it becomes a very deep-framed girder, and should be framed on the principle of the queen-post truss, in which the braces would represent the principal rafters, and the top plate would represent the straining-beam, and the bottom plate would be the tie-beam, which should be supported from the top plate and braces by the vertical studs; in such a framework the studs below the braces would be in tension; those above the braces in compression. The bottom plate might in such case support part of the weight of a floor or ceiling. In arranging the openings for doors and windows in wooden walls, great consideration should be paid to the position of the braces; the studs on each side of the opening should be made stronger than ordinary studs, in order to form the framework of the door or window; and with a careful arrangement of the braces in connection with these frames, these openings may be made to add to the stability of the wall.

Scarfs.—In all scarfs and joints in woodwork, it is an important principle that the bearing parts should have as large a surface as possible, in order to save the fibres from injury. For the same reason, timbers in framework should be cut as little as possible. Also, that the inevitable expansion and contraction of the wood should be borne in mind in the form of the joint.

The following notes on scarfs and joints are extracted from Tredgold's Carpentry:—

1. *Longitudinal scarf to resist tension only*, such as for some tie-beams, king-posts, and so on.

Fish-joint, Fig. 2058.—In this the two pieces of timber abut on each other, end to end, and an iron or wooden plate is fastened on each side by bolts passing through the beams; the tensile strain is thus passed through the bolts to the fibres of the timbers. The shrinkage of the timbers loosens this joint, and the pressure of the bolts injures the fibre; the total area of bolt-sections should be at least equal to $\frac{1}{10}$ the area of the section of beam.

Indented Scarf, Fig. 2059.—To determine the depths of indents and length of scarf, the tensile strength of bc should be equal to the compressile strength of ac and to the shearing strength of cd . Therefore, when the compressile and tensile resistances of the wood are equal, bc should be $\frac{1}{2}$ the depth of the whole beam.

mortice in the upper one. There is both a practical advantage in this, in being able to use long timbers, and a theoretical one, in getting a better bearing, and in having the upper beams virtually fixed at each end, instead of merely supported, as in the former method.

Cross-framing, Figs. 2066, 2067, as in wall-plates and such beams, which have to be connected together and are not subject to transverse strain.

The beams are *halved* into each other, as it is called, half the thickness of the beam being cut out of each. Sometimes the form of this halving is *dovetailed*, as in Fig. 2068, which is objectionable, because the shrinking of the timber causes the joint to become loose; for this reason no *dove-tailed* joints are to be recommended in carpentry. The better form for the halving is shown in Figs. 2066, 2067.

5. *Transverse joints, perpendicular*, Figs. 2069 to 2071; such as posts or studs into plates.—The object of every system of joints is to reduce all the pressures into the direction of the axes of the pieces.

The ordinary mode of connecting two beams, the one perpendicular and the other horizontal, is by cutting two shoulders in the end of the perpendicular piece, leaving a *tenon* or tongue between them, which fits into a corresponding *mortice* or hole cut in the horizontal pier. As the only object in the tenon and mortice is to prevent lateral motion, Tredgold recommends a short tenon having a thickness of about *one-quarter* that of the timber.

It is evidently of great importance that the tenon and mortice should be cut square and accurately; on account of the difficulty of ensuring this, Tredgold recommends an angular-shaped or a curved joint, as shown in Figs. 2070, 2071.

6. *Inclined joints*, Figs. 2072 to 2074; such as principal rafters with tie-beams.—The resistance of a joint is always most effectual where the abutment one piece rests against is perpendicular to the strain down that piece. Thus, in the figure, if the strain down the rafter is in the direction *cbe*, and *ba* is one of the abutting surfaces, then, if *ac* be drawn perpendicular to *ba*, and *bd*, the other abutting surface, be made parallel to *ac*, then in the triangle of forces *abc*, if *bc* represent the whole strain, *ac* will represent the strain on *ba*, and *ba* will represent the strain on *bd*: thus the two components of the whole strain will be perpendicular to the two abutting surfaces. Tredgold recommends that *bd* should be rather more than half the depth of the rafter. There should be a tenon at the under-side of the rafter, and a mortice in the tie-beam, to prevent the beams slipping over each other; the thickness of the tenon should be about $\frac{1}{4}$ that of the beam. As the shrinking of the wood, which is sure to occur after the framework is up, will have the effect of lowering the slope of the rafters, and thus bring a greater pressure about the point *a* of the joint, that part of the joint should be left a little open, as shown in the figure, in the original construction of it.

Tredgold recommends either of the accompanying forms for this joint, in which the tenon is made on the tie-beam, and the mortice on the rafter; it has the advantage of showing the whole of the workmanship of the joint more completely to view than the other method.

7. *King and Queen Posts*, Figs. 2075, 2076.—The upper end of the principal rafters may be framed into the king-posts in a similar manner to the lower end into the tie-beam. But in this case the joint, when originally made, should be left slightly open at *a*, as the effect of a settlement from shrinking will be to bring a greater pressure on that part. Or, the upper end of the king-post may be enlarged and cut with a shoulder at right angles to the direction of the rafter. In both these cases there should be a small tenon and mortice to prevent the beams slipping over each other sideways. The lower ends of the struts may be connected with the king-post by either of the above methods; if the king-post is in two pieces, a very good joint may be formed with the principal rafters, by letting them abut against each other between the two parts of the post, as in Fig. 2075, the two parts being bolted together above and below the junction.

The *struts* and *principal rafters* may be connected by a joint similar in principle to that of the rafter and tie-beam. The *purlins*, *pole-plates*, and *ridge-pieces*, are generally notched into their respective beams.

The following practical rules by Tredgold for determining the size of the beams in wooden roofs, of the description of framework before mentioned, are based on the theoretical calculations for the resistance of beams to deflection. He apparently considered that the amount of deflection in a framework is of as much importance as the absolute strength; then assuming that for security the deflection of any beam ought to vary inversely as its length, and starting with some fixed arbitrary deflection for a given beam, and assuming that the arrangement and intervals of the beams and the loads upon them are constant, he obtained from these data and his own judgment a set of constant coefficients for the different beams for fir wood and oak wood, in terms of their dimensions, span of roof, and so on. These rules generally give large dimensions compared with those for absolute strength.

Principal rafters, assumed central interval = 10 ft.

$$d = 0.96 \frac{l^2 L}{\delta^3} \quad \begin{cases} \delta d = \text{breadth and depth of beam in inches,} \\ l = \text{length of beam in feet,} \\ L = \text{span of roof in feet,} \end{cases}$$

which is virtually the theoretical equation for a long beam subject to compression in the direction of its length.

Straining-beam.— $d = 0.9 \sqrt{l \sqrt{L}}$, which is also the same theoretical equation, δ being taken constantly as $0.7d$, which is an arbitrary assumption.

Struts.— $d = 0.8 \sqrt{l \sqrt{L}}$, δ being taken constantly as $0.6d$.

King-posts.— $\delta d = 0.12 l L$.

This rule for a beam under direct tension, is evidently based on the same law that the elonga-

2075.

2076.

tion should be inversely as the length of beam: and this gives of course much larger dimensions than are required for absolute strength.

Queen-posts.— $b = 0.27 \sqrt{L_1}$; L_1 = length in feet of that part of tie-beam carried by the queen-post.

Tie-beams.— $d = 1.47 \sqrt[3]{\frac{l_1}{b}}$; l_1 = length in feet of longest part of tie-beam unsupported.

This is virtually the same as the theoretical equation for the deflection of a beam subject to transverse strain; in this case, apparently, the tensile strain on the tie-beam is expected to counter-balance to some extent the deflection caused by the transverse strain.

Common rafters.— $d = 0.7 \sqrt[3]{\frac{l_{11}}{b}}$; l_{11} = length in feet of bearing between one purlin and another.

Common rafters should be at least 2 in. thick to hold the nails of the laths or boards.

Purlins.— $d = \sqrt[4]{D^3 P_{111}}$; D = distance in feet of purlins from each other.

b is assumed constantly = $0.6d$. l_{111} = length of bearing of purlin in feet.

These two last are virtually the same as the ordinary theoretical equations for deflection of beams subject to transverse strain.

Roof Coverings.—The object of all roof coverings is to keep out the wind, rain, and snow, and to keep an even temperature inside as far as practicable.

A roof covering of small pieces is generally heavier, more difficult to keep dry, and requires a steeper slope than one of large pieces, but the material itself is cheaper.

In a roof covering, the crown or meeting of the planes at the top is technically called the *Ridge*; the meeting of two planes forming a salient angle down the slope of the roof, as frequently occurs at the end of a building, is called a *hip*, and such a roof is said to be *hipped*. The meeting of two planes forming a re-entering angle down the slope of the roof, as occurs at the junction of one roof at right angles to another, is called a *valley*; the lower edge of the roof, where it meets the wall, is called the *eaves*.

Slates form the most effective and durable roof covering of any stones or tiles. They are used all over England from the facility with which they are obtained. The strata of roofing slate are found in all the Silurian series of rocks to which they belong. They are quarried by blasting, and are split and cut into sizes at the quarry. As it is convenient to have slates all one size in one roof, they are cut to fixed dimensions according to the size of the blocks obtained from the quarry; consequently the larger slates are more expensive. The best slate for roofing is of a light sky-blue colour, and gives a clear bell-like sound on being struck; dark blue or blackish slate absorbs moisture and decays more rapidly.

The following, taken from Hurst's Tables for Engineers, are the sizes and the technical names of the slates in ordinary use for roofing in England:—

Name.	Size.		Gauge.	No. of Squares covered by 1200.	No. required to cover 1 Square.	Nails a Square.	
	in.	in.	in.			Iron, No.	Copper.
Doubles	12	8	4½	2.8	430	430	lbs. 5
"	13	6	5	2.5	480	480	5½
Ladies	14	12	5½	5.0	240	280	3½
"	15	8	6	4.0	300	300	3½
Viscountesses	18	10	7½	6.0	200	200	2¾
Countesses	20	10	8½	7.0	171	342	4
Marchionesses	22	12	9½	9.4	130	260	3¼
Duchesses	24	12	10½	10	125	250	3
				By 1 ton.			
Imperial	30	24	13½	2.5	48	96	3
Rags	36	24	16½	2.2	40	80	3
Queens	36	24	16½	2.5	40	80	2½

The slating of a roof begins from the eaves. The slates are shaped and trimmed on the ground, and two holes are punched through them near the upper end for the nails to fasten them to the boards or battens. Slates may be laid either on boards or battens; these are generally at right angles to the last course of bearers, and therefore generally horizontal; there is less cutting to waste of them when they are laid horizontally; the boards or battens are seldom less than 1 in. thick, on account of the slating nails which have to be driven into them; battens should be at the utmost at the interval apart of two consecutive courses of slates. Boards are generally used for important buildings, they are stiffer, and keep out the wet and the heat better than battens. The first course of slates at the eaves is little more than half the width of the other courses; it is called the doubling eaves' course, and the next course covers it completely, a special batten being laid under it to give it the same slope as the others: the second course is called the covering eaves' course. At the ridge another half-course is laid over the last course. Slating should have a bond or overlap of at least 2½ in., that is, the third course should overlap the first course by 2½ in., and the fourth should overlap the second by the same. Hence, if the overlap be deducted from the length of the slate, half the remainder will give what is called the margin or *gauge* of the slating. At the hips and valleys the slates are cut to fit the required angles.

For the nails for fastening slates *copper* is the best material, and is generally used in important buildings. Zinc and iron nails are sometimes used, but the former are not strong enough, and the

latter are soon destroyed by rust; the partial protection which is sometimes given them by dipping them in boiled linseed oil, does not preserve them much longer, and a coating of tin is an uncertain protection. Slates for ridges and hips are sometimes cut out of thicker pieces than ordinary; they are generally in two pieces, and are joined together on the roof with slate mastic, and form very effective and durable coverings.

Large slabs of slate are frequently used for special roofs, and for cisterns and other similar purposes. They are expensive and require great care in fixing, especially in forming the water-tight joints.

Tiles are now made in England in great variety of forms. They are made in almost all districts where clay for brickmaking is found; but they should be made of a more plastic clay than that for ordinary bricks, otherwise they are liable to lose their shape in the burning. The preservation of the shape is indeed the only limit to the size of tiles; the larger the tile the lighter the roof covering; large well-burnt tiles would be almost as effective, light, and durable a covering as slates, though requiring a steeper slope: and if a cheap method of glazing them should be discovered they will probably supersede slates to a great extent.

Plain tiles are the oldest and commonest form of tile in England. They are flat and about 10 in. by 6 in., and $\frac{1}{2}$ in. thick, and weigh 2-13 lbs.; they are generally laid on *laths* of fir about $1\frac{1}{2}$ in. wide and $\frac{3}{8}$ in. thick, nailed to the common rafters and therefore horizontal: two holes are formed in the tile, near the upper edge, through which they are fastened with wooden pins to the laths. The overlap of one course over the next is generally from 6 in. to 8 in.; rows of laths are fixed at intervals to give the required overlap, between each of which an intermediate row is placed: the tiles are bedded in mortar, which should of course be hydraulic: the tiles in one course are laid with their sides touching, the next course is laid with these joints occurring over the spaces between the joints of the course below.

There are flat tiles used in France 12 in. by $9\frac{1}{2}$ in.

A square of plain tiling requires 700 plain tiles; 1 bundle of laths, or 500 ft. lineal; 600 nails, 4 lbs. to the 1000; 4 cub. ft. of mortar; and 1 peck of wooden pins, or $\frac{1}{2}$ bushel.

Pantiles were introduced into England from Holland; they are curved in transverse section, with a kind of lip on one side to cover the joint with the next tile in the same course. They measure about 14 in. long and 7 in. to $9\frac{1}{2}$ in. across the chord of the curved part, and about $\frac{5}{8}$ in. thick, and weigh $5\frac{1}{2}$ lbs. They are made with a tongue projecting from the centre of the upper edge to the rear; by which they are hooked on to the laths. The overlap of one course over the next is from 3 in. to 4 in., consequently they form a much lighter covering than plain tiles. The laths are from 10 ft. to 12 ft. long, $1\frac{1}{2}$ in. wide, and 1 in. thick. The tiles should be pointed on the inside of the horizontal and vertical line joints with "hair mortar," that is, common mortar with a small portion of ox hair mixed with it. With pantiles it is usual to employ special tiles to cover the ridges, hips, and valleys.

The ridge and hip tiles are curved, and are about 12 in. long and $9\frac{1}{2}$ in. across the chord; they are laid in mortar without any overlap, and are fastened with nails or hooks. *Valley tiles* are curved and triangular-shaped, and are about $10\frac{1}{2}$ in. by 12 in.; they overlap, are laid in mortar, and fastened with wooden pins like plain tiles.

A square of pantiling requires 180 pantiles; 1 bundle of 10 ft. laths, or 120 ft. lineal; 150 nails, 10 lbs. to the 1000; and 6 cub. ft. of hair mortar.

Italian Tiles.—The system of roof covering that has been in use all over the Mediterranean from the earliest known periods, has been that of the ridge and furrow tiling; one set of curved or channelled tiles being laid with the concave side uppermost, to form a series of channels down the slope, and another set laid with the curved side uppermost, covering the joints of the former, and forming a series of ridges between the channels. This system is not so effective as plain tiles in countries exposed to heavy winds and snow, because the number of irregularities in the surface of the roof afford so many points for the wind to act on and for the snow to accumulate in. Sometimes the channel and ridge tiles are both the same, or about the same shape, as is the case in Chinese roof covering. M. Renaud mentions the following usual form now in use in Italy:—The channel tiles (*tegoli*) are flat, and about 16 in. long, 10 in. wide at the lower end, and 13 in. at the upper, with a ledge or rim down each side; the ridge tiles (*canali*) are curved, and about the same length, and $6\frac{1}{2}$ in. wide at the upper end and 9 in. at the lower; the overlap is about 3 in. On the common rafters of the roof (which are at about 1 ft. central interval) are laid common flat tiles, and on these the ridge and furrow tiles are laid. The proper slope for them is from 15° to 27° , and the weight of a square of 100 sq. ft. is 1800 lbs.

A *triple pantile* (as it is called) is made by Browne, of Bridgewater; it is $16\frac{1}{2}$ in. by 14 in., and 1 in. thick, and weighs $7\frac{1}{2}$ lbs.

Thatching is a name given to a kind of covering over roofs: it is generally made of wheaten straw, laid on lathing and rafters, which may be of the same strength and placed the same distance apart as for a common slated roof; but in country places, where thatching is mostly used, the rafters are generally formed of the branches of trees of from 3 in. to 6 in. in diameter; the slighter they are the better, provided they are sufficiently strong, as the lighter the roof is the less strain there is on the walls: of course, if the rafters are stout, they should be placed farther apart than slight rafters; and if the rafters are far apart, the lathing must be stronger, otherwise the thatching will bag, or lay in hollows between the rafters.

The straw is laid on the lathing in small bundles called hellams, until it attains a thickness of from 12 in. to 16 in.; it is fastened to the rafters with young twigs and rope-yarn.

A good pitch for a thatched roof is 45° , or, as it is technically called, a true pitch: if the pitch is made less, the rain will not run off freely; and if a greater pitch than 45° is used, the straw is found to slip down from its fastenings.

The Thatcher's Tools are:—

A *common stable fork*.—This tool is used to toss the straw up together when it is wetted, preparatory to its being made into bundles for use.

A thatcher's fork, Fig. 2077.—This is a branch of some tough kind of wood, cut with two smaller branches proceeding from it, so as to form a fork, as shown in the diagram; the joint of the two branches is generally strengthened by a small cord, to keep it from slipping when it is used. A small cord is fastened by one end into one of the ends of the fork, and a loop is spliced on the other end of the cord; this loop is made to pass over the other end of the fork, and to fit into a notch cut to receive it, as shown in Fig. 2077.

This tool is used to carry the straw from the heap, where it has been wetted and prepared, up to the thatcher on the roof, where it is to be used.

A thatcher's rake, Figs. 2078 to 2080.—The handle should be of ash or some tough wood, made not round but square, so that it may be grasped firmly without fear of its slipping round in the hand: the arrises may be slightly rounded off, so as not to hurt the hand. It will be seen by referring to Fig. 2079 that a crook is formed in the handle; the reason for this will be explained when we come to speak of the manner of using the different tools.

The use of this tool is, after the straw is laid, to comb it down straight and smooth.

A thatcher's knife, or eaves' knife.—This tool is similar in shape and make to the reap-hook, except that it is larger, and not curved so quickly.

The use of this tool is to cut and trim the straw to a straight line at the eaves of the roof.

The thatcher also requires a knife shaped something like a bill-hook, to point the twigs used for securing the straw.

A half-glove or mitten, of stout leather, to protect the hands when driving in the smaller twigs, called spars.

A long flat needle, Figs. 2081, 2082.

A pair of leather gaiters, to come up above the knees, to protect his knees and shins when kneeling on the rafters.

A sharp grit-stone to sharpen the knives.

The Timbering and Lathing necessary for a Thatched Roof.—As before stated, the rafters for a thatched roof may be of round timber, such as the branches of trees, and young trees, of from 3 in. to 6 in. in diameter, placed not more than 14 in. from centre to centre, but sometimes the rafters are of sawn timber: in that case they should be cut about the same scantling as for a slated roof, not as for a tiled roof.

The lathing in a thatched roof being very liable to rot, it should be split out of heart of oak, or some other equally durable wood: the laths are about $1\frac{1}{2}$ in. wide, and $\frac{1}{2}$ in. to $\frac{3}{4}$ in. thick, and are nailed on the rafters about 8 in. apart in a horizontal direction, just the same as for a tiled or slated roof.

If the laths are placed farther apart than 8 in., the straw is apt to bag or sink down between them; the rain lodges in the hollows, and of course soon rots the straw.

An eaves' board about 7 in. wide is required to start the first part of each course of thatching upon.

A description of the manner of executing a Thatched Roof.—The rafter and eaves' board being fixed, and the lathing nailed on in rows at the prescribed distance apart before mentioned,—

As much straw is taken as it is thought will be required for the whole roof, which may be got at by estimating a square to take from $3\frac{1}{2}$ to $3\frac{3}{4}$ cwts. of wheaten straw: care should be taken to keep the fibres or stalks as parallel to each other as possible. As each truss of straw is opened, it is spread out and wetted, using about 3 or 4 gallons of water to each truss. The straw is then tossed over and mixed together in one great heap with the stable fork, so that every part may get an equal portion of the water. If the weather is fine and dry, the straw may be used directly; but if the weather is damp or rainy, the straw should be allowed to lay for a day or so to drain, and be once more turned over.

The reason for wetting the straw is to make it lay close, and to enable the thatcher's labourer more easily to draw the stalks out parallel.

The thatcher and his labourer being now ready to commence, the labourer spreads as much of the straw on the floor as will make a bundle 12 in. wide and 4 in. thick; the labourer then stooping down, with his left hand draws the straw, little by little, to his feet, and while doing so, with his right hand draws out any loose straws that may be lying crosswise: by this means he gets a compact bundle of straw from 3 ft. to 4 ft. long, according to the goodness of the straw, and all the stalks are parallel. This bundle is called a "hellam." The labourer having placed four or six hellams crosswise in his thatching fork, he carries it on his shoulder up to the thatcher on the roof, in the same manner as a bricklayer's labourer carries a hod of mortar: the fork is secured on the roof by a small peg and a piece of string.

The thatching is now laid in courses 3·0 wide, beginning at the right end of the roof, so that the thatcher works from right to left. The courses are laid parallel with the rafters, and not parallel with the lathing (as is the case in slating and tiling). Care must be taken at starting the eaves to have a good firm body of thatch, letting the straw hang over, to be afterwards trimmed with the eaves' knife to a straight and good-looking edge. A row of three hellams is placed on each succeeding lath in the course, and each row of hellams is secured to the rafters with a young tough twig, called a ledger; it is about 4 ft. long and 1 in. in diameter: each row of hellams is also secured to the row underneath it with three split twigs, called spars: the spars are about 2 ft. long, and eight can be split out of a branch 2 in. in diameter; they are pointed at both ends, and are then doubled in two, and the thatcher gives them two twists round in his hand, in the same

manner as a rope is twisted: this gives the spar a splintery surface, and enables it to hold on when driven into the straw.

The thatcher has a leather glove on his right hand: and keeping his hand flat or open, he gives the spar two or three smart blows, sufficient to drive it into the straw, and the leather serves as a protection to the hand. The spars must be soaked in water for some hours before they are used, in order that they should not break in the doubling up.

The *ledger* is a tough twig, about 4.0 long and 1 in. thick, as before described: one end is pointed, and driven or rather pushed 6 in. under the outside rafter of the course: it is then brought over the top of two rafters, and over the top of the hellams, and then secured to the inside rafter of the course with about 8 ft. of rope-yarn, by means of the long flat needle, thus holding down the row of hellams, and preventing them from slipping off the roof. In speaking of the outside and inside rafter of a course, it is meant by the outside rafter, the rafter that is farthest from the thatcher; and by the inside rafter the one that is nearest to him; and thus the inside rafter of one course becomes the outside rafter of the next course.

The thatcher gives each course, as it is laid, a combing down with his rake, to get out the loose straws: he then takes a bucket of water, and throws it right down the course, and gives the straw a good beating with the back of his rake, to break any stubborn straws and to make it all lay close: he then finally gives it another combing, and after that smooths it down with the back or flat side of his rake, and it is finished.

It will be seen by referring to Figs. 2078 and 2080, that a crook is formed in the handle of the rake. The reason for thus crooking the handle is to keep the thatcher's hand from contact with the straw, and thereby save his knuckles.

The ridge and hips are managed thus:—The thatcher, in doing one side of his roof, takes care to leave a good length of screw hanging over and past the ridge. As he finishes the top of each course on the other side of the roof, he bends down the tops of the first side, and covers them over with the last row of hellams on the last side, bending these last in their turn down over the other side of the roof.

The ridge is then secured on each side with three rows of bands or spars, placed end to end, and each spar is secured with three other spars to thatch.

In the case of the hips, there are no bands of spars, but single spars, 12 in. apart, are bent crosswise over the hip, and secured with three other spars, as before. The eaves are also secured with two rows or bands of spars.

Wheaten straw thatching, done as here described, will last in our climate from fifteen to twenty years. Oat straw, about eight years.

Shingles, or wooden slates, are made from hard wood, either of oak, larch, or cedar, or any material that will split easily. Their dimensions are usually 6 in. wide by 12 or 18 in. long, and about $\frac{1}{4}$ in. thick. They are laid in horizontal courses of 4 or 5 in. gauge, nailed upon boards, the joints broken, commencing with the eaves' course. The ridge is secured by what is called a ridge-board, or a triangle of inch stuff of 6 or 8 in. each side. In America, where this roof is common, the mechanics have a special tool for shingling, called a shingle-axe, with a hammer at the back.

Metal Coverings.—*Metal coverings* are generally laid in large sheets or plates, and as they are for the most part composed of materials of great tenacity, one of the intermediate orders of bearers can generally be dispensed with, and the sheets of metal can be laid on the rafters or purlins. Metal coverings should be fastened in such a manner as to admit of expansion and contraction, and therefore not with nails as a general rule; also, because the nail-holes, if exposed, soon enlarge with rust and form leaks.

Iron.—*Cast-iron plates* are seldom used, except when the roof consists of a reservoir or tank, in which case it is frequently made of cast-iron plates bolted together by means of flanges. Cast iron is frequently employed in roofing, for eaves' gutters, and rain-water pipes, and is one of the most effective materials that can be used for these purposes. Both gutters and pipes may be made as thin as they can be efficiently cast; the gutters may be of any cross-section required to correspond with the other mouldings; for an ordinary roof they should not be less than 5 in. deep in this climate. With that depth they may be laid nearly horizontal, as it is an advantage to have some water always in the gutter. The lengths or pieces should be connected by flanges and bolts, to allow of the introduction of fresh packing. The connection of the gutter with the wall should be very firm, and such as to allow for its expansion and contraction. With such a gutter a *down-pipe* or means of escape for the rain should be provided at about every 50 ft. lineal of gutter; this should not be less than 4 in. in internal diameter, and should have a larger head with a grating over it to prevent leaves or other matter getting into it. *Wrought-iron plates* are used both flat and corrugated. With flat plates the mode of forming the longitudinal joints (down the slope) mentioned by Renaud is the most effective, namely, by bending the two edges of the adjacent plates over a roll of wood extending down the roof, so as to avoid nailing. *Corrugated wrought-iron plates* have been much used of late years in this country. They are made in sheets about 12 ft. long and 6 ft. wide, and in thicknesses from about No. 25 to No. 15 of the Birmingham wire-gauge (that is, from about $\frac{3}{16}$ to $\frac{1}{4}$); the corrugations are from 2 to 5 in. across. It is only necessary to support medium-sized corrugated iron at intervals of about 6 ft., hence the framework of the roof can be simplified; the corrugations being placed so as to form ridges and furrows extending down the slope of the roof, the overlap of the sheets at the sides forms of itself a nearly water-tight joint; it is necessary, however, to fasten the sheets with nails along the top and bottom of each sheet to horizontal purlins or battens, in order to prevent them being lifted by the wind. These nail-holes are sources of decay and leakage.

No thin sheets of wrought iron will last many years without some artificial coating, and no artificial coating at present in use will effectually prevent oxidation, without frequent renewal. With thick plates not liable to any disturbing causes, the coating of oxide forms an effective

covering in itself, for it will not penetrate far into the iron and resists further change; but the liability to decay from rust of thin plates, especially when exposed to the action of any acid, has checked the application of wrought iron as a roof covering. A coating of zinc is applied to such plates for this object, and preserves them for several years, but wherever the coating is broken through, both the zinc and the iron decay rapidly; for this reason no holes or cuttings should be made after the zinc has been applied, and a coating of paint is frequently desirable in addition to the zinc.

Lead is the most durable covering for roofs of all the metals. Its malleability requires that it should be supported on boards, and as it must be of considerable thickness to retain its shape, it forms a heavy covering. There are two kinds of lead used in roofing, *cast* and *milled*. The former is the harder of the two, and is preferred for flats, cisterns, gutters, and tanks; the latter being more malleable is preferred for hips, ridges, and flashings. Both kinds are made in sheets about 6 ft. wide, and the cast from 16 to 18 ft. long, and the milled from 18 to 25 ft. long, and it is generally designated by the weight per square foot: that for flashings being not less than 5 lbs.; for hips, ridges, and valleys not less than 6 lbs.; for gutters, flats, and cisterns, not less than 7 lbs. a sq. ft. 5 lb. lead is about $\frac{1}{16}$ in. thick, and 7 lb. about $\frac{1}{8}$.

As the expansion of lead is considerable with increase of temperature, the joints must not be fastened together by *solder* or by any other means: when a joint is required to be in the direction of the slope, it is made by a *roll* of wood as above mentioned for iron plates; when the joint is across the slope, it is made by what is called a *drip*, which is a small vertical fall arranged in the boarding over which the two edges of the lead sheets overlap. Lead on *flats*, that is roofs nearly horizontal, should be laid in widths not greater than half the width of the sheet; on gutters and flashings it should be in lengths not greater than half the length of the sheet. Gutters and flats should have an inclination of at least $\frac{1}{4}$ in. in a foot or $\frac{1}{8}$, that is when the cross-section of the gutter is nearly flat, as is frequently the case with lead gutter. When the sides or ends of gutters or flats are formed by walls, the lead should be turned up against the walls of about 6 in. high, and be covered by a separate piece of lead called a *flashing*, the upper edge of which is let into a mortar joint in the wall, and the lower edge covers the top of the gutter lead about 3 in. The joints of flashings, and of hips and ridges, are *lapped joints*; this joint is suitable only for such narrow pieces of lead in vertical or inclined planes. In a ridge, the lead is moulded over a wooden roll fixed to the ridge-piece, and laid over the roof covering on each side; its own weight is sufficient to keep it down without any nails. In hips there is a tendency in the lead to slide down: this might be prevented by the top of every piece being nailed down with ordinary nails, which would be covered by the lap of the piece above it.

In water cisterns and tanks lined with lead the joints must of necessity be made of solder to ensure their being water-tight.

Solder used by the plumber is composed of equal parts of lead and tin; it is run into the joint in a molten state, and smoothed down by what is called the *grooving iron*, and finished off by filing and scraping. The joints of the lead are first scraped clean and covered with borax, which easily melting forms a coating to prevent oxidation while the soldering is in process.

Copper is in itself very durable as a roof covering, but it is generally used in such thin sheets, on account of the expense of it, that it is liable to become ineffective as a covering before the material is worn out. It is used in England in sheets weighing about 16 oz. a sq. ft.; and in Paris in sheets measuring about 3½ ft. by 4½ ft., and weighing up to 28 oz. a sq. ft. It is not considered necessary in Paris to cover sheets of that thickness with paint or other coating, as the coating of oxide which soon forms on it is a sufficient protection. The mode of fastening copper sheets is similar to that recommended for lead: on account of the thinness of them, they should be laid on boards.

Zinc is frequently used for roof coverings on account of its cheapness as compared with lead and copper. It is not so durable as either of them, but being stronger than either it can be used in thin sheets without boards immediately under it; it is used in England in sheets weighing from 12 to 20 oz. a sq. ft., and in Paris in sheets about 6 ft. long and 18 to 30 in. wide, and weighing from 20 to 40 oz. a sq. ft. The thick sheets are said not to require any other coating beyond that of the oxide naturally formed.

Iron Roofs.—The facilities now available for the rolling of wrought iron into bars of various cross-sections, enable it to be used with efficiency and economy in the framework of buildings. The metal can be disposed in the cross-section in such a manner as to give the maximum of strength with a given quantity of material, and to give considerable stiffness at the same time, and its elastic force is much greater than that of wood. Therefore, beams of wrought iron can be used with efficiency and economy in larger spans and bearings than of wood: hence, a framework or roof of iron can be made of simpler construction than one of wood: a smaller number of orders of bearers can be employed, and the principal frames or trusses can be more simple and have greater bearings. The general arrangement of a wooden roof has been followed in iron roofs up to a span of about 50 ft.; there are principal trusses, but they are sometimes 15 and 20 ft. apart; the purlins are consequently stronger, and are sometimes framed, and in roofs that are covered with iron or zinc plates, these are frequently laid on the purlins direct. The facility of forming joints in wrought-iron work has caused other forms of trusses to be adopted, which bring the strains more directly on to the bars composing it. The principle of one of the most common of these trusses is, that the beam or bar representing the principal rafter is supported at one or more points by short struts at right angles to it, the ends of which are connected by a continuous bar or rod with both ends of the rafter; the whole strain which passes down the struts is thus transferred to the rafter, compressing it at each end in the direction of its length: owing to the inclination of the rafter there will be an unbalanced force at the lower end, which must be met partly by the wall or column, and partly by a tie-bar or rod connecting the lower ends of the two rafters or some other intermediate points on the rafters. When this tie-bar is placed at an intermediate

point, a cross strain is thrown upon the principal rafter near that point, as in the case of a collar-beam truss.

When the span of the roof is very large, a curved rib or rafter is frequently used, in which the line of pressure of the forces acting on the roof is kept within or nearly within the rib, and the horizontal force at the springing points is provided for by a tie-bar connecting them. This tie-bar being of comparatively small cross-section for its length, is supported by king or queen rods from the rib; sometimes it is curved, or rather polygonal, consisting of straight pieces between the supporting rods, forming a convexity upwards with the object of gaining height in the centre; in all such cases there is a horizontal force not taken up by the tie-bar, which has to be carried either by the rib or by the walls.

The rafter or rib in iron roofs has generally a T cross-section with the flange uppermost, for the convenience of fastening the upper parts of the structure to it; this, however, is evidently not the most effective cross-section, and consequently large ribs are generally made with an I section. Both sections can be rolled in one piece up to 10 in. in depth and $\frac{1}{2}$ in. thickness of metal, and to a length of 30 ft., without difficulty; above that size they must be built up of flat and angle plates riveted together. Struts are made of wrought iron of T cross-section, and sometimes of two T pieces bolted together flange to flange, forming a + cross-section: sometimes they are of cast iron, in which case they can be made of the best theoretical section, both transverse and longitudinal, to resist compression. Tie-bars are generally rods of a circular cross-section when small, or flat bars when large, any additional required strength in any part being generally obtained by using additional bars of the same cross-section. The same method of obtaining additional strength is adopted generally in the rafters or ribs, in which the thickness of the top flange is generally increased as required, by adding additional flat plates to it. Purlins are generally made either with an L cross-section or a bridge (Λ) cross-section, in both cases for the purpose of fastening other parts to them; for which purpose also the vacant space in each is sometimes filled in with timber. Large purlins are made of timber trussed with iron, or of framed ironwork entirely, and in these cases are sometimes framed in between the principal ribs to gain height and stiffness.

Provision should be made in all large iron framework for expansion and contraction. This is generally done by allowing one end of a truss or frame to be unfixed and free to move horizontally; and to reduce the friction, the bearing surface of the end is sometimes made to rest on iron rollers turning in an iron frame and working in oil: sometimes the end is suspended by or fixed to a short piece fixed to an iron support resting on the wall, which from the action of the two centres of motion admits of a small motion of the whole frame. With short iron beams, such as the girders for small bridges, it is considered sufficient to bed them on lead without other fastening, their own weight being sufficient to keep them in their places.

The bearing surfaces of ironwork are so small that it is impossible to frame them together in any manner depending on those surfaces, as in woodwork. There are two methods commonly adopted for connecting iron bars. 1st, *by large bolts*, which are used when the framework consists of a comparatively few pieces of large cross-section. It is an advantageous method when the bolts are so large that their efficient manufacture can be depended on. 2nd, *by rivets*, which are used when the pieces consist of comparatively thin plates, and are connected by a large number of small bolts called rivets. The joints in ironwork are always the weakest part of the structure: no joint has ever been used, except welding, of which the strength is at all equal to that of the solid part of the pieces joined: then, the manufacture of small bolts cannot be depended on, consequently at the parts of the framework where the greatest strain occurs, the material is weakest; and as those are the points on which oxidation is most likely to occur, it may be expected that the joints of ironwork will give way in course of time before the solid parts of the bars themselves. Therefore, when bolts are so large as to become bars, it is advantageous to use that method; otherwise there is an advantage in riveting, because there is a greater number of individual connections at one joint, and a rivet being hammered in red hot is a more effective connection than a bolt fixed cold, the pieces lie closer together, and upon the whole there are generally fewer separate joints in the whole structure when rivets are used.

2083.

Bolts which are subject to a shearing strain, as in Fig. 2083, should not have to bear more than 4 tons to a square inch of each section liable to be sheared. If fixed as in Fig. 2083 it is considered as having six shearing sections, and would therefore bear 24 tons per square inch of cross-section of bolt.

Bolts which are subject to direct tensile strain, as in Fig. 2084, should not have to bear more than 5 tons to a square inch on the cross-section at *ab*, or 4 tons a square inch on the cross-section of which *cd* is the depth, and the circumference of the bolt is the length, which is subject to shearing strain. Consequently, if the bolt is of equal strength throughout, *cd* must be equal to $\frac{1}{3}\pi ab$.

Screw bolts, which are subject to direct tensile strain, as in Fig. 2085, should have heads of double the depth of common bolt-heads, because it is estimated that half the resistance to shearing is lost by weakening the metal by the thread of the screw. Consequently, if the bolt is of equal strength throughout, the height of the head or of the nut should be equal to the diameter of the bolt.

2084.

The diameter of the nut is generally twice that of the bolt itself; but evidently the part *c g*, Fig. 2084, should not be subject to a greater pressure per square inch than the safe crushing strain of the metal.

Links, that is to say, two or more flat bars connected together by a bolt passing through their ends, and subject to tensile strain, should have those ends enlarged, as in Fig. 2086, so that the sum of the areas of the cross-sections *a c* and *b d* shall be equal to the area of the cross-section of the body of the link. The end is also subject to a shearing strain on the sections *a e* and *b f*, the areas of the cross-sections at each of those two points should therefore be calculated so as to have a strain of not more than 4 tons a square inch on them. Also, the compressible strain on the surface *a g b* should not exceed 5 tons the square inch.

Rivets.—The dimensions of rivets and of the plates at the joint may be calculated by the same rules as for single bolts. If it is a joint subject to tension, as in Fig. 2087, the effective strength of the joint and of the plate is the resistance of the cross-sections *a b* and *c d* to tension, and of the cross-sections *b e* and *c f* to shearing. If it is a joint subject to compression, as in Fig. 2088, the effective strength is the resistance of the section *g h* to compression. Hence, in a *tensile lap joint* the size of the rivets should be as small as possible, and the sections of the parts *a b c d* as large as possible; and in a *compressible lap joint* the size of the rivets should be as large as possible.

Lap joint is the name given to a riveted joint when the plates overlap each other. In a *single rivet lap joint*, as in Fig. 2089, the whole tensile or compressible strain being divided amongst the spaces between the rivets determines the interval of them. And the whole shearing strain being divided amongst the sections *a b*, *c d*, &c., determines the amount of overlap. Fairbairn considers that the strength of such a joint under tension is only 0.56 of that of the solid plate of the same general cross-section.

In a *double rivet lap joint* the amount of overlap and the intervals between the rows of rivets both ways, and the size of the rivets, are all determined by the above considerations, and by the rules for bolts. Fig. 2090 shows the joint recommended by Humber for tensile strains.

Fig. 2091 shows the joint he recommends for compressive strains.

In practice the diameter of the rivets is generally made a little more than the thickness of the plate, and the interval is from 2 to 4 times the diameter, according to the closeness of the joint required.

The practice in H.M. Dockyard at Chatham, in the construction of iron ships, is to use rivets rather larger in diameter than the thickness of the plate, and at intervals from 2 to 4 times the diameter. Thornton states that a water-tight joint can be formed with single riveting at intervals of 4 diameters; double riveting is commonly used, the first row being placed at a distance of at least one diameter (of rivet) from the edge of the plate, and the second row at about 3 diameters from the first. These rules determine the length of what is called the butt-plate, or fishing-piece. The rivets in the second row are placed directly opposite those in the first row, and not diagonally opposite the spaces. In all exterior plates the outer rivet-holes are countersunk and the rivets hammered flush.

Bolt-nuts are generally made in depth equal to the mean diameter of bolt, and india-rubber washers of about $\frac{1}{2}$ that thickness are used with bolts through thick plates.

The experiments in the testing-house of Chatham Dockyard show that if the total area of the rivets is equal to the area of the cross-section of plate at one row of rivet-holes, the strength of the rivets to resist shearing will be greater than that of the plate to resist tension; also, that the punching of holes in steel or hard iron injures the metal round the holes, so that the plate is considerably weakened at that part. Rivets with hammered heads are more liable to leak than with heads rounded in a swage, and the latter than countersunk conical heads: countersinking should always be drilled; and rivets fixed cold are tighter than those fixed hot.

The following extracts from the Regulations of the Society of Underwriters at Liverpool for Iron Ship Building show the practice in that trade for riveting plates:—

		Sixteenths of an inch.													
Thickness of plates		5.	6.	7.	8.	10.	12.	13.	14.	15.	16.				
Diameter of rivets		8.	10.	12.	13.	14.	15.	16.	18.	19.	20.				

Rivet-heads should be thin, and rivet-necks, under the heads, should be bevelled to fill the countersink formed in punching. All riveted seams and butts to be laid up quite close, so as to prevent the introduction of the thinnest knife used for trying riveted work.

Every hole requiring to be countersunk must be countersunk quite through the plate. Each rivet to fill the hole and to be laid up close round the head, and when finished to be flush and fair, neither projecting above nor sinking below the surface of the part through which it passes.

All double riveting to be in parallel rows, or what is termed chain riveting. All butts to be double riveted. Breadth of lap in seams and butts, for double riveting, to be $5\frac{1}{2}$ times the size of the hole punched. Rivets to be 4 diameters apart, from centre to centre, longitudinally in seams and butts. Rivets in framing to be 8 times the size of the hole punched, apart.

Iron decks to have their butts treble riveted amidships.

Extract from Lloyd's Rules.—Rivets not to be nearer to the butts or edges of the plating, or of any angle iron, than a space not less than their own diameter, and not to be farther apart from centre to centre than 4 times their diameter, or nearer than 3 times their diameter. In single riveting the overlap is not to be less in breadth than 3 times the diameter of the rivets. No rivet to be less than $\frac{1}{2}$ in. in diameter.

TABLE OF THE WEIGHT OF ROOF COVERINGS AND THE SLOPE FOR THEM SUITABLE FOR THE ENGLISH CLIMATE, FROM TREDGOLD.

Material.	Weight a square of 800 sq. ft.		Slope.
	lbs.		
Ordinary slates		500 to 900	26 $\frac{1}{2}$ °
Large slates		1120	22°
Plain tiles		1780	50°
Pantiles		650	50°
Thatch		same as slates	45°
Copper		100	3° 50'
Lead		700	3° 50'

The weights here given include the covering and the immediate bearers underneath, but no rafters or other framework. An allowance for the pressure of wind and snow must be made in addition. Tredgold recommends that the former should be calculated at 40 lbs. a square foot of horizontal pressure on a vertical surface.

Floors.—Under this head we include all kinds of floors and pavements of stone and wood, both the framework and the floor covering. The technical builder sometimes includes under the name flooring only the boards or covering; but it is evidently more correct to treat under one head all the parts of those platforms which form the living places in houses, of whatever material they are.

The same general principles of framing apply to all floors of wood framing as were applied to roofs; being simplified in the case of floors, because they are almost always flat. The problem in floors of this class is to provide the smallest number of bearers that will carry an effective floor covering with the greatest economy and stiffness.

Single Floors.—The simplest description of wooden floor, when there is only one order of bearers supporting the boards, is technically called a *single floor*, and the bearers are called *joists*. Tredgold recommends that single joisting should not be applied to a bearing above 15 ft., on account of the deflection, which then becomes so great as to be inconvenient. As a joist has only to bear perpendicular transverse strain, the deeper it is the better; but such beams have a tendency to buckle or turn over on their sides, and to counteract this, they should be strutted against each other; such strutting may be composed of short pieces of wood nearly the depth of the joists, and fitted in at

Girders.— $d = 4.2 \sqrt{\frac{l^3}{b}}$, the central interval of girders being assumed to be 10 ft.

Bridging Joists.—The same rule as for common or single joists.

Ceiling Joists.— $d = 0.64 \sqrt{\frac{l^3}{b}}$, the central interval of joists being assumed to be 10 to 12 in.

In this case the formula is the same as that for deflection; hence Tredgold has apparently assumed that the actual amount of deflection should be the same in all ceiling joists.

Wall Plates.—

For a 20-ft. bearing	$4\frac{1}{2} \times 3$ in.
" 30-ft. " 	6×4 in.
" 40-ft. " 	$7\frac{1}{2} \times 5$ in.

Floor Coverings.—Almost the only kind of covering used in England for floors of wooden framework is of boards. The thickness of floor boards is a practical rather than a theoretical consideration; they are destroyed chiefly by wearing away, and for the economy of replacing them comparatively thin boards and close bearers are better than thick planks and open bearers, as in the deck of a ship. They are seldom thicker than $1\frac{1}{2}$ in.; this is a necessary thickness for barrack-floors which are soon worn away: common house floor boards may be 1 in. and $1\frac{1}{4}$ in. thick. The narrower in breadth the boards are the less danger there will be from shrinking after they are laid; to guard against this, the floors of important rooms are laid with boards, about 6 in. wide, technically called *battens*; more common floors are laid with yellow deal boards, 9 in. wide. It is evidently of great importance that they should be of straight-grained, clean and sound and well-seasoned timber; and to provide for this as far as practicable, they should be brought on the ground and wrought and stacked at the commencement of a new building, and if possible a new floor covering should be laid in its place without being nailed down for at least a year. As a part of the strength and elasticity of the covering depends on the length of the boards, the more completely the ends of them break joint in the several courses of boards the better for this object; therefore, it is advantageous to lay the boards along the room and not across it, as in the former case the joints can be more efficiently broken and the whole floor laid without cutting the timber to waste so much as the latter would require.

The upper face and all the edges of floor boards are wrought, that is, planed to a smooth even surface.

There are four ways practised in laying floor boards, in each of which each board is laid and fastened separately.

1. *Square edged.*—That is when the boards are simply laid close together without any connection between two adjacent boards, and are fastened by one or two nails driven straight through the boards into the joists; there is therefore a line of nails over every joist. The longitudinal joints run in straight lines from end to end of the room; the transverse joints, formed by the ends of the boards, are broken as much as possible. In this method the slightest shrinkage of the boards leaves an open joint to the ceiling of the room below.

2. *Rebated.*—That is when a rebate is cut on one longitudinal edge of the boards, and a corresponding but reverse rebate on the other longitudinal edge, the adjacent boards thus overlapping; the nails may be driven obliquely through the rebates of the outer face before the next board is laid, by which no nails will be visible. This is called *edge nailing*.

3. *Rebated and Filleted.*—That is when a similar rebate is cut on each edge, on the under-side, leaving between two boards laid together a square groove below, which is filled with a small piece called a *fillet*. The rebate in this case need be only half the width of that in the last case. From the facility of making this joint and of repairing it, it is generally adopted in barrack-floors. The boards are generally *face nailed*, that is nailed straight through the breadth into the joists, with two nails to each crossing of a joist. But they may be both face and edge nailed, one nail being driven into the face and one into the edge at every crossing of a joist.

4. *Ploughed and Tongued.*—That is a narrow deep groove is cut in each longitudinal edge of each board, and a thin strip of hard wood or of hoop iron is inserted into the outer edge of the first board, and is pressed into the groove of the next board. The boards are generally face nailed. Sometimes dowels or pins with corresponding holes in the edges of the boards are used instead of continuous tongues, and then the boards may be edge nailed.

Warehouse floors require thicker floor covering than ordinary floors, on account of the heavy traffic and liability to shocks; consequently, the bearers or joists may be farther apart. On account of the wear, oak or some hard wood is frequently used for these floors.

French floor coverings are generally of ornamental parqueterie or inlaid woodwork, the climate not requiring the constant use of carpets as in England. The parqueterie is laid on ordinary rough boards on framework, and as a large bearing surface is desirable with this kind of covering to prevent injury to the inlaid work by deflection as much as possible, the joists in French floors are generally broader than in English floors.

Fireproof Floors.—One of the greatest preventatives to the spread of fire in buildings is lime; a wooden floor well cased in mortar on all sides will resist a considerable action of fire; but the difficulty of thoroughly casing timber in mortar and of preventing its decay has checked the application of it to these purposes. The introduction of cast-iron beams was the first step towards thoroughly fireproof floors, for they can be made of such size and shape as to be convenient and effective for the support of brick arches between them. Many floors have been made, and some are still made with cast-iron girders and brick arches between them. The limit to the interval and consequently to the size of the beams or girders is that the brick arch shall be just strong enough to carry itself and any load that may come upon it, and that the total quantity of iron in the floor shall be the least possible. With arches of one ring of common bricks, that is $4\frac{1}{2}$ in. deep, a span

of 6 or 7 ft. is found to be most effective. The use of cast iron admitted the employment of girders of uniform depth, which is advantageous in floors, the requisite strength in the different parts of the length of the girder being obtained by varying the size of the bottom flange.

The exposed ironwork on the under-side of this kind of floor causes a condensation on it from the moisture in the atmosphere of the room below, which not only rusts the iron, but forms lines of droppings on the floor below each girder. A more serious defect is that the exposed ironwork becoming readily heated by fire is very easily cracked by the sudden contraction caused by throwing water on it; the fall of several floors from this last defect led to the more general use of wrought-iron girders.

The facility with which wrought iron can now be rolled into various forms of bars suitable for these constructions has tended to increase the use of them in floors generally. The same advantages of elasticity and strength and favourable arrangement of metal in the cross-section, which rendered the application of wrought iron so efficacious in roofs, tells equally in its application to floors. It is seldom necessary with wrought iron to use more than single joists; sufficient stiffness can generally be obtained by increasing the depth of joist or girder, or by using box-girders. As rolled-iron joists or girders must necessarily be of the same size throughout, there is a waste of metal in them. They are now rolled solid direct from the rolls of all forms of rectangular flanges up to about a foot in total depth. When they are of double flange or I section, they can be used as girders to support the wooden joists of common floors, or as girders to carry brick arches turned between them and resting on the bottom flanges. Another method of using them, which is now commonly adopted for fireproof floors in England is that generally called Fox and Barrett's plan. The iron joists in this method are placed at about 2 ft. apart, and small fillets of wood about 1 in. or $1\frac{1}{2}$ in. square are laid across between the joists resting on the bottom flanges, and with intervals of $\frac{1}{4}$ to $\frac{1}{2}$ in. between them: a temporary platform is erected close under the bottom flanges of the joists, and a fine concrete made with good lime is poured in from above, passing through the intervals between the small fillets and forming a key or tongue below. The total thickness of the concrete must depend on the circumstances of each case: sometimes the concrete is filled in up to the level of the top flanges of the iron joists, and small wooden joists are laid in it to carry the floor boards of the room above; sometimes the concrete is laid no thicker than is necessary to resist ordinary fire, and to stop the conduction of sound, for which purposes probably 4 to 6 in. is sufficient; the small wooden joists of the upper floor are in this latter case carried on the upper flanges of the iron joists. To complete the fireproofing on the under-side when the concrete has set, the temporary platform is removed from below and the under-side of the floor is plastered, the projecting tongues of concrete below the wooden fillets forming a key to the plaster, small pieces of wood being fastened to the under-side of the lower flanges of the iron joists to form a key for the plaster over them.

There are several other methods of forming these iron and concrete floors; the general principle of them is all the same. In all the object is to have a thickness of several inches of good cement and to cover the under-side of iron and woodwork with plaster. The coating of plaster underneath both checks the spread of fire and prevents the condensation and oxidation on the ironwork. It is advantageous to have a quick setting lime for the concrete, as the deflection of the framework caused by its weight may affect the efficiency of the floor; when once the lime has set, the concrete adds to the strength and stiffness of the floor by forming a solid block between the joists.

Sometimes it is desirable, either for purposes of traffic or for better security against fire, to cover the floor of the upper room with stone. In these cases the concrete is generally filled up to the top flanges of the iron joists, and a layer of finer concrete or mortar is laid over it, and the stones or tiles are bedded in that.

These descriptions of floors might be advantageously applied to the construction of flat roofs, as they can be increased to a considerable strength and used for spans or bearings up to 30 ft. Above that span it is desirable to introduce another order of bearers, which would generally consist of framed or plate girders of wrought iron. The intervals between the iron joists are sometimes filled up with tiles made expressly for the purpose, both flat and curved; sometimes with thin iron plates. Curved iron plates are recommended by W. Fairbairn, who has written upon these floors, instead of the brick arches between cast-iron girders, the upper side of the plate being filled with concrete. The ends of the iron joists should be laid upon a continuous stone wall-plate extending round the walls; a bearing of from 9 to 12 in. on the wall-plate is sufficient for ordinary floors, and it is only necessary to bed the iron joist on some slightly elastic material, such as lead or some resinous compound, to distribute the pressure uniformly; the friction on the bed will be sufficient security against motion. The ends of large girders should be laid on lead plates resting on stone templates, or on cast-iron beds expressly prepared to receive them, and bolted down in such a manner as to allow for expansion and contraction. Very large girders should have one end bedded on iron rollers, as in the case of large roof ribs, to allow for expansion and contraction.

A further advantage of these floors is that pipes or other arrangements for ventilation can be readily provided for in between the iron joists in the course of construction; or, if box-girders are used, they could be employed for the same object.

Maltese Floors.—A good fireproof floor is commonly made, in Malta and other places in that part of the Mediterranean, of the same construction as the flat roofs, before mentioned. Arched ribs of stone are built across the room from wall to wall at about 4 ft. interval, and having a horizontal surface at top; these carry the ceiling stones, which are, consequently, about 4 ft. long, and are 10 or 12 in. wide and 3 in. thick; they are laid close together without mortar; then stone chippings are laid over them for a depth of about 2 in.; then the flooring stones of the room above are laid; these are from 18 to 24 in. square and 3 in. thick, and jointed with fine hydraulic mortar.

It must be remembered that in Malta there are great facilities for obtaining suitable stones for

this work, and that the stone, when dry and scraped and covered with a coat of warm oil, soon becomes hardened and polished.

Pavements.—In ground floors and in yards and other similar parts of buildings, the flooring is frequently of stone, on account of the nature of the traffic. Such floorings, in England, are generally made of large thin square stones, commonly called *flag-stone*. These stones are in size from 2 ft. square upwards, and from 2 to 4 in. thick. They are generally laid on a substratum of a few inches of concrete, having a bedding layer of fine concrete on the top, and jointed with mortar. Where there is wet of any kind to be dealt with, the lime of the concrete and mortar should be hydraulic. Careful attention to these matters in the laying will save unevenness in the wear, and fracture of the stones afterwards. If the floor is intended to carry off water at any time, the stones should be rubbed on the face and tooled on the edges, and laid, of course, to a slope in the required direction. Tooled-faced stones may be used for ordinary dry floors, and quarry-faced stones for exterior pavements.

Thick paving tiles are now frequently used for ground floors; they should be laid on a bed of mortar on a substratum of concrete and jointed with fine mortar. From the small size and softer material of the tiles, they do not generally form so durable or even wearing a floor as flag-stones.

That which is technically termed *paving* in London is what is used for heavy carriage traffic, and is made with small hard stones, about 9 in. square and 3 in. thick, set together on edge; the stones are dressed slightly to a wedge form, and as the roadway is generally laid with a slight curve, they form a rude kind of arch. Where no hard substratum exists, they should be laid on from 6 to 9 in. of concrete; the stones should be set dry, as close as possible, and grouted with coarse liquid mortar. Granite and siliceous stones form the best paving of this description; lime-stones wear too smooth.

Pavements of Stables.—The requirements in the flooring of a stable are that it should be as level as the necessary drainage will admit of, hard and not too smooth, and impervious to water. Hard-burnt bricks made in a machine so as to be uniform in shape, and chamfered on the upper edge so as to give a rough surface, form perhaps the best flooring for a stable. They should be laid on a few inches of concrete, according to the substratum, and jointed with cement. Granite paving-stones, cut carefully to shape and with an even upper edge, form a good and durable pavement; they should be laid on concrete and jointed with cement.

The pavement of each stall should be laid with a slight slope from each side towards the centre of the stall, where there should be an open drain with a slope to the rear into a longitudinal drain running along the outside of the heel-posts. The best construction for these open drains is to cut a broad shallow channel from 6 in. to 12 in. wide in a solid stone, and lay these stones very carefully to the required slope of the drain. There should be no covered drains inside a military stable.

The *terrazza* floors used in Italy at the present day are made in the following manner:—1st coat; a concrete consisting of common lime $\frac{1}{2}$, sand and fine gravel $\frac{2}{3}$, laid 6 in. thick and well beaten with wooden rammers; after two days in that climate, it is sufficiently dry for the next coat.

2nd coat; a *terrazza*, consisting of pounded brick or tile $\frac{1}{3}$, common lime $\frac{2}{3}$, sand $\frac{2}{3}$, of the consistency of mortar, laid $1\frac{1}{2}$ in. thick, well beaten with a light flat rammer. After two or three days it is hard enough for the next coat.

3rd coat; a similar *terrazza*, but with the grit of broken stones instead of sand in it, laid on like a coat of plaster with a trowel. After this has been laid for one day, a layer of small hard broken stones is pressed into it; these stones should be of some substance that will take a polish, and be of uniform size (they are passed through a gravel screen) of about a walnut; these being afterwards rubbed to a smooth even surface with some smooth hard stone, form a kind of mosaic-work; the stones are frequently selected by colour, and laid in the third coat to a rough pattern. They should be moistened with oil or water till hard set.

The French use these concrete floors both on the ground floor and upper floors: in the latter case on boards and joists. When on the ground floor, it is made with *beton* 0^m·15 to 0^m·20 thick; when on boards, it is 0^m·5 thick, and is made with plaster of Paris.

Asphalte floors are now commonly used in England for light traffic. The asphalte is formed and laid very similarly both for floors and roof coverings; but for floors the mixture is coarser and thicker. When applied to a floor, a foundation of common coarse concrete is laid 3 or 4 in. thick, according to the traffic; on this, when set, a thin layer of fine concrete is laid with a very even surface, and when this is quite dry, the cakes of asphalte are melted, and a layer of it, about $\frac{1}{2}$ in. thick, is poured on with ladles and reduced to an even surface by hand with a small board. The whole area is laid in breadths of about 3 or 4 ft. at a time, each ladleful being enough to cover that breadth of 3 or 4 ft. for a length of about 18 in. The liquid asphalte is kept in its place by strips of wood along the edges; thus there are series of joints or seams all across the area covered, which are parts liable to cracks and leaks; therefore, in floors and roofs where it is a matter of importance to keep out the damp, it is desirable to have two layers of asphalte, the joints of the upper layer occurring over the spaces of the lower layer. For light foot traffic, or for the protection of the asphalte against the sun, coarse sand is sprinkled over it while it is soft; for heavier traffic, it is necessary to mix grit or broken stone with the asphalte before laying it on, and to lay it 1 in. thick and upwards.

It is very necessary that the layer of fine concrete should be quite dry, otherwise the hot asphalte will convert the moisture into steam, and cause blisters on its surface.

The disadvantages of an asphalte floor are, that its general low temperature makes it a cold floor, and by condensing the moisture of the room on it, a damp floor; and that it is liable to crack and become broken in holes, and is difficult and expensive to repair.

Tar Pavement.—This is a mixture of tar, chalk or lime, and broken stones or sand. It is a concrete more or less fine, according to the traffic of the roadway on which it is to be laid, and in

which tar and lime or chalk take the place of the lime and sand of ordinary concrete. It is too soft, especially in hot weather, to be applicable to heavy carriage traffic; but for light carriage traffic and foot traffic it makes a good and tolerably durable road covering. For carriage traffic the stones should be about the size used for macadamizing; they should be coated with or soaked in tar, and then mixed on the road with the tar and lime or chalk. A coating of sand should be strewed over the surface while the tar is soft, and the road should be well rolled. In forming a pathway, a layer of the tar pavement made with small broken stones should be laid down first, and over that a layer made with sand; the surface should be strewed with sand and well rolled.

Weight of Floors.—Tredgold gives the following Table of the weight of ordinary wooden floors;—

	lbs. a square of 100 sq. ft.			
Single-joisted, without counter-flooring	1260	to	2000	
Double-framed floor, with counter-flooring	2500	„	4000	
Wooden partitions	1480	„	2000	

It is evident that these weights are intended to include the ordinary moving weight which the floor of a common living room would have to support; for it has been ascertained by experiment at Chatham that the weight of soldiers standing in the ranks, armed and accoutred, is about 56 lbs. a square foot, which is as much as the floor of an ordinary living room would be exposed to. The weight of men unarmed and packed as closely together as conveniently practicable, and which is the heaviest moving weight a floor could be subject to, except, perhaps, of some exceptionable carriage, is 110 lbs. a square foot. The weight of corn stacked on a floor in bulk and 10 ft. high, is 500 lbs. a square foot, and that is the heaviest weight the floor of a general storehouse is ever likely to be subject to, for it is assumed that such articles as guns, shot, and heavy gun-carriages and platforms would be placed on the ground floor of a storehouse. Corn, however, is seldom stacked more than 4 ft. high.

Doors, Windows, and Stairs.—The great difference between the principles of the framing of large timbers required in roofs and floors, and the joining of small pieces to form doors and windows, and such like fittings, is that in the former the main object is to direct and resist great strains; in the latter, the main object is to make close-fitting joints and smooth surfaces. This difference between the two systems has caused this trade in England to be divided into two branches—the carpenter proper, and the joiner; the former dealing chiefly with heavy framework and rough timbers, the latter with fine woods in small pieces fitting nicely together. The joiner uses finer kinds of wood, more carefully selected and better seasoned.

In all kinds of joiners' work one of the chief objects is to reduce the framing into narrow pieces of wood, so that the work may not be sensibly affected by the shrinking; for timber in joiners' work, however well selected, is almost certain to contract when exposed to the constant dry warm atmosphere of a living room, and the chief shrinkage is laterally, and not longitudinally. Therefore panels of framing for doors, and the like, should not be more than 15 in. wide and 4 ft. long. Woodwork in joinery is connected together generally by mortices and tenons. The tenons and mortices should be very truly made, or there will be a danger of one of them splitting when the parts are brought together; tenons should be about $\frac{1}{4}$ the thickness of the timber, and their width should not exceed five times the thickness, otherwise they are liable to bend or warp; therefore, with wide pieces of timber, two tenons and mortices should be made. Sometimes pieces of wood in joinery are *keyed* together with small wedge-shaped pieces of hard wood, as in the curved ribs of small arches. Tredgold recommends screw-bolts in preference. Sometimes pieces are framed together with *dovetailed* joints, as in the sides of boxes: the dovetailed mortice and tenon-joint, which is disadvantageous in large framework, is useful and effective in joinery.

Doors.—The door and the door-frame are two distinct parts of this *house-fitting*. The door-frame consists essentially of four pieces, two vertical pieces, called stanchions or posts, and a top sill or lintel, and a ground sill. For external doors, the posts are generally of solid timber cut with a rebate on the inner faces for the door to shut against; the top sill or lintel is almost always of solid timber, as even if it has no superincumbent weight to carry, which it should not have, the stability of the door depends much on the bonding of the top sill into the wall. The ground sill is generally of hard wood or stone, in order to withstand the wear of the traffic. The framing together of these four pieces is done in the manner of ordinary carpenters' framing, and the timber is generally wrought or planed. It is fixed in the reveal constructed in the wall to keep the wind and rain from passing between the frame and the wall; hence an external door always opens inwards, an arrangement suitable both for convenience and defence. The frame of an internal door may be made in the same manner as that of an external door, and set in a reveal in the wall; but it is usual in ordinary houses to line the whole of the door opening in the wall with wood for the sake of appearance, and the vertical and top pieces of this lining are used as the posts and top sill of the door-frame; hence an internal door-frame is a kind of box, the pieces of which are dovetailed together, and are thick enough to allow of a rebate being cut in them for the door to shut against. As the efficiency of a door-frame depends more on its stiffness than its strength, the scantlings should never be very small; probably 3×3 in. is the smallest cross-section that should be given to any solid door-frame; and a barrack solid door-frame should be 4×4 in. An internal door should be flush with the wall of the room it leads into, and should open into the room.

The door itself is composed of a frame of four or more pieces, consisting of two vertical, called *styles*, one horizontal at the top and bottom, called the *top rail* and *bottom rail*, and one or more intermediate horizontal pieces, called the *lock rail* and *frieze rails*, and sometimes an intermediate style to reduce the breadth of the panelling. According to the mode of filling in this framework, the door receives its technical name. The rails are framed in between the styles with common

mortices and tenons, driven up tight with little wooden wedges. The intermediate styles are framed in between the rails. The filling in is sometimes of boards or battens nailed against the framework, or let in flush with the framework on one side; this method is generally used with common doors, as for barrack-rooms, and is called a *framed and batted door*. Sometimes the filling in is of thin panels of wood morticed into the frame with a continuous groove all round; this is used with doors of more important rooms, and is called a *framed and panelled door*. It is the strongest description for ordinary purposes. In large batted doors a diagonal brace is sometimes introduced, extending from the upper outer corner to the lower inner corner.

The thickness of the framework determines the strength and weight of the door; 2 inches is sufficient for the framework of barrack-room doors, and $1\frac{1}{2}$ in. for common living-room doors. The width of the framework is more a question of appearance. Tredgold says it is commonly about $\frac{3}{4}$ that of the panel. The lock rail is generally wider than the others.

The mouldings and ornamentation of doors are questions almost entirely of appearance, and not of construction. Sometimes the panelling is flush with the framework on one side, and therefore sunk on the other; sometimes a double panelling is inserted, so as to make them flush on both sides; sometimes the edges of the sunk part are square, and sometimes moulded. That moulded woodwork, which extends round the door-frame or door-opening, and which is commonly called the architrave, is chiefly for effect, its only constructive use being to form a stop or finish to the plastering of the wall, covering its junction with the door-frame.

Panelling.—There are several other fittings in the interior of houses which are made by the joiner, such as skirtings, door and window linings, shutters, wainscoting, and so on. Most of these are constructed of a framework filled in with boards, and therefore the principles of the construction of doors apply to almost all of them. A *skirting* is the kind of plinth or base, generally of wood, which extends round the walls of a room at their junction with the floor; its constructive object is to cover the junction of the floor with the walls, but for the sake of effect is commonly enlarged much beyond the requirements of that purpose. It consists commonly of a wooden board framed to battens fixed to the wood bricks built for this object into the wall. The battens are called *grounds*. They should be carefully fixed, as on them depends the accuracy of the finished work. The boards of the skirting, as in the case of all panel-work, should be so fixed as to allow for expansion and contraction without splitting. Tongueing and grooving is the best method for this object; one side of a skirting board may be fixed, and the other let in with a groove and tongue.

In barrack-rooms a skirting is frequently made with a flat wrought-iron bar fastened to the floor; this would not be sufficient in rooms the walls of which are liable to be injured by the feet of the inhabitants.

Window and door linings and shutters and wainscoting are constructed on the same principle as doors, with framing filled in with panelling. The linings and wainscoting are fixed to grounds, the shutters are hung to the window or door frames. Wainscoting is the term applied to the lining of walls with woodwork, because when it was generally used, before plastering was much adopted, the commoner kind of oak, called wainscot oak, was used for it. *The lining of walls* and other parts of houses may be made with boards laid like those of a floor. The framework, when there is a masonry wall, need consist only of battens fixed to that wall at intervals of about 2 ft. The principles of laying floor boards apply also to lining boards; they should be narrow, and grooved and tongued or filleted, and it is more convenient and economical to lay them horizontally than vertically. With walls composed entirely of wood-framing the vertical posts should be at about 1 ft. apart, in order to prevent as much as possible the warping of the boards; the boards should be of well-seasoned timber, to reduce as far as practicable the inevitable shrinking which takes place in timber exposed to the warm dry air of rooms. The exterior covering of such wooden walls is frequently made of boards; but in order to carry off the rain, it is necessary to lay them horizontally and with a small overlap. This is done either by cutting a kind of rebate in the lower edges of the boards, the shoulder of which fits on to the upper edge of the board below, or by bevelling the inner face of the lower edges, and the outer face of upper edges, so as to avoid a great projection. An overlap of $\frac{3}{4}$ in. is sufficient if the timber is good and properly fixed.

Windows.—There are two ordinary methods of arranging the opening of windows, requiring two kinds of construction.

1st. *The sliding sash*, in which the window slides vertically up and down in its frame, being counterbalanced by two weights, one on each side, moving in boxes made in the frames and connected with the windows by cords passing over pulleys at the top. This is the method commonly used in England, and is the most effective one in climates of much wind and rain. There is a window-frame, just as there is a door-frame, for the windows to work in, and this is made of four pieces, like a door-frame, two side pieces, a top sill, and a bottom sill. The side pieces, instead of being solid, consist of the boxes before mentioned, or *cases* as they are called, made of thin boards, the sides of which project slightly towards the window, forming a kind of groove for the window to slide in. The top and bottom sills are cut with a rebate for the window to shut against, and the bottom sill is *weathered*—that is, sloped on its upper surface, to carry off the rain. The bottom sill is generally of hard wood, on account of its exposure to wet, it rests on the stone sill. The frame is made by the carpenter, and fixed in its place by the mason or bricklayer.

The window, or *sash*, as the joiner calls it, is made like a door, of a frame of four pieces, two styles and two rails: they are put together on the same principles as in a door; the intermediate pieces to hold the panes are called *sash-bars*; the vertical sash-bars extend continuously from top to bottom; the horizontal bars are framed in between them. The bars and frame-pieces are cut with a rebate on the outer sides, forming a shoulder against which the glass is laid; the under-side of the bottom rail is bevelled to fit the weathering of the bottom sill of the window-frame.

When the window is in two separate pieces, or is *hung double*, having an upper and a lower

sash, each piece is hung separately to a pair of counterbalancing weights; the upper sash slides downwards to open, and the lower sash slides upwards, the upper one being placed outside the lower one for this object partly. The *meeting rails* of the two sashes are cut with a bevel on the inner and outer edges respectively, in order that they may fit quite closely when shut.

The size of the panes or intervals of the sash-bars are determined by the most convenient and economical sizes of glass which can be obtained. The pulleys of the counterbalancing weights are generally made of brass, and the weights of lead, and the cords of a small white rope called sash-cord. The only other fastening required is one connecting the two meeting rails together, which should be such that when open it shall not interfere with the movement of the sash; it is partly for convenience of arrangement of this fastening that the upper sash is placed outside the lower one.

2nd. Casement Windows.—The second method of opening windows is that generally used on the Continent, of hanging them with hinges to the frame to open like a door. It is very difficult to keep out the weather with this method. The window-frame is in this case solid, and is cut with rebates on the side pieces and sills for the windows to shut against, otherwise the frame is made on the same principles as a door-frame. The window is generally divided in two parts or *leaves* vertically, like a folding door, in order to reduce the breadth of the moving part. Each part is made of a frame of four pieces with sash-bars; but in this case the horizontal bars should extend continuously through, and the vertical bars should be framed in between them. Several different methods have been proposed of forming the rebates and the junction of the two centre styles, with the object of effectually keeping out the rain and wind; the most effective appears to be to make a curved groove in one part, and a corresponding curved tongue or projection on the other, so as to fit close to each other when shut.

Besides the hinges, a fastening similar to a door lock and bolts are required for this window.

Another method of arranging the opening of a window, common in factories, is by swinging it on two horizontal pivots in the side styles, a little above the centre of their height, so that it is opened and shut by means of two lines, one from the top rail and one from the bottom, the upper part opening inwards and the lower part opening outwards. This is, therefore, an advantageous plan for windows out of ordinary reach of hand. The horizontal sash-bars in this window should extend continuously across, and there should be a centre rail to hold the two pivots. It is easier to make this window water-tight than the casement window, because a rebate forming an effective stop can be put in the inner side of the top part and the outer side of the bottom part. It is not applicable to large windows, on account of the strain from the mode of hanging.

The weight and strength of a window depends much on the thickness of the woodwork, as in the case of a door; $1\frac{1}{2}$ in. is a suitable thickness for an ordinary barrack-window. The sash-bars are generally the same thickness as the frame.

Skylights.—This is the name given to windows formed in the roof of a house, and more or less corresponding to the slope of the roof. The difference between that and the ordinary vertical window is, that being on a slope the framework must be stronger to resist the greater transverse strain, and that the glass must be fixed in such a manner as to allow the rain to run off. Skylights in general are not made to open; when they are required to open, it adds considerably to the difficulty of construction. In order to carry off the rain, all the sash-bars should lie down the slope of the roof, and the glass panes should overlap each other like slates, without any cross-bars. The panes are kept in their places by the friction and putty in the grooves cut for them in the side sash-bars, and by small metal clips suspending the bottom of one pane to the top of the one below it, the bottom panes of all being sustained by nails or clips to the bottom rail. To connect the sides of the skylight together, iron rods or bars are passed through the bars horizontally. The frame of a skylight is fastened to the beams of the roof, and should project 3 or 4 in. above the roof covering. The styles and rails of the skylight itself should project over the frame, and have a deep rebate cut in or a projecting piece fastened on to the outer edge to close over the frame. A lead flashing should be laid round the outside of the frame and under the roof covering on all sides. When the skylight is required to open, the woodwork should be stronger and the rebates or projecting stops deeper, and a strip of lead should be laid round the styles and rails hanging down over the lead flashing on the sides of the frame.

The panes should be so wide that the sash-bars will necessarily require to be of considerable depth to carry their weight, and thus become in fact descriptions of rafters; by which arrangement an additional system of bearers will probably be saved. They should also be of a size that will allow of an economical division of the sheet of glass of the ordinary dimensions of which the particular glass used is made, and not too large to be expensive in renewing.

Dimensions of Doors and Windows.—**Doors.**—The minimum width for a door of a living room is that through which a man can conveniently pass; that is to say, about 2 ft. There are few internal doors less than 2 ft. 9 in. in width; those of the soldiers' barrack-rooms in Brompton Barracks are 3 ft. 7 in.; they are too large for one man and too small for two, and form very heavy doors. Those of the single officers' quarters are 3 ft. 3 in. wide, and are large and heavy doors. When doors are required to exceed 3 ft. in width, it is better to hang them in two leaves, meeting in the centre, or *folding*, as it is technically termed, in order to reduce the weight of the door. The weight of a door, besides being a question of convenience, is often a cause of injury from the strains caused by it. The exterior doors of the soldiers' houses in Brompton Barracks are 3 ft. 10 in. wide, and *hung folding*. They are sufficiently wide to allow two men to pass, which should be the case with all exterior doors of soldiers' quarters. The minimum height for a door of a living room is 6 ft. 3 in., but barrack-room doors should be 7 ft. high, to allow for the passage of soldiers with their chacos on. Those in Brompton Barracks are 7 ft. 7 in. high. The exterior doors of barracks should be 8 ft. high, to allow soldiers to march in or out with bayonets fixed.

The following extract from Chambers on Decorative Architecture and from Renaud show the dimensions of doors, recommended by those authors on the double grounds of convenience

and beauty of proportion. The dimensions of doors are measured from *out to out* of the door itself.

General dimensions for breadth of doors;—

	Minimum.			Maximum.	
	ft.	in.		ft.	in.
Internal doors	2	9		3	6
External doors	3	6		6	0
Doors " for churches	6	0		12	0
Gates	9	0		20	0

(From Rickman's 'Gothic Architecture');—

Gothic (decorated) doors, height to crown equal $2\frac{1}{2}$ times the breadth.

(From Renaud, 'Cours d'architecture');—

	Breadth.		Height.
	Below.	Above.	
Doors of the Erechthæum Temple, Athens ..	2.44	2.35	5.21 mètres.
Palazzo Massini (Rome, Peruzzi, 1500) ..	2.170	2.170	4.64 "

The heights of doors vary from 2 to $2\frac{1}{2}$ the breadths.

Windows.—The width of a window between the frame is generally a question of appearance and of the distribution of the light in a room; the maximum limit, as far as construction is concerned, being that which can be conveniently opened.

The following extracts from Chambers and Renaud give the principal considerations, as far as appearance is concerned, for the dimensions of windows.

Dimensions of Windows.—Palladio agrees with Vitruvius that the height between the floor and the ceiling should be divided into $3\frac{1}{2}$ parts, and that the height of the window should be two of those parts and the breadth $1\frac{1}{2}$ part.

Vitruvius says the breadth of windows should be from $\frac{1}{2}$ to $\frac{1}{3}$ the breadth of the room, and the height $2\frac{1}{2}$ times the breadth.

James Morris' rule for window-space;—The total area of light = $\sqrt{\text{cubic content of room.}}$

Chambers' rule;—Breadth of window = $\frac{1}{2}$ (breadth + height of room).

The window-sill should be at such a height from the floor as will enable a person to lean on it. The breadth of the windows in upper stories should be the same as those of the lower stories. The breadth of the interval between windows should be from 1 to 2 times the breadth of windows; the end interval should be at least equal to breadth of window. Palladio says the jambs (or reveals) should be from $\frac{1}{4}$ to $\frac{1}{2}$ breadth of window.

From Renaud;—

	Breadth.	Height.
Windows in the Louvre, Paris, P. Lescot	1.955	4.557 mètres.

From Rickman;—Gothic decorated windows; height to crown equal $2\frac{1}{2}$, $2\frac{1}{4}$, and $2\frac{1}{3}$ times the breadth.

The heights of windows vary from 2 to $2\frac{1}{2}$ times the breadths.

These rules give windows of greater width than is convenient for opening in one piece, but the practice in modern houses is to employ the large widths based no doubt on these rules for the sake of the appearance, notwithstanding the inconvenience. In the casement window the effect of the great width is quite taken off by constructing the window in two leaves or *folding*, thus forming a broad dividing *style* in the centre. The casement window also admits of the opening part being further reduced in size, by placing a rail or *transom*, as it is called, at a convenient height from the bottom, dividing the window into two parts; the upper part being fixed or opening independently of the lower.

It is an important consideration in barracks to make windows of a size convenient for opening, and for construction and repair; and although it is probably more effective to introduce light into a room through as large area as possible, the purposes of ventilation require a distribution of the openings throughout the walls of the room, and the convenience of the men also requires a general distribution of the window-space. Further, it is recommended by the Sanitary Commissioners that windows should extend as nearly as construction admits to the ceiling, for the sake of ventilation. All these considerations taken together are in favour of employing narrower windows than those usual in modern English buildings, and of obtaining the necessary area of light opening, by increasing the height, at the loss of the ordinary proportion between breadth and height recommended by Chambers and Renaud.

In hospitals and places where light and ventilation are of more importance, the necessary area of light opening might be obtained by a row of small windows near the ceiling, thereby allowing the lower ordinary windows to be reduced to the ordinary proportion between breadth and height.

Stairs.—The following are the technical names for the parts of stairs;—

Flight is the term for one continued series of steps without any break.

Landing is the level flat between two flights.

Tread is the horizontal surface of a step.

Riser is the vertical part between two steps.

Winders are the winding steps round a curve when there is no landing.

Stone Stairs.—The most simple arrangement for the construction of stairs is to build two parallel walls, to carry the ends of the stones forming the steps, and if the width of the stairs is great, to build intermediate parallel walls underneath the steps to support them. In this case the stones are subject to scarcely any transverse strain if they are properly laid. It frequently happens, however, that the arrangements of the house prevent the employment of two parallel walls; in such cases one end only of the stone step is let into the side wall, leaving the other end unsupported,

excepting that the outer and lower edge rests on the inner and upper edge of the stone below; this, theoretically, gives a support to each stone from bottom to top of the stairs; practically there is a certain amount of transverse strain even when extraordinary care is taken with the laying. To ensure a good bearing of the upper stones on the under, the bearing edges are cut with a bevel, which Renaud recommends should be $\frac{1}{4}$ the height of the step; he also recommends the bearing of the step on the wall to be 0m·20 for ordinary steps. When, on account of the arrangements of the house the steps wind round to change their direction, the theoretical support of each on the step below is still greater, and becomes complete when the steps form a continuous spiral stair round a common centre. In this latter case, the inner ends of the stones are sometimes cut with cylindrical heads, which, resting on each other, form a continuous column from bottom to top. Sometimes the inner edges are cut short of the centre, so that they do not rest vertically over each other, but form a kind of inner spiral, leaving a small well-hole in the centre from top to bottom.

In barracks of more than two stories, the steps of the lower story should be of stone, on account of the greater wear upon them. It is desirable that all stairs in barracks should be of stone in order to be fireproof. The stone should not be a limestone or any stone that will wear to a very smooth surface; such steps, after they become slightly worn, are dangerous for men to descend quickly.

Wooden Stairs.—Stairs may be constructed of wood in the same manner as of stone; but for the sake of economy it is usual to take advantage of the elasticity of the material and construct them as follows:—

Two or more strong beams are fixed at the slope determined on for the stairs, framed into the beams of the floor below and into those of the floor above, or into some beams specially provided if there should be a landing. The sloping beams are called *bearers* or *strings*. Their upper edges are cut into vertical or horizontal notches to correspond with the risers and treads of the steps; sometimes boards are fixed to the bearers parallel to and projecting above them, and the notches are cut in them instead of in the beams themselves. The steps are formed with boards, a vertical board for the riser and a horizontal board for the tread of each step; these are framed together with a special tongue and groove joint; the tread-board projects over the riser and is finished with a rounded head or *nosing*. The tread-board is also framed with the riser of the step next above it. The treads of barrack-stairs should be made of hard wood, and be at least 1½ in. thick to withstand the wear; the risers should be at least 1 in. thick: with such dimensions the bearers of an ordinary stair may be about 4 ft. apart.

When there is a landing at some intermediate part between two floors, horizontal beams are fixed in the wall, to carry it and the bearers of the stair; these beams are like the joists of a floor, and are covered with boards in the same manner. When there is no flat landing, but the steps wind round a central well-hole to change the direction of the stairs, a horizontal beam to carry each winding step is fixed into the wall, and framed into one or more vertical posts about the well-hole: these posts are not necessarily supported from the floor below. Or sometimes a curved and winding bearer is specially constructed for this part of the stair. The treads of this part are necessarily wider at the outer end than at the inner, according to the degree of winding. When no wall is close enough to be available, the joists of the landing must be supported by vertical posts from the floor below.

Handrails.—A convenient height for the handrail of a stair is about 3 ft. from the surface of the treads. The upper surface of it should be semicircular and about 2½ in. diameter; it should be continuous without break of any kind from top to bottom of the stairs. The *Balusters* which support the handrail are sometimes also intended to fill up the space between it and the stairs, so as to prevent any one falling through. When for the former object only, as is generally the case in barracks, the fewer balusters there are the better, as they are very liable to injury and so cause expense either to the public or the soldier in repair; for this reason it is better to have a few strong posts well framed into and connected by iron straps with the bearers of the stair. In private houses where the balusters are generally required to fill up the space, the ordinary practice is to make them square wooden bars of small size, and to place iron balusters of the same size at intervals to strengthen the whole structure. But in all public buildings, especially in military buildings, it is desirable to use balusters of a much larger size, and more firmly fixed to the stairs, and at just sufficient interval to prevent children falling through.

Dimensions of Stairs.—*Treads and Risers.*—The proper angle of inclination for a stair, that is, the height of the riser and breadth of the tread, is that which will enable a person to ascend it with the least fatigue. The theoretical rule for determining this originated apparently with the French architect Blondel, and is based on the supposition, that as there is a certain length of pace which is least fatiguing to a man on level ground, there is also a certain interval between the rungs of a vertical ladder which can be ascended with the same ease. Assuming this proposition and assuming the average length of pace and vertical interval of rungs, this equation will then give the breadth of tread for any assumed height of riser in a stair.

$$h = H - \frac{H}{P} P \left\{ \begin{array}{l} H = \text{horizontal distance of each step.} \\ P = \text{vertical height which can be} \\ \quad \text{ascended with equal ease.} \end{array} \right. \left. \begin{array}{l} P \\ h \end{array} \right\} = \text{tread and riser required.}$$

M. Renaud assumes the length of the pace of an ordinary man on level ground to be 0m·64; and that he can ascend a vertical ladder with equal ease when the steps are 0m·32 apart. Consequently by this rule the breadth of any step plus twice its height ought always to be equal to 0m·64. This rule is however not true either theoretically or practically. M. Renaud says that in Paris experience has restricted the height of steps between 0m·11 and 0m·19, which by the preceding rule gives for the breadth 0m·42 and 0m·26. Low steps are not absolutely an advantage, because there

are more of them to rise to a given height. When the total height is considerable the latter dimension is preferable; when it is a stair of one flight only, the former is better. In ordinary dwelling-houses the heights are generally between 0^m.16 and 0^m.17, and the breadths consequently between 0^m.32 and 0^m.30.

The above dimensions correspond very nearly with those used in England in ordinary houses. In Brompton Barracks, Chatham, in the soldiers' stairs, the risers are 7½ in. and the treads are 10½ in., which latter is too narrow for a man to descend rapidly with safety; 12½ in. would be better, though it might make the ascent a little more laborious. The breadth of the tread must be measured from nosing to nosing of step, and the height from surface to surface of tread.

Width of Stair.—The minimum width for the stair of an ordinary house is that which will admit of the passage of a man, that is to say about 2 ft. Renaud mentions a spiral stair of which the diameter was 1^m.20. The ordinary width for a barrack stair is that which will allow two men armed to pass each other conveniently; the barrack stairs in Brompton Barracks are 4' 2" wide, which is not sufficient for two men to pass; 5 ft. would probably be enough. The maximum width for a stair is a question rather of effect than of convenience. The width should be measured inside the balusters.

Size of Flight.—It is not desirable or generally convenient to have a stair between two floors in one continuous flight or even in one straight line with an intermediate landing: considering convenience and effect together it seems desirable to limit the height of one flight to about 7 ft., and to avoid having two flights in one direction.

Lath and Plaster.—The plaster used for covering the walls of buildings is a mortar composed of various kinds of limes or cements, and various descriptions of sand, mixed in various proportions and generally with a little hair or some such material to give it a little more elasticity. It is laid on by hand with a trowel in several thicknesses of about ⅓ to ½ in. each, and either on the bare masonry wall or on a special screen of lathing made for it, to either of which it adheres by entering into and keying itself in the joints and openings and by its adhesive quality. With some variations in the materials and mixing, it is used for exterior and interior work and for ceilings. That material which is more properly called plaster, or plaster of Paris, namely, the sulphate of lime obtained by burning gypsum is commonly used for mouldings and ornamental work; several cements are now made in England for that same branch of the work.

The constructive advantages in the use of plaster for covering walls and ceilings are chiefly connected with dryness and cleanliness, otherwise the chief object of it is for the effect of a smooth surface and as a preparation for ornamental painting. For the purpose of assisting to keep the interior of the rooms of a house dry, it is advantageous to employ lathing, which being detached from the masonry of the walls forms a lining distinct in itself and not liable to the effect of any moisture which may be in the walls, and which would in time destroy the plaster if placed on the walls themselves, or if the plaster should be made with hydraulic lime would tend to separate it from the walls and always keep it damp and cold.

The following extracts from the article on Building, by Hosking, in the Encyclopædia Britannica, and from other sources, explain the ordinary method of forming a lath-and-plaster lining to a wall or ceiling in England;—

Different kinds of Plaster used.—*Coarse stuff* is composed of a mortar made of equal parts of lime and sand and clean long ox hair; 1 lb. of hair to 3 cub. ft. of mortar is the usual proportion. The hair should be as long as it can be procured and free from grease and dirt, and as finely separated in the mortar as possible. Nothing but clean sharp sand should be used with this lime and hair in the composition of this any more than of building mortar. *Fine stuff* is a mortar made of fine white lime exceedingly well slaked with water, or rather formed into a paste in water to make the slaking complete: for some purposes a small quantity of hair is mixed up with it. Fine stuff very carefully prepared, and so completely macerated as to be held in solution in water, which is allowed to evaporate till it is of sufficient consistence for working, is called *putty*, plasterers' putty. *Gauged stuff* is composed of ⅔ of this putty and ⅓ calcined gypsum or plaster of Paris; this must be mixed in small quantities at a time, as the gypsum causes it to set rapidly. *Common stucco* is composed of ⅔ clean sharp sand and ⅓ lime. *Bastard stucco* is composed of ⅔ fine stuff, without hair, and ⅓ of very fine clean sand.

All kinds of limes and cements may be used for plaster; with respect to the quantity of sand they will bear, see the article on *Lime and Mortar*. Where the plastering is intended to hold water, as in a tank, it is evidently necessary that a hydraulic lime should be used.

Lathing.—Before the plasterer begins to lath a ceiling he proves the under face of the joists by the application of a long straight-edge, and brings them all to one horizontal plane. This is done by nailing on strips of wood, and is called furring. If it be a framed floor it is tolerably sure to be straight; when the ceiling joists are fastened to the binding joists of the room above, nothing of this kind is necessary. It is an important point to be attended to in plastering on laths, and in ceilings particularly, that the laths should be attached to as small a surface of timber as possible, because the plaster is borne not so much by its adhesion to the wood, but by the keying of it between and behind the laths. Under a single floor in which the joists are necessarily thick a narrow fillet should be nailed along the middle of the whole length. *Plasterers' laths* are narrow strips of some straight-grained wood (generally fir in England), split with an axe to give roughness of surface, and cut into lengths of 3 or 4 ft., about 1 in. broad, and $\frac{3}{16}$ or ½ in. thick. These are single laths; double laths are ⅔ in. thick. Lath nails are either wrought, cut, or cast, varying in length to suit the single or double laths: cast nails are commonly used in England. The laths are laid in courses or bays, and these should break joint over the whole surface of the ceiling; the rows of laths are about ⅔ in. apart, and there is one nail in the centre and one at each end, which latter also secures the ends of the adjacent laths in the same row.

In lathing on walls the bonding of the bays of lathing is not of so much importance, nor is the breadth of the timbers behind the lathing, because the toothing which the thickness of the lath

itself affords to the plaster is sufficient to support it vertically. The laths for walls may be weaker than those for ceilings; weak laths in a ceiling are sure to produce inequalities by sagging to the weight attached to them. When the lathing is on a wall, the timbers to which it is fixed, being supported by the wall, need only be battens of $1\frac{1}{2}$ to $2\frac{1}{2}$ in. thick, which are fixed to wood bricks in the wall, their object being both to support the lathing and to provide a space between the plaster and the wall, so that they shall not come into contact.

Laid and set is the technical term for two coats of plaster on laths. The first coat is a thick coat of coarse stuff of a consistency thin enough to pass between the laths and form a key behind, and stiff enough not to fall apart in the operation, a contingency which not unfrequently occurs in practice, in consequence of the workmen using thin mortar in order to avoid the extra labour of working stiff mortar through the latter. It is put on with a trowel, and when sufficiently dry is swept with a birch broom to roughen its surface. The second coat is a thin coat of fine stuff, and is put on with a trowel with the assistance of a hog's-bristle brush to keep the surface of the second coat wet while the operation is going on. If the first coat has become very dry it must be wetted, or the second coat in drying will shrink from it.

Plaster, float and set is the term for three coats of plaster on laths. The first or *pricking-up* coat is of coarse stuff put on with a trowel to form a key behind the laths, and about $\frac{1}{4}$ or $\frac{3}{8}$ in. thick on the laths: while it is still moist it is scratched or scored all over with the end of a lath in parallel lines 3 or 4 in. apart, the scorings being made as deep as possible without exposing the laths; the rougher the edges are the better, as the object is to produce a good key for the next coat. When the *pricking-up* coat is sufficiently dry not to yield to pressure in the slightest degree, the second coat or *floating* is put on. The *floating* is of fine stuff with a little hair mixed with it; ledges or margins, 6 or 8 in. wide, and extending across the whole width of a ceiling or height of a wall, are made at the angles and at intervals of about 4 ft. apart throughout: these must be made perfectly in one plane with each other with the help of straight-edges. These ledges are technically called *screeds*. They form gauges for the rest of the work, and when they are a little set the spaces between them are filled up flush, for which a derby float or long straight-edge is used. The screeds on ceilings ought to be levelled, and those on walls plumbed. When the *floating* is sufficiently set it is swept with a birch broom for the third coat or setting. The third, or setting coat, should be of plasterers' putty if the ceiling or wall is to be whitened or coloured. If it is to be papered, the third coat should be of fine stuff, with a little hair in it. If it is to be painted, the third coat should be of bastard stucco trowelled. Trowelled stucco should also be hand-floated. In this operation the stucco is set with the trowel in the usual manner, and brought to an even surface with that tool to the extent of 2 or 3 yds. The workman then takes the hand-float in his right hand, and rubs it smartly over the surface, pressing it gently to condense the material. As he works the float he sprinkles the surface with water from the brush in his left hand, and eventually produces a texture almost as fine and smooth as that of polished marble.

Plaster of Walls.—The process of plastering on the naked brick or stone wall differs in little except in name from the mode on laths. The first coat is called *rendering*, and differs only from the first coat for laths, in the quantity of hair, which may be less, and in the consistency of the mortar, which may be more plastic, because in a moister state it will attach itself more firmly to the wall: the wall itself should be wetted before the rendering is applied. The second coat is called *setting*, and is the same in every respect as the setting coat on laths. In three-coat work the first, or *rough rendering*, should be made to fill up completely whatever crevices there may be in the work behind it, and be incorporated with it as much as possible. Its surface should be left rough, but it is not scratched or lined as the similar coat on laths is. For the second coat, or *floating*, screeds must be formed, as before described. The consecutive processes are exactly the same as on laths, both for the *floating* coat and for the setting coat. In almost every case in which plastering has to be floated, the workman finds a guide for the feet of his wall screeds, in the narrow grounds which the joiner has previously fixed for the skirting. From these he plumbs upwards, and makes his work perfectly flush with them.

In plastering a wall with common stucco (its use is mostly for outside work), the dust is first removed from it by brushing, and it is then well wetted. If the wall to be stuccoed be an old one, or one of which the joints have been drawn, the mortar of the joints must be chipped, or even raked out, and the bricks picked, to expose a new and porous surface to the plastering before brushing and wetting. The wall is then covered with stucco in a fluid state, applied with a broad and strong hog's-bristle brush, like common whitewashing. When this is nearly dry the stucco must be laid on as in common rendering. When the work is to be floated the process is nearly similar to that in floated plastering. Screeds must be formed at the highest and lowest extremities of the wall, and be returned at the angles, putting the whole surface into a sort of frame; inner screeds must then be made at every 3 or 4 ft. apart over the whole surface, and the interstices filled in as before. As the work is made good it must be well rubbed with the hand-float to compress the material and produce a hard and glossy surface. Preparations for cornices and other projections should be previously made by bricks or tiles projecting from the brick or stone work, forming a core on which the mouldings are run with moulds in stucco. No plaster of Paris should be used for external work, as the wet will dissolve it. When the stucco is dry it may be painted in oil colours, or coloured in distemper.

Rendering in *Roman cement* is executed almost exactly in the same manner as stucco rendering, only it is laid on the saturated wall directly without the preliminary operation of roughing in, or washing the surface with a solution of the material. The same process is also followed in floating this cement, and with the same exceptions. A quick-setting cement like this is far preferable to common lime for mouldings. Roman cement may be painted in oil or coloured. In the latter case the colour should be mixed with dilute sulphuric acid instead of size.

Rough cast is a cheap and useful covering for external walls which are well protected by eaves. The surface is first roughed in or rendered with lime and hair. When that is dry another coat of

the same material is added, laid as evenly as it can without floating; and as soon as a piece of 2 or 3 yards is executed the workman lays on it an almost fluid mixture of fine clean gravel and lime. This is immediately washed with any ochreous colour, and the whole dries in one mass. The lime in rough cast should be a strong lime.

Mouldings and Ornamental Work.—If a moulding which is to be made in plaster does not project beyond the plane of the wall more than 2 in. it will be sufficient to make a foundation for it in lime and hair after the first coat of plaster. If any one part of the moulding should project more than that, a row of nails, 6 in. apart, and driven into the plaster, will be sufficient to support it. But if the general mass of the moulding project more than 2 in. a rough form of it must be made by brackets of wood fixed at intervals, and cut roughly to the outline of the moulding, and covered with laths. The first, or pricking-up coat, must be laid over this form. The second coating of the moulding, if interior work, should be made of *gauged stuff*, and laid as follows:—A *mould*, or piece of board with the section of the moulding cut out of it is made to move along the line of the moulding guided by two battens, one above and one below, fixed temporarily to the wall, and so as to have a space of about $\frac{1}{4}$ in. between it and the first coat of plaster. One man lays on the gauged stuff in almost a fluid state with an angular trowel; another works the mould backwards and forwards over it until it takes the form of the mould, the superfluous stuff being swept off by the action. If the whole height and projection of a moulding be too large and heavy to be executed at once in this manner, it can be done in parts, one at a time.

This method evidently applies only to plain mouldings of the same continuous section. Enriched mouldings can be commenced in the same manner, and the space for the enrichment can be left vacant in the *mould*, and completed afterwards by hand. The angles formed by two lines of moulding meeting from different directions must also be finished by hand. Such joinings are termed *mitres*, and the workman uses what is called a *joining tool* for them. Such enriched parts of a moulding as cannot be executed in the above manner are generally cast in *plaster of Paris* in moulds. These moulds are made of plaster of Paris or wax or gutta-percha from wooden models of the design. These cast parts of the moulding, when set and trimmed, are fixed in their places in the moulding with plaster of Paris, if there is any projection to support them, or with white lead or iron cement if they have to depend entirely on the cement. Such ornamental castings as are too large to be trusted to cement alone must be fixed with screws to woodwork behind them specially provided for the purpose.

Hosking says the most general cause of the decay of stuccoes and cements on external walls is the impurity of the materials. If the sand is quite clean and the lime good of its kind, and the work be well hand-floated and trowelled, particularly on the upper surfaces of projections, where wet is liable to penetrate, the plastering, with common attention to the painting of it, will last as long as anything of the kind can be expected to last.

In repairing plastering, the surface should first be well washed to remove the dirt. The cracks and fractures are then repaired with new plaster, and when the new work is quite dry the joinings are scraped to produce an even surface, and the whole is re-coloured or whitened once or twice. Stuccoed walls that have been painted must be rubbed with pumice-stone to take off the old paint before they are repainted.

TABLE OF MATERIALS IN PLASTERING REQUIRED TO COVER SUPERFICIAL YARDS AS UNDER.

Materials.	Render 1 coat and set.	Plaster 1 coat and set.	Render 2 coats and set.	Plaster 2 coats and set.	Plaster float and set.
1 cubic yard common chalk lime	sq. yds.	sq. yds.	sq. yds.	sq. yds.	sq. yds.
2 " sand	75	70	65	60	60
9 lbs. hair					
<i>Lathing.</i>					
1 bundle laths					
600 nails					
		4½ sq. yds.			
<i>Stuccoing.</i>					
1 bushel Roman cement without sand, $\frac{3}{4}$ in. thick		1½ sq. yd.			

Painting Woodwork.—The useful object of painting materials used in construction is to protect them from the action of such causes of decay as heat, gases, moisture, &c., by covering them with an almost impervious and a very durable coating; but probably the origin of house painting is due to purposes of ornament rather than use. The most effective known composition that combines both objects is a mixture of white lead and linseed oil. The mixture of white lead and oil to a consistency that can be readily used with a brush, when spread on any material sinks into it, and dries in a few days, forming a covering durable under ordinary circumstances, and impervious to ordinary damp. It can be mixed freely with almost all colours, and is sufficiently economical in England to be applicable to houses generally.

The *linseed oil* is the material in this mixture which forms the durable coating. This oil, in common with a few other vegetable oils and with some resinous matters, possesses the property of drying, after it has entered the surface of the material, into a resinous compound, which thus fills up the pores of a material like seasoned wood with a substance similar to the natural resin, and so prevents further decaying action going on. The *dryer*, as it is called, is some oxidizing substance, such as *litharge*, added to expedite the drying process, and a solvent, such as *spirits of turpentine*, is added to dilute the mixture, and which soon evaporates again. The *white lead* gives body and opacity to the mixture. It combines readily, and to a certain extent chemically, with the oil into a creamy compound, drying into a saponaceous substance.

White lead is the carbonate of that metal, obtained in this country from the metallic lead. It is a fine white powder, weighing about 400 lbs. a cubic foot. There are other powders of the same appearance, which, being cheaper, are sometimes used to adulterate the white lead with, such as whiting, sulphate of baryta, Paris white and zinc white. As there are none of these so durable or useful as white lead, it is essential that it should be pure. They can be detected either by the specific gravity or by resolving the powder back into metallic lead, which should weigh $\frac{1}{10}$ less than the powder, or in the case of the sulphate of baryta, which is the most usual adulteration, by nitric acid, which will dissolve the lead but not the baryta. White lead combines more readily and effectively with oil than any other of these pigments.

Linseed oil, in its natural condition, dries slowly to the resinous varnish required for coating materials, and rather injures the brilliancy of delicate colours by its strong amber colour. As the operation of drying is an oxidizing process, the addition of good oxidizing agents expedites the drying of paints. *Boiled linseed oil* also causes it to oxidize quicker; but, as it makes it thicker it is not so suited for in-door or delicate work. Linseed oil can be *clarified* by mixing it with an acid, such as oil of vitriol. It must be well washed with water to get rid of the acid.

Driers.—The ordinary oxidizing agent used is *litharge*, or oxide of lead. *Oxide of manganese* is also used, and is a quicker drier than litharge. These driers generally contain some inert matter, such as chalk or sulphate of baryta, as an agent, as well as the acetate as an oxidizer.

The proportion of litharge generally used is about $\frac{1}{4}$ lb. to a gallon of oil. The oil is then called a *drying oil*, and can be made clear and colourless by leaving it exposed to the air in shallow vessels for two or three days.

Solvents.—Some substances are required to dilute the mixture of white lead and oil, which would not otherwise penetrate into the pores of the material. This solvent should be light and easily evaporated.

Spirits of Turpentine (commonly called *turps*) is generally used for this purpose; it is a solution of resin in spirit, and evaporates perfectly. The best test for its purity is by evaporating it; it deteriorates by keeping. Some natural drying oils could be used as solvents, but they generally contain foreign substances, which will not dry and which cannot be easily got rid of.

Pigments.—The object of adding all pigments to the drying oil is to give it opacity and body and colour.

They should be always of a permanent character, and are almost all mineral. Besides white lead the following are used in house painting.

Patlinton's White is an oxy-chloride of lead, and not a carbonate. It has not so much body as white lead, but it mixes freely and is not readily discoloured.

Sulphate of Baryta has not so much body as white lead, in the adulteration of which it is much used; it is durable, and forms the basis of several *whites* employed by house painters: it is heavier than white lead.

Zinc White is the oxide of zinc. It is cheaper than, but not so durable as, white lead; it is light, and not opaque, and is readily attacked by salts, therefore is not durable and is easily acted on by wet and acids in wood. It does not dissolve so readily as white lead, and therefore requires more oil. For, as long as it lasts, it keeps its colour better than white lead and is not so easily adulterated; it takes longer in drying, and when adulterated is liable to change colour. Lead driers should not be used with zinc white: sulphate of manganese is the best drier.

Chromes or Yellows.—All consist of oxide of lead and chromic acid: when boiled with lime the mixture is lightened in colour; when boiled with acid it is darkened; when boiled with saltpetre orange colour is formed. Chromes combine well with oils, and are therefore the best of all yellows.

Prussian Blue is made from animal refuse (such as horns, blood, &c.), burnt with potash and iron at a high temperature.

Smalt Blue is oxide of cobalt, and is made by roasting cobalt ore and mixing silica with it, and the fusion of it with sulphur produces blue smalt.

Ultramarine Blue was formerly made from lapis lazuli and was very expensive: it is now made artificially and of better colour by fusing together carbonate of soda, silica, alum, and sulphur, and then washing the compound and fusing it again, and washing it again, and then heating it with sulphur, which gradually colours it.

Greens are almost all obtained from copper. *Verditer* is oxide and carbonate of copper: other greens contain arsenate of copper. They are durable colours.

Brunswick Green is made of Prussian blue and chrome, mixed with carbonate of lime or sulphate of baryta to dilute it. If the chrome has an acid in it the colour fades: therefore, to test it, the powder should be exposed for a fortnight to a strong sunlight.

Red Lead is oxide of lead: on account of its durability it is frequently used as a priming or first coat on ironwork; but care should be taken that no salt is present, otherwise a chemical action commences, blisters are formed, and the lead is reduced to the metallic condition.

Oxide of Iron paints.—These are the most effective and durable paints to use on iron, as they have no tendency to change or affect the surface of the iron. There are several preparations of them. *Grant's Black* is made of shale containing oxide of iron. The *purple brown oxide* is a hydrated

peroxide of iron. The *Torbay paint* is a protoxide of iron. But the most effectual coating that can be used for heavy ironwork, such as thick plates, is the natural surface fresh from the rolls or hammer; wrought iron, after such treatment, has always a coating of magnetic oxide on its surface, which is hard and thoroughly attached to the body of the iron, and which as long as it is left unbroken, will prevent any further action on the iron.

In painting woodwork, the surface must be first prepared by counteracting the effect of anything that may prevent it from becoming identified with the material. Thus, in painting pine-woods of any kind, the resin contained in the knots which appear on the surface must be neutralized, or a blemish will appear over every knot; this is done with two or more coats of red lead ground in water and mixed with size laid over the knots; this is called *killing the knots*. A preparation under the name of patent knotting is also extensively used; it is composed of shellac, naphtha, and perhaps some other drying agent. A single application of the mixture will effectually kill the knots, and as it dries almost instantly it is greatly esteemed by painters as a substitute for the red-lead mixture. All nail-holes (the heads of nails having been punched in) and other defects must be *stopped*, or filled up with putty or wood. The surface of the wood is then rubbed smooth with sand-paper or pumice-stone.

In laying on the paint, the white lead and oil and dryer are mixed to the consistency of thick cream; this is done either on a flat stone by hand or in a mill; the necessary colouring matter is mixed with it. The brush should be held at right angles to the face of the work, so that only the ends of the hairs touch it, for thus the paint is forced into the pores of the wood and distributed equally over the surface. Painting, when properly executed, will not present a shining, smooth, and glossy appearance, as if it formed a film or skin, but will show a fine and regular grain, as if the surface were natural, or had received a mere stain without destroying the texture. Before the paint is applied the wood should be free from moisture of any kind and seasoned, or it will at the least prove useless, and probably injurious. Dampness or moisture or unseasoned substances in woods, stopped in or covered over with paint, will, under ordinary circumstances, tend to their destruction.

New woodwork should have four coats of paint. The first coat, which is called the *priming coat*, need have very little, if any, of the final colouring matter in it. After priming, all nail-holes or other superficial defects are carefully stopped up before the next coat is applied. The remaining coats are laid on as the previous coats become dry, which is generally in about two days. When the painting, after a lapse of four or five years, requires to be renewed, two coats only are usually applied.

For fine work, each coat should be carefully rubbed down with pumice-stone or glass-paper and dusted before the next coat is added.

Painting on Plaster.—Plaster, being more absorbent than wood, requires a greater number of coats to saturate the exterior face, and that the first coat should be thinner. The plaster, being quite dry and hard and well sized with the common thin glue size, the first coat consists of white lead diluted with linseed oil to a thin consistency, with the addition of a small quantity of litharge: the oil is entirely absorbed, thereby hardening the plaster to the depth of about $\frac{1}{2}$ in. The second coat is also thin, in order that the plaster may be thoroughly saturated. The third coat is thicker, and contains a little turpentine, with some of the colouring pigment. The fourth coat is as thick as it can be used, equal parts of oil and turpentine being employed, and sugar of lead as the dryer. A finishing coat is frequently added of pure white lead diluted with spirits of turpentine only. A small quantity of japanner's gold-size is sometimes used as the dryer, and the proper pigment to give the required colour is added; this coat, from its drying without any gloss, is called the *flattening coat*.

The *flattening coat* is also sometimes put on woodwork.

Distemper is the name given to paint composed of white lead and other colouring matters ground in water instead of oil and mixed with size to make it set; it is, in fact, a *water-colour*. It can be used in the same manner as oil colour, but will not stand exposure to rain as the latter will. Sometimes whitening is used instead of white lead.

Whiting.—This material is pure chalk, reduced by levigation to a fine powder. When mixed with size in water it is used to cover plastered ceilings and walls of common rooms, and sometimes for external work of common buildings. The proportions recommended by Vanherman are 12 lbs. of whiting to 2 quarts of double size, the whiting to be covered with cold water for six hours and then mixed with the size and left in a cold place till it becomes like jelly in appearance, and then, but not till then, it is fit for use. The colouring matter should be first ground in water and then added to the whiting before the size is put in. About 1 lb. of this composition will cover 6 yards.

Size is the glue extracted from animal tissue: it is used by itself as a priming coat sometimes, and sometimes as a varnish.

Anti-corrosive paint, as it is called, is made of equal parts by weight of whiting and white lead with half the quantity of fine sand, gravel, or road-dust, and a sufficient quantity of colouring matter. This mixture is made in water and can be used as a water-colour; but it is more durable to dry it in cakes or powder after mixing, and then use it as an oil-paint by grinding it again in linseed oil. The preparation of oil recommended for this purpose is 12 parts by weight of linseed oil, 1 part of boiled linseed oil, and 3 parts of sulphate of lime, well mixed. One gallon of this prepared oil is used to 7 lbs. of the powder manufactured as above mentioned.

Painting old Work.—If the work is much soiled it should be washed with soap and water and scoured; if foul with smoke and grease, it should be washed with lime and water. It should be then rubbed with pumice-stone; then the first coat of the new colour (corresponding to the second of new work) may be laid on; when it is dry, the *stopping* should be done, and the whole rubbed with glass-paper.

To remove old paint from painted work, a solution composed of the following ingredients is used,

namely:—soft soap $\frac{1}{2}$, potash 1, and quick-lime $\frac{1}{2}$ or $\frac{1}{3}$. The soap and potash are first dissolved by boiling in water: the lime is then added, and the whole applied, while hot, with a brush, care being taken that all portions of paint to be removed are covered with the solution, which must be left on from twelve to twenty-four hours, after which the whole of the painting (no matter how many coats) will easily be removed by washing with hot water. Paint may also be removed by burning, but this is not to be recommended except for very plain and common work.

White Copal Varnish.—4 oz. of copal, $\frac{1}{2}$ oz. of camphor, 3 oz. of white drying oil, 2 oz. of essential oil of turpentine. Reduce the copal to powder, mix the camphor and drying oil, then heat it on a slow fire and add the oil of turpentine and strain it.

Mastic Varnish.—A quarter of a pound of mastic melted over a slow fire with a pint of essential oil of turpentine, and strained.

Common Colours. in house painting, are considered to include lampblack, red lead, and the common ochres. *Superior colours* include blues, greens, rich reds, pinks, and yellows. White is a common colour, except when flatted.

Whitewash.—This is the name given to a mixture of common lime and water, which is frequently used for coating the interior walls and ceilings of barracks and such buildings. It is mixed to a thin consistency, and laid on with a large flat brush. It does not last long, and rubs off to the touch and will not stand rain; but being cheap and easily applied and healthy, it is a very useful preparation for the purpose. It will not adhere to very smooth surfaces, such as wrought timber, paint, &c.

Silicate of Soda.—A solution of silicate of soda has been found by Abel, when applied like paint to wood, to give it a very considerable protection against fire, as well as to form a hard coating durable for several years; it can be used with the ordinary colours like distemper.

Directions for covering Timber with a Coating of the Silicate of Soda and Lime as a Protective from Fire.—*Materials employed.*—The silicate of soda must be in the form of a thick syrup of a known degree of concentration, and is diluted with water when required for use, according to the prescriptions given below.

The lime-wash should be made by slaking some good fat lime, rubbing it down with water until perfectly smooth, and diluting it to the consistency of thick cream. It may be coloured by admixture with mineral blacks, ochres, &c.

Treatment of the Wood.—The protective coating is produced by painting the wood, firstly with a dilute solution of silicate of soda; secondly, with a lime-wash; and lastly, with a somewhat stronger solution of the silicate.

The surface of the wood should be moderately smooth, and any covering of paper, paint, or other material, should be first removed entirely, by planing or scraping.

A solution of the silicate, in the proportion of one part by measure of the syrup to four parts of water, is prepared in a tub, pail, or earthen vessel by stirring the measured proportion of the silicate, first with a very small quantity of the necessary water until a complete mixture is produced, and then adding the remainder of the water, in successive quantities, until a perfect mixture in the requisite proportions is obtained.

The wood is then washed over with this liquid, by means of an ordinary whitewash brush, the latter being passed two or three times over the surface, so that the wood may absorb as much of the solution as possible. When this first coating is nearly dry, the wood is painted with the lime-wash in the usual manner.

A solution of the silicate, in the proportion of one part by measure of the syrup to two parts of water, is then made as above described, and a sufficient time having been allowed to elapse for the wood to become moderately dry, this liquid is applied, upon the lime, in the manner directed for the first coating. The preparation of the wood is then complete. If the lime coating has been applied rather too thickly, the surface of the wood may be found, when quite dry after the third coating, to give off a little lime when rubbed with the hand. In that case, it should be once more coated over with a solution of the silicate of the first-named strength.

Table of Materials in Painting required to cover Superficial Yards as under.

1st coat	$\left\{ \begin{array}{l} 10 \text{ lbs. white lead} \\ 4 \text{ pints linseed oil} \\ 2 \text{ oz. litharge} \\ 1 \text{ oz. red lead} \end{array} \right\}$	25 superficial yards.
2nd coat	$\left\{ \begin{array}{l} 10 \text{ lbs. white lead} \\ 2\frac{1}{2} \text{ pints linseed oil} \\ 1\frac{1}{2} \text{ pint spirits of turpentine} \\ 2 \text{ oz. litharge} \end{array} \right\}$	40 superficial yards.
3rd and subsequent coats	$\left\{ \begin{array}{l} 10 \text{ lbs. white lead} \\ 2 \text{ pints linseed oil} \\ 2 \text{ pints spirits of turpentine} \\ 2 \text{ oz. litharge} \end{array} \right\}$	50 superficial yards.

For coloured paints, the last two coats have the colour added to the composition in the proportion of 1 lb. to 2 lbs. for every 10 yds. of surface to be painted; and the quantity of white lead is reduced in proportion.

Glazing.—There are three kinds of glass used in England for glazing windows:—1st, *crown glass*; 2nd, *sheet glass*; 3rd, *plate glass*.

The constituents of the three kinds are nearly the same, but the latter, from its mode of manufacture, is made in larger and thicker plates, and is much more perfect and expensive.

Crown glass is made in circular discs blown by hand; they are about 4 ft. diameter, and the

glass averages about $\frac{1}{8}$ in. thick. Owing to the mode of manufacture there is a thick boss in the centre, and the glass is throughout more or less striated in concentric rings, and frequently curved in surface, and thicker at the circumference of the disc. Consequently in cutting rectangular panes out of a disc there is a considerable loss, or at least variety in quality: one disc will yield about 10 sq. ft. of good window glass, and the largest pane that can be cut from an ordinary disc is about 34×22 in. The qualities are classified into *seconds*, *thirds*, and *fourths*.

Sheet glass is also blown by hand, but into hollow cylinders about 4 ft. long and 10 in. diameter, which are cut off and cut open longitudinally while hot, and therefore fall into flat sheets. A more perfect window glass can be made by this process, and thicker, and capable of yielding larger panes with less waste. Ordinary sheet glass will cut to a pane of 40×30 in., and some to 50×36 in. It can be made in thicknesses from $\frac{1}{10}$ in. to $\frac{1}{2}$ in.

Plate glass is cast on a flat table and rolled into a sheet of given size and thickness by a massive metal roller. In this form, when cool, it is *rough plate*. *Ribbed plate* is made by using a roller with grooves on its surface. Rough and ribbed plate are frequently made of commoner and coarser materials than polished plate, being intended for use in factories and warehouses. *Polished plate* is rough plate composed of good material and afterwards polished on both sides, which is done by rubbing two plates together with emery and other powders between them. Plate glass can be obtained of almost any thickness from $\frac{1}{8}$ in. up to 1 in. thick, and of any size up to about 12×6 ft.

In the glazing of a window the sizes of the panes, that is to say, the intervals of the sash-bars, should be arranged, if practicable, to suit the sizes of panes of glass which can conveniently be obtained, so as to avoid waste in cutting; this consideration is of more consequence in using crown and sheet glass than with plate glass. But in barracks, where the soldier has to pay for broken glass, the panes should never be large nor of expensive glass. The woodwork of the sash should receive its priming coat before glazing, the other coats should be put on afterwards. With crown glass, which is sometimes curved, it is usual to place the panes with the convexity outwards. When the glazier has fitted the pane to the opening with his diamond, the rebate of the sash-bar facing the outside of the window, he spreads a thin layer of putty on the face of the rebate and then presses the glass against it into its place, and holding it there, spreads a layer of putty all round the side of the rebate, covering the edge of the glass nearly as far as the face of the rebate extends on the inner side of the glass, and bevelling off the putty to the outer edge of the rebate. The putty is then sufficient to hold the pane in its place, and hardens in a few days.

The glass should not touch the sash-bar in any part, on account of the danger of its being cracked from any unusual pressure; there should be a layer of putty all round the edges. This precaution is especially necessary in glazing windows with iron or stone mullions or bars.

Putty.—Glaziers' putty is made of whiting and oil. The whiting should be in the form of a very dry fine powder; it should be specially dried for the purpose, and passed through a sieve of forty-five holes to the inch, and then mixed with as much raw linseed oil as will form it into a stiff paste; this, after being well kneaded, should be left for twelve hours, and worked up in small pieces till quite smooth. It should be kept in a glazed pan and covered with a wet cloth. If putty becomes hard and dry, it can be restored by heating it and working it up again while hot. For special purposes white lead is sometimes mixed with the whiting, or the putty is made of white lead and litharge entirely.

Paperhanging.—Decorative paper for covering the walls of rooms is manufactured in *pieces*, which are 12 yds. long and 20 in. wide.

The walls of rooms which are to be finished in a superior manner are generally plastered three coats, and upon the plaster when quite dry a coating of what is called *lining paper* should be laid to ensure a smooth surface. The decorative paper is laid on this. The *paste* used by paperhangers is made of flour and water and a little size or glue; alum also is added to paste to make it flow or spread more freely without losing any of its tenacity or sticking quality. Sometimes a common thin canvas is used instead of lining paper, and sometimes instead of plaster, in which latter case battens should be fixed against the walls to fasten the canvas to and prevent it from touching the walls. Canvas is an unsatisfactory substitute for plaster, in consequence of its expanding and contracting according to the hygrometric state of the atmosphere.

In renewing old paper, if the old paper merely requires cleaning, it can be done by first brushing it well, then rubbing it with stale bread crumbs, and then with a dry linen cloth. If the old paper cannot be cleaned it should be taken down and a coating of size laid on the walls, preparatory to a coat of paper: or a coat of size may be laid on the old paper, and a coating of whiting and size or distemper over that. See BOND, MENSURATION, of Artificers-work.

COOLER. FR., *Bac*, *Bac-refroidissoir*; GER., *Kühlschiff*, *Kühlstock*.

Wort-coolers and Refrigerators.—After being drawn from the hop-back, the wort has to be cooled down to the temperature at which it is to be pitched or placed in the fermenting tun. This temperature varies somewhat in different cases; but it may be taken as averaging from 54° to 64° , and therefore, allowing for some loss of heat in passing through the hop-back, traversing-pipes, and so on, the temperature of the wort has to be reduced about 150° . This reduction of temperature is effected sometimes by exposing the wort to the air in shallow vessels or coolers; sometimes by passing it through a refrigerator, or apparatus in which water is used as a cooling agent.

Coolers are shallow vessels, generally about 6 in. or 8 in. deep, made of wood, iron, or copper. Wooden coolers are most frequently met with, probably on account of their cheapness, but they are open to many objections. They are usually made of Dantzic deals about $1\frac{1}{2}$ in. thick, the boards being pegged to the joint-pieces with wooden pins. The coolers should be laid with a slight inclination towards the point at which the wort is drawn off, and the boards forming them should be planed as smooth as possible, so that they may be more readily kept clean. Too much care cannot be paid to the cleanliness of coolers, and to ensure it they should be frequently washed with lime water. If the coolers are not in almost continual use, it is advisable to keep them covered with water in the intervals when they are not required, as the pores of the wood which

have been opened by the action of the hot wort are thus to a great extent prevented from absorbing air, which would, when the next gyle was poured on, come in contact with the wort, and be apt to cause a creaming of the surface, or incipient fermentation, generally called the fox. Wooden coolers, also, if allowed to get dry between the times of the wort being poured on, cause a considerable loss by absorption.

To avoid the objections to those of wood, coolers are made of iron or of copper. Coolers are placed so that their under sides are exposed to the air as well as their upper sides, and the cooling effect is thus increased. This arrangement should be adopted in all metal coolers.

At Truman's there are two very fine copper coolers, which have been put up under the direction of King, the engineer to the brewery. These coolers are each 110 ft. long by 25 ft. wide, their weight the square foot being about $3\frac{1}{2}$ lbs., and they are supported on joists, the under-sides being freely exposed to the cooling influence of the air. The wort is not allowed to rest on these coolers, but is run over them in a thin stream to one of Morton's refrigerators, which completes the cooling process. These coolers are capable, under ordinary circumstances, of cooling about fifty barrels of wort an hour from boiling-point to a temperature of 110° ; and as the combined surface of the coolers is 5500 sq. ft., this corresponds to work = $\frac{(212 - 110) \times 50 \times 360}{5500} = \frac{102 \times 50 \times 360}{5500}$

= 333.8, or—allowing for the wort being rather below boiling-point when delivered on to the coolers—say about 300 pound-degrees a square foot of surface the hour. This is a very high result, and is partly due to the wort being kept in motion over the coolers, and being thus kept in a state of circulation; and partly to the fact of the coolers being made of thin copper, thus rendering the bottom cooling-surface very effective.

Figs. 2092 to 2094 represent the standard form of refrigerator made by Morton and Wilson. The wort enters at *a*, passes over and under the tubes *b b*, in the direction of the arrows, and finally passes out at *c*.

The cold water is admitted at *d*, passes through the tubes in the direction of the arrows across the current of the wort, and escapes at the opposite end by the pipes shown at the top on the left-hand side of Fig. 2092. Caps, *f f*, connect the tubes together at their alternate ends, by which means a continuous passage is formed from end to end. These caps may be hinged to the ends of the tubes, so that they can be readily removed for cleaning the inside of the latter; but this is only necessary where the water is impure, and tends to leave a deposit inside. The tubes are

formed of four separate pieces for strength, these pieces being united, so as to form apparently a single flat tube. The tubular surfaces and casing are formed of copper surrounded by a wooden frame *g*; the caps are of gun-metal tinned. The spaces between the tubes are drained from the worts remaining after the brew by means of the continuous valve arrangement *h*, which is opened and shut by the lever *i*.

Figs. 2095 to 2097 exhibit further improvements. In these figures *a* is the casing to which is attached the tubes *b b b*, each of which is a flattened tube formed by the union of three round

tubes, the spaces between the circles being filled up. These tubes are connected at their alternate ends by the caps *c c c*. The wort is distributed on the external surfaces of the tubes *b b b*, from the trough *e*, placed immediately above, and the bottom of which is perforated, or covered with metallic cloth. The worts percolate through the bottom of the trough, and, falling upon the upper tube, flow round it and descend to the second, and, in the same manner, fall from tube to tube until they are received by the trough *f*. The water enters at *g*, and passes in the direction of the arrows from tube to tube, finally escaping at *h*. The whole tubular surface is surrounded by an outer casing *a*, hinged at *i i*, and secured at *j j*. Vertical air tubes *k k* are attached to this outer casing, these tubes having horizontal air tubes *l l l*, extending from them on each side. The latter air tubes are perforated, and currents of attenuated air are driven into *k k* by a fan or other arrangement, and diffused throughout the casing which encloses the tubular cooling-surface.

The refrigerator, Figs. 2098 to 2100, constructed by Pontifex and Wood, is very complete. Like Morton, Pontifex and Wood employ flat tubes, traversed by the water; but instead of passing the wort alternately under and over them, they cause it to follow the course shown by the arrows marked on the plan of the apparatus. It will be seen from Fig. 2098 that each end of the casing

of the refrigerator is touched by the alternate tubes only, so that a zigzag channel is formed for the passage of the wort. The tubes are, as we have said, traversed by the water; and one of the

main peculiarities in the refrigerator is the manner in which the tubes are connected together so as to form a continuous channel. The required connection is effected at their alternate ends by castings, which form water bridges, beneath which the wort can pass. The form of these bridges, or connecting castings, is shown in Figs. 2099, 2100. The stream of water flows in the opposite direction to that of the wort, and the course of the current is shown in Fig. 2098 by arrows. The casing of the refrigerator is of wood, and its ends are made to slope slightly inwards towards the bottom, so that a tight joint can be readily made between them and the ends of the tubes. These ends are formed by brass castings, each of which carries a piece of india-rubber projecting from a groove formed in it, this india-rubber bearing against the end of the casing and making the joint tight. The tubes are all fastened on their upper sides to a frame of wood which is hinged to the side of the trough or casing, so that they can be readily raised for cleansing. Each tube is, like those employed by Morton, formed of three or four separate tubes or pieces joined together so as to present the appearance of a single flat tube. This plan is resorted to in order to prevent the tubes from bulging in the event of their being supplied with water under pressure.

Another form of refrigerator is that which we illustrate, Figs. 2101 to 2104. This refrigerator was designed by Joseph Stirk, the engineer of Messrs. Allsopp's Brewery at Burton-on-Trent, and

Section on line C D.

Section on line A B.

little work. This will be understood when it is considered that each transverse tube acts independently, and the water passed through each tube cannot therefore be raised to a higher temperature than that of the wort with which that particular tube is brought into contact. Thus the water passing through the tubes near the end at which the wort escapes will probably not be heated to more than from 60° to 70°, whilst near the end at which the wort enters it can be raised to within a few degrees of the initial temperature of the wort. The result of this is that a greater proportion of water will be required to cool a given quantity of wort than if there was a single

continuous current of water flowing in an opposite direction to that of the wort. To a certain extent this coil can be remedied—although it cannot be entirely overcome—by so regulating the openings of the cocks connecting the transverse tubes with the supply mains, that those tubes which are nearest the end at which the wort enters may receive the largest supply of water, the supply being gradually diminished towards the other end of the refrigerator. See ATTEMPERATOR. BREWING APPARATUS.

COPPER. FR., *Cuivre*; GER., *Kupfer*; ITAL., *Rame*; SPAN., *Cobre*.

Pure copper is of a light reddish-brown colour and of a high lustre. It is one of the most ductile and malleable metals. Sheets and wires may be formed of it with the greatest facility. Its fracture is similar to that of tin, or wrought iron. After hammering, its appearance is silky and its lustre seems increased. Its specific gravity when cast is 8·85, in wire 8·93 to 8·94, in sheets 8·95. Copper fuses at 1922° Fahr., and absorbs oxygen from the air when that is accessible, so as to reduce its specific gravity to 8·7 or 8·8. It may be welded when pure. Heated to fusion it absorbs oxygen and oxidizes the surface, and becomes covered with a black crust; by a strong heat in the muffle it may be converted into suboxide altogether. Heated to a white heat, it burns with a light-green flame. In dry air, copper is unchangeable; in moist air and in that containing carbonic acid, sulphuretted hydrogen, or other acids, it becomes dark green and assumes a bronze colour.

Copper ores form an extensive class of minerals, which it is difficult to distinguish by mere ocular inspection. However, at all copper veins oxides more or less green are found on the surface, which, in connection with other marks, form a sure indication of the presence of copper ore.

Native Copper.—This occurs in crystals disseminated through rocks, usually massive, in the form of scales; and compact masses ramifying the rock in all directions. It is found in beds, veins, and detached masses and grains, in solid rock and imbedded in loose soil. Most of the copper-ore veins contain metallic copper. Native copper is distributed over the whole surface of the globe, but nowhere is it found more generally and in larger masses than in the United States. It occurs in the greatest abundance at Lake Superior, near Keweenaw Point; at the Ontonawgaw River, and other localities of that region. Masses of native copper, of 80 tons weight, have been excavated in the Cliff Mine at Lake Superior. The copper occurs here in trap or sandstone rock, or near their junction, in the form of injected veins.

The usual copper ores are sulphurets and oxides; the former are more abundant than the latter. Copper is also found combined with arsenic, selenium, antimony, iron, silver, and acids.

Sulphuret of Copper.—This occurs in various forms. Copper glance is one of the varieties frequently met with in copper-ore veins. Its specific gravity is 5·5, lustre metallic, colour and powder black or lead-grey, fracture conchoidal. It occurs frequently massive, but also granular and in fine powder. When pure it consists of 77·7 copper, 91 iron, 20 sulphur, and some silica.

Copper Pyrites, or yellow copper ore, is the most common sulphuret used in the smelt-works. It is rather light; its sp. gr. 4·1 to 4·3, colour brass-yellow; it is subject to tarnish in the air, and is then iridescent. It forms a greenish-black powder, of sharp edges. It always contains much iron, and is on that account highly esteemed in the smelt-works. Its composition in crystals is 34·40 copper, 30·47 iron, 35·87 sulphur, and sometimes a little quartz. It is often largely mixed with iron pyrites—in fact, so far that the latter fills the vein—and there are either only traces, or but a small percentage of copper ore in the mixture. Copper pyrites is the principal ore of the English smelt-works, as well as those of America, along the Atlantic coast. The bulk of copper is manufactured of this ore. Although copper pyrites is found in great profusion, the ore is always poor; it does not often yield more than 12 per cent., and frequently the body of a vein does not often contain more than 2 per cent. of copper. When it can be brought at reasonable prices to the smelt-works it is valuable, for it is much liked in the furnaces. It yields its copper with great facility, requiring but little labour and the use of little fuel. The contents of copper in an ore of this kind may be estimated by an experienced person on mere inspection. A bright yellow colour and softness indicate a rich ore; a dull yellow, or pale yellow, and great hardness, are indicative of a poor ore. Copper pyrites is readily distinguished from iron pyrites by its inferior hardness—it may be cut by a steel point or a knife; this is not the case with iron pyrites, which will strike fire with steel, but not so that of copper. Spangles of this ore are distinguished from those of gold by their brittleness.

Grey Copper.—This is a variety of sulphuret of copper, which, on account of its interesting composition and its good behaviour in the furnace, is much liked by the smelter. It occurs massive, granular, in a fine powder, and also crystallized. It is of a steel-grey, often iron-black colour; its sp. gr. is 5·1, and it is rather soft and brittle. The composition of this ore varies greatly, but on an average it contains from 25 to 40 per cent. of copper, from 20 to 30 of sulphur, and nearly as much antimony. This forms the bulk of the ore; but it contains besides arsenic, zinc, silver, quicksilver, lead, platinum, and other metals.

Oxide of Copper.—Red oxide of copper is hardly used as an ore. It occurs as an accidental admixture with other ores—particularly with native copper. It is of a cochineal-red colour, occasionally crimson-red, or various shades of red. It occurs in the form of a powder, granular, massive, and crystallized. Other varieties of oxide of copper, such as the black oxide, are of no practical interest.

Silicate of Copper.—This occurs chiefly as an accidental admixture of other ores, and is a constant companion of them. It is green, varying from the emerald-green of the diopside to the sky-blue of the chrysocolla; when impure, it is brownish or of an earthy colour. It is most frequently translucent, not often opaque. Its sp. gr. is 2 to 2·2. The ore contains frequently carbonic acid.

Carbonate of Copper.—Malachite, green carbonate of copper. This is similar to the silicate of copper. It is an ore which accompanies other copper ores. As an ore of copper it is of little consequence, however rich it may be, because not much of it is known to exist. Its composition is 71·82 protoxide of copper and 20 carbonic acid, 18·18 water.

Besides these ores of copper, there are sulphates, phosphates, arseniates, chlorides, and others, all of which are of little practical interest; they are companions of other copper ores, and occur only in small quantities.

Alloys of Copper.—Of all other alloys, those of copper are of most interest. Copper alloyed with arsenic is extremely white, similar to silver; but it is brittle and hard. With zinc it forms brass; and the amount of the respective metals determines the variety of this alloy. Pure copper does not form close and compact castings. Instead of pure copper, about 99 of copper and 1 zinc is considered pure cast-copper. Zinc is introduced by adding about 2 oz. of brass, poor in copper, to every pound of copper. This quantity may be varied from $\frac{1}{2}$ oz. of brass to 3 oz. for every pound of copper. Gilding metal consists of 1 oz. to $1\frac{1}{4}$ oz. of zinc to 1 lb. of copper; it is of a bronze colour. Red sheet is 3 oz. of zinc to a pound of copper. Manheim gold, pinchbeck, 3 oz. to 4 oz. of zinc to a pound of copper. Ordinary brass of a red colour, for being soldered, contains 6 oz. of zinc to a pound of copper; 8 zinc, 16 copper, is a fine brass. Any proportion between 50 zinc, 50 copper, and 37 zinc, 63 copper, will laminate well and make good sheets. Common brass is 50 copper, 50 zinc. Solder may be made by melting brass, and casting it through a broom or faggot of brushes, into a tub of water. Or, the whole metal may be cast into iron moulds in the form of small cubes, of about 1 lb. or 2 lbs. each. When these are gently heated, nearly to melting, they may be broken up into small fragments by a smart blow of a hammer after placing the hot metal on an anvil or a thick cast-iron plate. It is stated that 50 copper to 52 or 58 zinc forms a dark-coloured metal, which on dipping forms a gold-coloured metal—mosaic gold. Zinc 32 to 16 copper forms a bluish-white, brittle metal, which may be pounded in a mortar. Zinc 8 and 1 copper forms a white metal little differing from zinc except in tenacity; this alloy is stronger than pure zinc.

Copper and zinc appear to mix in all proportions, and the extremes of both assume the characters of the principal metals. The red colour of copper is blended by the white of zinc to all shades from red to white. In forming brass by melting the two metals together, a heavy loss of zinc, which varies from $\frac{1}{10}$ to $\frac{1}{3}$, is always experienced. The usual plan of smelting brass is to melt the copper in a blacklead pot first, dry and heat the zinc near to the melting-point, and drop it gradually, in small pieces, into the copper, when the latter is not hotter than barely to continue fluid. The Editor of the present work found, by experiment, that the zinc should be added when cold but dry. When the surface of the hot metal is covered by fine charcoal, which is prevented by renewal from burning, the smallest loss of zinc is sustained. Tombac consists of 85 copper, 15 zinc; prince's metal, 75 copper, 25 zinc; fine brass for turning, 66 copper, 32 zinc, and 2 lead.

Copper and tin form another most interesting series of alloys; 20 copper and 1 tin is a flexible, tenacious alloy, good for nails and bolts; 9 copper, 1 tin, was ancient bronze—7 to 1 is hard bronze; the addition of a little zinc improves this article. Soft bronze, which bears drifting, rolling, and drawing, is generally composed of 16 copper to 1 tin; 12 copper to 1 tin is metal for mathematical instruments; 8 to 1, bearings for machinery; 9 to 1, a very strong metal; it may be considered the most tenacious of this series. Copper 5 to 1 tin, is very hard, crystallized, good for hard bearings in machinery. A soft metal for bells is formed of 3 tin, 16 copper; 7 tin, 32 copper, is for Chinese gongs and cymbals; 1 tin, 4 copper, is for house bells; 9 to 32, large bells. Speculum metal ranges from 1 tin and 2 copper to equal parts of both metals. Ordinary bronze is 78 copper, 17 zinc, 2·5 tin, 2·5 lead. Large bells are cast of 80 copper, 6 zinc, 10 tin, 4 lead. A very fine large bell consisted of 71 copper, 26 tin, 2 zinc, 1 iron. A good average bell composition is 75 copper, 25 tin. 90·5 copper, 6·5 tin, 3 zinc, is an imitation of gold; 91·4 copper, 5·5 zinc, 1·4 lead, 1·7 tin, composes bronze for large statues. Copper 80, tin 20, is common statue bronze; 92 copper, 8 tin, is bronze for medals; 85 copper, 14 tin, 1 iron, is the composition of ancient weapons. Copper 62, iron 6, tin 32, is the composition of ancient mirrors.

The melting together of tin and copper is less difficult than that of zinc and copper, because tin is not so liable to evaporate as zinc, and little metal is lost. The appearance of the alloy may be improved by covering the melted metal with about one per cent. of dried potash; or, which is better still, a mixture of potash and soda. This flux has a remarkable influence on the colour, and particularly on the tenacity of the alloy. The former becomes more red, and the latter stronger. The scum forming on the surface by this addition ought to be removed before the metal is cast. Tin and copper are liable to separation in cooling; this can be prevented, at least partly, by turning the mould containing the fluid metal, and keeping it in motion until it is chilled.

The ancients manufactured their tools of copper, and hardened them as we harden iron. This art appears to have been understood over the whole world, for the Asiatic nations, Africans, and Europeans, as well as the American Indians, knew how to render copper hard. The copper of these ancient people was always impure, very likely in consequence of the composition of their ores. Their bronze-metal contains always more or less tin, lead, zinc, arsenic, silver, and gold. The hardening extended frequently through the body of the metal, but generally it was confined to the surface.

A remarkable difference is perceptible between the alloys of copper and those of iron in respect to hardening. Iron alloys, and most others, become hard on being heated and suddenly cooled, while copper alloys become softer by such an operation. Compression has a similar effect on these alloys, as on all other metals—it renders them hard.

Copper and lead unite only to a certain extent; 3 lead and 8 copper is ordinary pot-metal. All the lead may be retained in this alloy, provided the object to be cast is not too thick. When the cast is heavy, or much lead is used, it is pressed out by the copper in cooling. One lead, two copper, separates lead in cooling—it oozes out from the pores of the metal; 8 copper and 1 lead is ductile, more lead renders copper brittle. Between 8 to 1 and 2 to 1 is the limit of copper and lead alloys. All of these alloys are brittle when hot or merely warm.

Alloys of copper are subject to the same laws as others; and as they are generally more tenacious, more use is made of them. Phosphorus renders copper very hard, brittle, fusible, and oxidizable.

Clean copper, held in the vapours of phosphorus, is successfully hardened. A very little of this substance melted together with copper, causes it to be very hard, similar to steel. Carbon combines with copper and causes it to be brittle. Silicon also combines with it, hardens it, and, if present in a small quantity only, does not impair its malleability. Arsenic has only a faint affinity for copper; still the last traces of it cannot be driven off by mere heat; the combination is brittle. Equal parts of copper and silver, and 2 per cent. of arsenic, form an alloy similar to silver, a little harder, however, but of almost equal tenacity and malleability. Antimony imparts a peculiarly beautiful red colour to copper, varying from rose-red in a little copper and much antimony, to crimson or violet when equal parts of both metals are melted together.

Uses.—The application of copper, either in its pure condition or as an alloy, is so universal that but little can be said on this subject. It is used for sheathing and bolts for ships, for boilers in factories, distilleries, dyeing establishments, steam-boilers, &c. Rollers, shaft-bearings, engravers' plates, and kitchen utensils, are manufactured of pure copper or its alloys. For cylinders, water-pumps, coins, wire, and a multitude of purposes it is also used. Its oxides form fine colours, but are deadly poisons.

Manufacture of Copper.—Smelting of copper is an extremely simple process, because it is as permanent as iron, and little affected by heat and oxygen. The metal which occurs mixed with gangue, consisting chiefly of silicious rock, is cut into small lumps that may enter the furnace; these are in some instances of a ton weight and more. Or, if the metal is disseminated through the mass of the rock, either in grains or in small veins, it is pounded and washed in a stamping mill, and the contents so far concentrated that the sand contains from 70 to 75 per cent. of copper. This is called stamp-work, and sent in barrels from the mines to the smelt-works. Copper from this kind of native metal is smelted chiefly in reverberatory furnaces. Small blast furnaces are often employed to smelt copper. For smelting it thus, from stamp-work or lumps, any reverberatory furnace may be used, either of those in which copper is refined or smelted, or a roasting furnace may be easily converted into a smelting furnace. The operation is simple, and will be described hereafter.

Smelting in Reverberatory Furnaces.—There are two distinct methods of smelting copper ores; the one is in reverberatories, and the other in blast furnaces. As the operations are similarly conducted in the various countries where they are practised, and as the smelting of copper ores in reverberatories is done with skill and much experience at Swansea, we will first describe the operation as it is there performed.

In all instances the copper ores are sorted at the mine, the lumps broken, and large pieces of rocky matter thrown away. The ore is then classified in various qualities, of which the impure ore is sent to the stamps to be crushed and washed. Clay ores are broken into small pieces and washed by hand. All the rich ore, or that ready for smelting, is broken with the beater to lumps of the size of nuts, and freed from light impurities by riddling.

The small and impure ore is washed with a sieve in water, which carries away the stony parts and leaves the metalliferous ore in the tub. Those parts of the ore which are very impure, but will pay for crushing and washing them, are sent to the stamping mill.

The stamping mill is similar to the one given, p. 273. The ore is here converted into powder, more or less fine, and separated from gangue in the labyrinth or slime troughs; or, the ore is washed on the sweep-table, shown in Fig. 2105. In fact, the purifying of copper ore does not essentially

differ from that of other ores. But as the specific gravity of copper ore is small, much care should be taken not to crush it very fine in the stamps.

The furnaces used in this operation are five in number; they are all of similar construction, and so far all the various operations may be performed in the same furnace at different times. Still it is found to be profitable to divide the operation, and perform it in different machines. In Fig. 2106, A, is shown a plane, and in B, Fig. 2107, a vertical section of a reverberatory calcining furnace. This furnace is not essentially different from other reverberatory furnaces. The vault C is an addition; into this the ore is discharged when calcined. The furnace is constructed partly of fire and partly of common bricks, and strongly bound. The hearth is from 18 ft. to 19 ft. long, and 14 ft. to 16 ft. in width. The fire-grate is 5 ft. by 3 ft. The fire-bridge is hollow, and through it fresh air is conducted to the ore under treatment. Two hoppers *h, h*, serve for letting in the ore. The chimney is low.

The first process is the calcining. Three and a half tons of clean ore are charged into the

furnace at a time, which is, with occasional stirring at intervals of two hours, ready to be withdrawn after a heat of twelve or fifteen hours, and let into the cab—vault—beneath. Here it remains as long as possible in a close heap, at least so long as the vault is not needed for the next charge. When the ore is withdrawn it is spread evenly on a floor and damped. In this operation it loses much of its sulphur, and after being cold and wetted is ready for the next operation.

The second process is the smelting of the ore. The furnace for this purpose is much smaller, only 11 ft. long, and 7 or 8 ft. in width. The grate is as large as the one in the calcining furnace, because a higher heat is here required. The furnace has only one work-door at the flue, and in one side a similar aperture for cleaning the hearth. The hearth is formed of coarse sand, and slopes slightly towards the door in the side. Below this door there is an iron grating which covers a vault of water, into which the metal is discharged and granulated. A hopper is placed in the top of the furnace for letting in the charge.

A charge in one of these furnaces consists of 21 to 24 cwt. of roasted ore, which takes four hours for smelting, adding slags from refining, and also fluxes, if such are necessary. Two cwt. of slags are generally charged with the ore, besides lime, fluor-spar, or other fluxes, according to the quality of the ore. The time of smelting these charges is four hours, after which the slag at the top of the metal is skimmed off by means of a rabble, and drawn out at the work-door into a bed of sand. The metal is not drawn at every heat, but only once or twice each twenty-four hours. A second charge of ore is therefore thrown into the furnace, after the poor slags are removed; the furnace is then shut once more, and that charge melted. When the metal, which is matt, an alloy of all the metals in the ore, and sulphur, rises as high as the bridge at the work-door, the tap-hole below is opened, and the matt either run into the basin of water below the furnace for granulation, or into a bed of damp sand. The metallic grains which are thus formed oxidize rapidly, particularly on their surfaces. The colour of this crude metal is a steel-grey, its fracture compact, and it is of much lustre. The scoria rejected after this process contains always some metal; copper and tin are found to be present in 1 or 2 per cent. in this silicious slag. The matt produced contains about 33 per cent. of copper, or four times as much as the ore; the other 66 per cent. is chiefly sulphur and iron. If with the use of the refining slags the ore does not flux, the addition of fluor-spar is resorted to. Great care must be taken not to use too much of these fluxes, for all scoria, no matter of what description, will contain copper; and the more slag there is made, the greater must be the loss in metal. The size of the smelting furnace is so regulated, that it consumes all the ore which is calcined in the first furnace.

The third operation is that of smelting the crude metal, or matt, of the second process, with the slags of the fifth process. This slag is chiefly a peroxide of iron, and the operation may be called on this account a roasting one. This calcination is performed in the large furnace, represented in Figs. 2106, 2107. The charges consist of 2 tons of matt, with nearly an equal amount of slags. The operation lasts twenty-four, and sometimes thirty or thirty-six hours, under repeated puddling of the ore. In this process much care must be taken to regulate the heat; it should be performed on the principles of roasting, by commencing with a low heat, which is gradually increased to the melting-point. The ore is tapped into the vault under the furnace, and oxidized by exposure.

The fourth process. This is again a smelting operation performed in the smelting furnace, of which Fig. 2108 shows a plan. The charges are 28 or 30 cwt., and a heat lasts from five to six hours, or when slow, eight hours. At every charge the metal is tapped, which now is a rich matt of 66 per cent. of copper. It is frequently very pure, and then it is called fine metal, and run into moulds, forming pigs; sometimes all of it is pimpled copper. In this operation there should be still so much sulphur in the metal as to cause sufficient fluidity; if there is a lack of it, some green ore is charged with the matt. When the metal from this operation is far from the reguline state, it is run into water and granulated.

The slags from this last smelting, together with some other slags, are sometimes melted in a furnace by themselves, which forms a particular operation. The matt obtained from these slags is a white and brittle alloy. The slags are also partly thrown away, but most of them are used in

the first process. The matt obtained is smelted separately, and then added to the first smelting, or the second operation.

Fifth process. The fine metal in the form of pigs of the foregoing operation, is charged to the amount of $2\frac{1}{2}$ or 3 tons at once in the calcining furnace, and exposed for twenty-four hours to a gentle heat. It should not melt, at least not for sixteen hours, and when melted afterwards it is to be repeatedly skimmed. The metal from this calcining operation is drawn into a bed of sand, and formed into pigs, which are fine metal for the refining furnace.

The sixth process is that of refining or toughening the metal. This operation is done in the smelting furnace; a charge of metal is from 3 to 5 tons. The pigs are exposed in the furnace to a roasting heat for twelve or sixteen hours, then the charge is melted, skimmed, and worked as clean as possible. A test of the metal is, after twenty hours' heat, taken by means of an iron ladle. A small wrought-iron foundry ladle is washed and heated in the fluid copper until it becomes red hot, or as hot as the metal itself. A ladle full of metal is now taken from the furnace and exposed to a slow cooling in the air. If the copper is fine enough, it will settle considerably in the ladle. The surface of the metal in the furnace is now covered with fine charcoal and prepared for refining. If the copper in the ladle swells up, or shows veins or black spots, it is not fine enough. In order to accelerate the process, a pole of wood is now used for stirring the metal diligently for ten minutes, after which another ladleful is taken for trial; it is now found to be fine, it will settle in the ladle. Good fine metal is brittle, of a deep colour, coarse grain, porous, and crystalline. The surface of the melted copper is now covered with fine charcoal, and the metal repeatedly stirred by means of wooden poles. The grain of the copper becomes finer by this operation, and the metal tougher. A test of the metal is now repeatedly taken in a small iron ladle, and when considered sufficiently refined, it is tried by means of a hammer on the anvil, while still red hot. If the metal forges soft, does not crack on the edges, and the refiner considers colour and grain sufficient, it is ladled out of the furnace with large ladles and cast-iron moulds. These form either pigs or slabs, 12 in. wide, 18 in. long, and 2 or $2\frac{1}{2}$ in. thick. These slabs are ready for the rolling mill.

In the progress of these different operations, the use of the slags forms a remarkable point for consideration. From the last smeltings the slags go back to the first process, to be either calcined or smelted. The refining slags are smelted with the metal in the formation of matt; and those from the smelting of matt are used in the calcining operation. The arrangement is such that the slag from the last operation is returned to a previous one. In each smelting some of the slags are thrown away, as too poor for the further work of extraction.

The fine metal of the sixth operation should be blistered or pimpled metal, containing from 94 to 96 per cent. of copper. Pimpled metal always assumes blisters, like those on converted steel, when cast into a sand-bed. The heat on the fine or blistered metal is longer or shorter according to its purity; an impure metal requires more heat than a pure metal. In some instances but a few hours' roasting are sufficient, in others a longer time is required. When the copper is melted in the refining furnace there is no harm done in stirring and cooling it, alternately, so as to chill the metal, and then melting it again. The rabbling, or puddling, must be continued until the copper is fine; in this operation the foreign metals become oxidized and vitrified. The slags of all the various operations contain more or less copper, particularly those of refractory ores. Neglect in skimming causes the slags to absorb and retain much metal. The slags of the coarse metal, or matt, take up the oxides of iron and tin, and often contain 5 per cent. of copper; they are therefore re-smelted. If the ore contains much tin, antimony, lead, and other metals, the slags of the fourth operation are smelted in a slag furnace, and the metal obtained used as pot-metal, either for brass and copper nails, or, if much tin and lead are present, pewter is formed of it.

When the point of refining is passed, in the operation of refining copper, the metal deteriorates in value, it becomes carbonized; this is prevented by exposing the hot surface to the action of the flame, and in skimming charcoal and slags off. Good metal is bright on the surface in the furnace. It is of a fine red colour when cold.

In the Blast Furnace.—The other method of smelting copper ores is in the blast furnace. The ore for this operation is sorted, washed, stamped, and in fact prepared as lead or silver ores. Poor ores, such as copper stists, are roasted in heaps, for fifteen weeks or longer. In smelting, matts are formed, as in reverberatories, which are re-smelted, and finally refined. In Figs. 2109 to 2111, two vertical sections, A and B, are shown of a blast furnace; and in C, Fig. 2111, the plane section with its two basins D D. The height of the furnace is about 14 or 15 ft.; the widest part of the boshes 29 in.; the hearth is 2 ft. square. The basins D D are 3 ft. in diameter and about 21 in. deep.

The copper ores, after having been roasted, are smelted by charcoal or coke—anthracite is perhaps preferable to either. The tuyere is generally pushed far into the furnace, so as to concentrate the heat in its centre. About 4 tons of ore are smelted in twenty-four hours with a considerably strong blast. In this operation a matt and a slag are smelted; the first contains from 30 to 40 per cent. of copper, and the latter frequently 5 or 6 per cent. more or less, according to the kind of ore. The matt contains sulphurets of copper, iron, silver, zinc, arsenic, cobalt, and in fact all those metals which were originally in the ore. It is tapped alternately into the basins and the slags removed from its surface. In cooling, it forms on its surface round plates which may be lifted from the

2108.

fluid metal. These contain matt of a variety of compositions, according to the height of the metal in the basin.

The matt thus obtained is generally roasted, either in kilns, or more generally, at present, in reverberatories, of which Fig. 2112 represents a vertical section of a German one. Fig. 2113, B, shows the same furnace in an opposite section to that of A, Fig. 2112. Above the two furnaces there is

a condensing chamber C, into which the volatile metals are conducted. These two furnaces, one above the other, are so arranged that either of them may be used separately. The flame is then conducted from the lower furnace in a separate flue into the condensing chamber, the partitions in which are so arranged that the gases are conducted from one into the other until they escape into a chimney.

The matt is roasted in these furnaces from three to six times; this is, therefore, an extremely slow operation; subsequently it is exposed to smelting again in the blast furnace. Crude copper is now obtained of a granulated fracture, which is ready for refining. After the above-mentioned roasting is performed, the ore is lixiviated in water, in order to extract the soluble sulphate of copper, which is precipitated by means of metallic iron. The coarse or black copper forms the lowest stratum in the smelting furnace, and also the basins; above this floats a poor matt covered by a silicious slag, which is thrown off and rejected. The matt and the metal underneath are gradually lifted out as it cools, and are in the form of rosettes.

The fine copper thus obtained from the blast furnace is most generally refined in reverberatory furnaces. In all instances that copper which has been smelted in blast furnaces is subjected to refining in the reverberatory, if it is brought into market directly from the blast furnace: this kind of copper is quite impure, which renders it unfit for being rolled into sheets. The impurities are most successfully removed in the reverberatory, as they consist chiefly of carbon and oxidizable metals.

A copper-refining furnace, as it is used by the Germans, is shown in Fig. 2114 in plane. The hearth A, 7 ft. in diameter, is formed of sand, or clay and fine charcoal. B B are two receiving basins, for lading out the copper, or forming rosettes of it. Three tons of black copper are melted at once, and as soon as the metal is fluid the bellows are set in operation, which, by means of the tuyeres C C, furnish blast on the surface of the metal, and oxidize it rapidly. A thick slag is thus formed, which is constantly drawn off, so as to expose a clean surface to the action of the blast. The refining lasts about sixteen or seventeen hours, and the loss of metal amounts to 3 per cent., which is absorbed by the slags. The latter is returned to the blast furnace.

The expenses for smelting copper ores are high, on account of the many and tedious operations which must be performed. Poor sulphureous ore, or that which contains but 8 or 10 per cent. of copper, is the most profitable in the reverberatory; rich ores should be smelted in the blast furnace. Ores of 9 per cent. consume 20 tons of mineral coal for the production of 1 ton of metal; poorer or richer ores than these cause the use of still more fuel. The labour spent in working the ore amounts to still more than the fuel consumed.

Copper is brought into market in different forms. For melting brass it is sold in a granulated form—bean-copper. This is produced by pouring it through an iron strainer, made of a ladle, into cold water. Hot metal causes round beans, cold metal oblong beans. Russian copper is sold in small square slabs; Spanish copper in the form of pigs.

The rollers used for laminating copper or brass are plain cylinders, as shown in Fig. 2115, not often more than 36 or 40 in. long, and 16 in. in diameter. Rollers 5 ft. long and 20 in. in diameter are used for large sheets. Slabs for rolling are gently heated on the hearth of a reverberatory furnace, Fig. 2116, to a dull red heat. At first singly, and as the sheets become thinner, they are passed in pairs, or three sheets and more at once, through the rollers. In the process of lamination the metal becomes cold, and by compression hard; it is therefore reheated, which serves in the meantime, when performed slowly, for annealing. When large sheets are to be rolled, the annealing furnace must be of a sufficient size to contain them. They are greased before passing them between the rollers.

Some kinds of copper contain large quantities of silver, for which the Lake Superior copper is particularly distinguished. We shall allude to the extraction of this metal under the head of silver.

Theory of Smelting Copper.—The copper of commerce is not pure; it is an alloy, as well as other metals. A quality of Norway copper, much esteemed by brass manufacturers, contains 99·5 copper and ·5 lead. Hard Hungarian copper contains 99 copper, ·7 antimony, ·1 iron. A superior quality of Swedish copper was composed of 8·66 copper, ·75 lead, ·05 iron, ·23 silver, ·05 silicon, ·02 aluminum, ·03 magnesium, ·12 potassium, and ·09 calcium. These assays show how much impurity copper may contain, and still be considered as a good article. The purest kind of copper should be employed for sheets. A minute quantity of lead causes copper to roll badly, and iron causes it to be brittle. Other mixtures are less injurious than these metals. It has been observed that the purest copper contains protoxide of the metal, a fact which is established in most other metals. The best kinds of copper are those which have been smelted by charcoal, and contain minute quantities of potassium. Bell-founders and other workers in bronze and brass are in the habit of covering the metal with potash or soda. This causes it to be close, sonorous, and of a fine grain. The substances most injurious to copper are lead, iron, antimony, silicon, carbon, sulphur, phosphorus, arsenic, and some other. Small quantities of lead, iron, nickel, silver, aluminum, magnesium, calcium, sodium, and potassium, improve the tenacity and general qualities of the metal. In refining copper, it must be therefore of advantage to have the surface of the metal covered with charcoal which has been soaked or damped with a solution of carbonate of potash or soda. These alkalis cause the removal of lead, tin, zinc, and iron, and prevent the flying or boiling of the metal.

The fine copper of the smelter, pimpled copper, black copper, or blistered copper, is an impure copper which contains much iron. This kind of metal is so far purified copper as to show its colour and faint metallic properties. Black copper, smelted of pyrites, contained 95·7 copper, 2·9 iron, ·6 zinc, and ·8 sulphur. Some crude copper, smelted of carbonates and oxides in the blast furnace, was composed of 89·3 copper, 6·5 iron, 2·4 peroxide of iron, ·3 sulphur, and 1·3 silica. We may mention that silica, combined with the protoxide of iron, exists in the form of slag in the copper. A coarse metal, which was derived from a refining cinder, contained copper 27·6, iron 2·5, cobalt

19·7, nickel 35·2, lead 12·4. A metal which furnished a prime quality of copper, in refining it, consisted of 95·5 copper, 3·5 iron, ·4 bismuth, ·6 silver.

The composition of the crude metal depends on the composition of the ore. In metal derived from sulphurets much sulphur is found; and in that from oxides other metals form the impurities, which must be removed before the metal is saleable. Iron forms, in most instances, the bulk of the impurities, and it must be the object of the refiner to remove it entirely. The presence of silica is required to oxidize and remove iron; but, as the oxide of copper has also a strong affinity for silica, the heat should be low, and the iron slag, as soon as formed, should be removed by skimming the metal. In crude copper derived from pyrites, the iron may be supposed to be present as sulphuret; and as, in oxidizing this, the metal is oxidized to the highest degree, it is necessary that carbon should be present to reduce the peroxide of iron thus formed, and convert it into protoxide, suitable for a union with silica. Such crude copper should therefore be refined under cover of charcoal, agitated by means of wooden poles. Copper smelted of oxides contains the iron in a metallic state, in the form of grains; for the affinity between these two metals is so faint that they do not unite chemically. The proper mode of refining this kind of crude copper is to melt it at a pretty strong heat, and stir or puddle it by means of an iron rod or hook, such as shown in Figs. 2117, 2118. Other substances than those above mentioned are easily removed from copper.

Lead, zinc, bismuth and arsenic are volatile, or their oxides combine readily with potash or soda, by the addition of which they will separate from the metal. A small quantity of precious metal does no harm to copper, and large quantities, such as one per cent. of silver or gold, may be profitably extracted from it.

Cobalt is removed with the iron, and nickel does no harm, for the alloy may be used as argentan in case much of this metal is present. When iron chiefly is to be removed, a clean surface of the melted metal is required in order to facilitate its oxidation. All other metals ought to oxidize slowly, and the oxides should be supplied with some alkali to combine with.

The impurities of copper are brought into the metal either by the ore, flux, or fuel. Iron is generally used as flux; if there is not sufficient of it present in the ore, it is added in smelting. But, as this method of using iron causes the formation of balls or lumps of refractory metal, or slag, in the furnace, the poor copper ore which contains iron as a natural admixture is preferred, since it is not liable to balling. The iron is in sulphuretted slags, in the form of sulphuret of iron. In slags derived from oxidized ores, it is in the form of protoxide. In the first kind of slag, sulphur causes its fusibility; in the second slag, silica. The former is a sulphuret, the latter a silicate. Both these compounds may be present in a slag; this, however, is not often the case. Generally, the silica separates from the sulphuret, and, as the first is not so heavy as the latter, it floats on its surface. In smelting, we thus obtain a slag which is a silicate, as the highest stratum, and a slag which is a sulphuret below that; the latter is called matt. When metals are present which have only a faint affinity for sulphur, such as lead, gold, or silver, these gather below the matt and slag, as we have seen in smelting lead. So long as sulphur is present in the slags, we cannot succeed in removing all the iron from the copper, nor all the copper from a sulphureous slag. Silicate of copper is refractory. All the metal may be extracted from a silicate, provided the union of copper and silicic acid is prevented. The metal should be separated before silicic acid is admitted to act on its oxide. Thus we have a series of operations in the reverberatory, all calculated to remove iron by means of silicic acid, and retain and concentrate the copper in the form of a sulphuret or matt. The addition of silica to rich ores is, therefore, a necessity; but as it is difficult to estimate the proper quantity to be used, such rich ores are not always so profitable to work as the poorer kinds. Too much silicic acid causes a stiff cinder which absorbs copper; and too little silicic acid does not absorb all the iron, and forms a stiff slag which cannot be separated from the copper, and causes it to form balls and oxidize. In smelting copper, as well as other metals, the slags are never too fusible; stiff pasty slags always retain grains of metal. It makes no difference by what means copper slags are rendered fusible, provided they melt at a lower degree of heat than the metal itself. Copper cannot be reduced from its sulphuret—it should be oxidized; therefore the smelting of copper is divided into a succession of processes, consisting of alternate calcinations and smeltings.

Slag from a smelting of copper pyrites in a reverberatory contained 48·2 silica, ·5 protoxide of copper, 37 protoxide of iron, 3 oxide of tin, 4 lime, 1 magnesia, 1·8 alumina. This slag is thrown away, because it contains but little copper. Slag from roasted pyrites, smelted in a low-blast furnace, contained,—silica, 51·8; protoxide of copper, 1·4; protoxide of iron, 29·2; baryta, 8·8; alumina, 5. The same kind of ore, smelted with more iron, furnished,—silica, 35; protoxide of iron, 41; oxide of zinc, 3; baryta, 12; lime, 3; magnesia, 2; alumina, 4. This composition furnishes a more fluid slag than the former, and is consequently free from copper. When the addition of iron is necessary, it should be made in the form of forge cinder, or puddling-furnace cinder, from the iron-works; because that form of iron fluxes well, without furnishing metal. The following is an assay of a slag which contained too much iron; silica, 33·6; protoxide of copper, 3; protoxide of iron, 51·5; lime, 5; alumina, 5·6. This slag, besides containing much copper, caused the deposition of considerable iron in the smelted copper, which formed balls of refractory metal consisting of 89·4 iron, 2 copper, 7 cobalt, and 1·8 sulphur. We thus see that the quantity and form in which fluxes are used is of much importance in this operation. Copper may be smelted from crude ores with success, as it is performed in Sweden; but the operation requires skilful hands to manage it. The fluxes are arranged so as to form a silicate, consisting of silica 56·5; protoxide of iron, 14·9; lime, 6·3; magnesia, 14·3; alumina, 6. This is a first-rate slag, and works well in

the low-blast furnace. The flux commonly used is limestone and forge cinder. More lime and less iron causes the copper to be very impure, and the slags contain copper; it also causes vexatious work in the furnace. Slags from copper-smelting resemble the forge cinder of the iron-works; they are, however, generally not so glassy, and often contain oxide of iron not combined with silica.

The matter obtained in the various processes is a compound of metals and sulphur, differing with the kind of ore from which it is obtained and the mode of operation by which it is formed. Roasted pyrites, smelted in a low-blast furnace, such as is used for smelting lead, furnishes a matt consisting of 27 copper, 40 iron, 25 sulphur, and 8 earthy matter. Rich matt, smelted in a blast furnace 16 ft. high, from roasted ore, contained 58·6 copper, 13·2 iron, 23·2 sulphur, and ·6 earthy matter.

The slags obtained in refining furnaces are a combination of the oxides and sulphurets which are contained in the crude metal. Refining is at present exclusively performed in reverberatory furnaces, either with the assistance of blast or without it; in either case the metals are oxidized by the oxygen of the air, and the sand of the hearth furnishes the silica for vitrification. These slags always contain a large quantity of copper, and are therefore re-smelted, either by themselves, or returned to earlier operations. The predominance of other metals than iron in the slags is indicative of a corresponding quantity of copper. Oxide of antimony is particularly apt to form and absorb oxide of copper. Lead has a similar effect, but in a far less degree. The slags obtained from the refining operations are easily reduced in a small blast furnace, and furnish an alloy. Smelted in a crucible with black flux, an assay of them is obtained in which all the other metals are present except iron. Their appearance varies greatly; when they contain much iron and sulphur, they are grey or black. Slags which contain no sulphur are brown, semi-transparent, and often blood-red, magnetic, of all shades of colour between black-brown and light red.

On whatever principle the extraction of copper from its ores is conducted, the composition of the ore and flux is so arranged that the yield does not amount to more than 7 or 8 per cent. The first smelting yields then a matt of 30 per cent. of copper; the second smelting, one of 60 per cent.; and the third smelting, crude metal or pimpled copper of 75 to 85 per cent. In blast furnaces, ores of 2½ per cent., or less, in yield, may be smelted to advantage. Rich ores are smelted in a low furnace, the height of which varies from 5 ft. to 18 ft. The first smelting of a 2½ per cent. ore yields, in Sweden, in the first smelting, a matt of 60 per cent. of copper; and the second smelting, after roasting the matt, yields crude metal of 85 or 90 per cent. copper. In Germany, an argenteiferous copper is smelted of bituminous slate in high-blast furnaces, which yields only from 1 to 3 per cent. of copper; the copper has not quite ¾ per cent. of silver. In all these various forms of smelting copper ore, a rapid oxidation by a high heat cannot be permitted, in order that the formation of silicates of copper may be prevented. Calcining is performed at a low heat, because if the ore was subjected to fusion in the operation, much copper would unite so closely with the silica as to become inseparable in the smelting furnace. Sulphur and silica are necessary fluxes in the reverberatory. In the blast furnace, copper ore may be smelted by fluxing it with lime or silicate of iron; and where the latter can be obtained in sufficient quantity, there is no doubt but that the smelting is cheaper when performed in the blast furnace than in the reverberatory. Refining should be invariably done in the reverberatory.

That ingenious and experienced manufacturing chemist, Peter Spence, of Manchester, has introduced some useful and important improvements in the metallurgical process of copper-smelting. Spence observes, in the *Mining and Smelting Magazine* (1864);—

"It is well known to those conversant with our staple chemical manufactures that, for many years back, a large proportion of the sulphuric acid required in them has not been produced from the sulphur imported from Sicily, but has been made from iron pyrites (bisulphide of iron) which is largely found in Ireland and Cornwall, and is also largely imported from Belgium and other parts of the Continent; and that, more recently, immense deposits of pyrites, rich in sulphur and containing from 2 to 4 per cent. of copper, have been found in the Peninsula, on the borders of Spain and Portugal. These last-named pyrites have come into extensive use, and, from their richness in sulphur, are preferred to the pyrites derived from other sources; so that the importers get a higher price for them than the value of the copper they contain, and consequently seldom sell them to the copper-smelters. The chemical manufacturer, in fact, has to purchase these ores at the value of both the copper and the sulphur, and, after extracting the sulphur, has generally to sell the ore to the copper-smelter, thus incurring a heavy cost in carriage on an article of small value per ton, and sometimes also a large loss from the uncertainty of the ordinary mode of assaying.

"From these circumstances, I found that in using Spanish pyrites the sulphur was costing me rather a heavy sum; and in 1861 I began to look round for some mode of lessening this cost. By extracting the copper from the burnt ores, if it could have been done without loss, I found I could save 600*l.* per annum in the mere carriage of the burnt ore to the smelters.

"I first, in connection with Rumney, of Manchester, went into the wet method of extracting copper. But having operated on nearly 2000 tons by various modifications of this method, our success seemed so problematical that the experiment was abandoned, with a loss of about 2000*l.* Indeed I am fully convinced by my own experience, added to that of almost all who have tried the extraction of copper by purely chemical wet processes, that such processes are not applicable in practice.

"I next turned my attention to the fact that the large copper-smelters in South Wales and elsewhere, were then, as they are at this moment, throwing out into the atmosphere, as to them an utterly useless product, the sulphurous acid gas which the chemist is so anxious to get cheaply, and that in quantities that would more than meet all the demands of the staple chemical manufactures. I asked myself whether I could not avail myself of this sulphur, which cost nothing and had no value to the smelter. The first difficulty was a mechanical one. All the pyrites then used in chemical works (whether Irish, Belgian, or Spanish) were imported in large masses, which were broken up into fragments of from 1 to 5 cub. in. in size. From these the sulphurous acid was extracted by

combustion in kilns somewhat similar in construction to small lime-kilns; but before charging the pyrites into these kilns all the dust or small had to be sifted out, as otherwise it would choke or damp the draught of the kilns and prevent combustion.

"When, however, attention was directed to the ores used by the copper-smelters, it was found that all the ores sold in Cornwall, and nearly all those imported, were crushed up before being sent to market, and that, in fact, the smelter used only small ores. Now, no method was then known by which these small ores could practically be calcined so as to economize the sulphur; for though repeated experiments had been made, at great expense, by the large copper-smelting firms to calcine their ores in such a way as to condense the sulphur, all such attempts had ended in failure—so much so that all endeavours on their part to effect this object have been abandoned.

"To prove that such is the case, I take the liberty of giving an extract from the evidence given by Dr. Percy before Lord Derby's Committee on noxious vapours.

"Lord Derby.—The statement of Le Play, that 46,000 tons of sulphur are annually lost, only goes to this, that if there were any known means of preventing the evolution of that sulphur, there would be a saving to that extent?

"Dr. Percy.—Undoubtedly, if it could be collected economically, it would be an advantage to the copper-smelters.

"Lord Derby.—You are not prepared to say that it could be.

"Dr. Percy.—I am not prepared to say that it can, by any known method. I am acquainted with all the attempts which have been made to obviate this nuisance—for a nuisance it undoubtedly is—but I believe they have not been found effective.

"Lord Derby.—What, in your opinion, is the reason why it is impossible to condense, or in any way to dissipate, this vapour?

"Dr. Percy.—I do not say it is impossible at all; all I say is that I know of no method, at present in existence, whereby it can be completely and economically condensed."

"One of the attempts probably referred to by Dr. Percy was a furnace used by a Lancashire copper-smelter, chiefly for producing arsenic from the copper ores, but partially used for the production of sulphuric acid from these ores. While my attention was directed to the subject of copper ores as a source of sulphur, a friend of mine in Manchester got the plans, and erected one of these furnaces, which were called dummy furnaces. At his request I saw it while building, and without hesitation said it would be a failure, which it turned out to be; for, after being used for a few months, it was pulled to pieces, its fallacious principle becoming apparent. This being then considered the best thing hitherto tried for the purpose, I at once determined to attempt the erection of a furnace on what I considered sound chemical principles. The furnace I erected was successful in calcining the small ores with a small expenditure of fuel and labour, with elimination of all the sulphur, if that was required, and enabling me to send all the sulphur so eliminated into the vitriol chamber, as sulphurous acid gas. Very soon after, I erected additional furnaces; and all the sulphuric acid made at my works at Manchester and at Goole since the end of 1861 has been made from these small ores, treated in furnaces similar, with slight modifications, to the first one I erected. I have now (1864) eight calcining furnaces at work, and am using from 125 to 180 tons of ore a week; and, in fact, am doing exactly what Dr. Percy stated he knew no method in operation that was capable of doing—for all the ores used are precisely the same ores as those used by the copper-smelters. I buy them in Cornwall, at the same market as the copper-smelter—paying only for the copper, the sulphur not being of any value to the smelter, who would rather have his ores nearly without it, if he could so get them.

"The amount of sulphur wasted in copper-smelting, and which could be economized by the use of calcining furnaces similar to those used by myself, is something enormous. Le Play, who many years ago investigated the subject with great care, gave the ores then used at 4000 tons a week, and the sulphur in them as averaging 23 per cent. The quantity now used exceeds 5000 tons a week, which (by the result of many analyses made in my own laboratory) contain on an average 28 per cent. of sulphur. This gives 70,000 tons of sulphur per annum, which at the present price of brimstone (6*l.* 10*s.* a ton) gives a money value of 455,000*l.* This, however, is hardly a fair way of putting it, as sulphuric acid is more cheaply made from pyrites than from brimstone. But from the 250,000 tons of copper ore now used annually by the smelters, 200,000 tons of brown sulphuric acid (of specific gravity 1.75) could be produced—for I am actually making acid at that rate from these ores. This acid sells at from 3*l.* 10*s.* to 4*l.* a ton; but at the very low estimate of 2*l.* a ton, its cost price to the maker, the smelters are actually throwing away 400,000*l.* a year. Now, whatever may have been the position of the copper-smelter a few years ago, he is at the present time wasting all this sulphur when there is not the slightest difficulty in economizing nearly the whole of it as sulphuric acid, without at all interfering with the smelting processes."

2119.

2120.

In Spence's first arrangement, the calciner, Figs. 2119, 2120, had a flat bed for the ore 40 ft. long by from 6 ft. to 9 ft. in breadth. Under this bed the fire-flues traverse nearly the whole

length of the furnace, to which furnace, however, the fire itself has no access. The ore is charged on to one end of this furnace-bed every two hours, in charges of from 5 cwt. to 8 cwt.; and, after two hours, is transferred, by iron paddles or slices, to some distance from the point where it was first charged; being replaced by another charge. This transference goes on every two hours, until the ore reaches the other end of the furnace, where, being fully calcined, it is dropped into an iron truck and removed. This charging and transference goes on periodically, air being continuously drawn in at the part of the furnace where the burnt ore falls out; which air, traversing the whole surface of the ore on the bed and effecting combustion, ultimately arrives at the other end highly charged with sulphurous acid gas, and passes up a special flue or chimney into the vitriol chambers. Nitrous gas is, as usual, found mixed with it as it enters the chamber. This process goes on day and night; and the furnaces are so regularly kept at the same temperature that their wear is exceedingly small—one having been at work upwards of two years, with only three days' stoppage for repairs.

Fig. 2121 represents a modification of the furnace, Fig. 2119. Both of these arrangements were found to work well. The one shown in Fig. 2121 consists in combining the calcining furnace with the smelting furnace, so that the ore falls out of the calciner into the smelter at a red heat—thus saving the labour and nuisance of removal, and the cost of reheating it when put cold into the smelter. In addition to this, the waste heat

2121.

from the smelter, instead of passing direct to the stack, is made to pass under the bed of the calcining furnace, thus saving all the fuel now used in calcining.

Fig. 2122 represents a longitudinal section, and Fig. 2123 a cross-section, of Spence's final arrangement, now (1870) in active operation.

2122.

2123.

The bed of the furnace is at *a*, in which are mounted two rails *b*; upon these rails are wheels *c* mounted loosely upon axles which are attached to a frame *d*; to this frame is bolted a bar *e* carrying

on its under-side a rack *f* and resting upon rollers, one of which is shown at *g*; but there are several placed at intervals, carried by any suitable bearings, the length of the bar *e* being such as not to pass off the innermost of the said rollers when the frame *d* is at the back end of the furnace. The frame *d* carries two rows of instruments *h* *h*¹, which project downward nearly to the bed of the furnace, and the two rows are so placed that an instrument in one row is opposite to a space in another; at Figs. 2124, 2125, they are shown detached, the latter showing their horizontal section, and it will be seen that on one side they are pointed and on the other flat. At *i* is the fire-place, and at *k* the chamber, through which the products of combustion pass, and by means of which the furnace becomes heated. At *l* is one of a series of doors extending at intervals along each side of the furnace. At the front of the furnace is an inclined shute *n*, through which the material passes when calcined.

The ore having been first ground, or otherwise brought into a state of fine division, is fed across the furnace through one of the doors at the back thereof, and motion is communicated by means of the shaft and pinion *m* to the rack *f*, whereby the frame *d* will be caused to advance towards the back of the furnace; the instruments *h* moving in the direction of the arrow, Fig. 2125, the pointed parts will therefore advance through the material, and their curved bottoms, seen in Fig. 2124, acting as ploughshares will stir and turn the material over. When the frame has reached the back of the furnace the motion of the shaft *m* is reversed, and the frame *d* with its instruments travels towards the front of the furnace, and the flat parts of the said instruments will now therefore act against the material, a portion of which will be carried forward. The frame *d* and its stirrers is now in a highly-heated state; and in order to allow it to cool, the motion of the shaft *m* is arrested, so that the apparatus may remain stationary for a period, and as it is now over the shute *n* it receives the current of air passing through the same. When the desired cooling has been effected, say in four or five minutes, the shaft *m* is again put in motion and the operations above described are repeated. The charge is repeated at the back end of the furnace about every hour, and it has been found that a charge may be about 1½ cwt. for a furnace 32 ft. long and 6 ft. wide, the speed of the rakes being about two minutes from the front of the furnace to the back and back again; and as the charging continually goes on for each hour, a portion of the material is carried forward each time by the flat part of the rakes, and is ultimately delivered through the shute *n*; but as such portions are continually falling off the rakes they are only carried forward through short spaces at each raking, and they therefore only gradually make their way to the delivery end.

The mechanical means of causing the forward and backward motion of the rakes may be varied to a considerable extent. The means employed will be readily understood by referring to Figs. 2126, 2127, the former being a side view, and the latter a plan of a pair of engines and other parts

2126.

which may be used separately for each furnace, or for two or more. At 1, 2, are two steam-cylinders communicating motion by their piston-rods to the crank-shaft 3, upon which there is a pinion 4 taking into a wheel 4* which is on the shaft *m*, the same as that denoted by the same letter of

reference in Fig. 2122. Upon the crank-shaft 3 is a bevel 5 taking into another 6 upon a shaft mounted in a bearing 7, and this shaft is provided with a worm 8 in gear with a worm-wheel 9

mounted on a shaft 10; on this shaft is a tappet 11, which at intervals, as will be described, arrives in contact with a pin 12 projecting from a lever 13 turning loosely upon the shaft 10, and the said lever 13 also carries another projecting pin 14, situate beneath the ordinary eccentric rod 15, which at its end is connected to the valve-rod by the usual gab-motion 16. The steam-pipe for the cylinders is at 17, provided with a stop-tap 18, upon which is mounted a lever 19, 19*, the end 19* thereof being pressed in the direction of the arrow by a spring 20, and the said end 19* is jointed so as to be capable of turning against the force of the said spring in one direction. Adjoining the steam-cylinders 1, 2, is a supplementary small steam-cylinder 21, the piston of which is constantly going and communicates motion to a crank 22, on the shaft of which is a worm 23 taking into a wheel 24, which then drives the train of clockwork 25, 26, 27, 28, on the last of which there is a projecting pin 29 arriving at certain times in contact with the lever 19. According to the positions of the parts shown, the rakes are proceeding from the front to the back of the furnace, and have nearly reached that position, they having been driven forward by the wheel on the shaft *m*. The tappet 11 will therefore soon arrive in contact with the projecting pin 12, and when that takes place the said lever will be turned over until the weight thereon has passed the vertical line, after which it will fall over and bring the pin 14 to bear against the eccentric rod 15, which, by turning upon the rocking-lever 30, will shift the position of the gab-motion 16, and thus reverse the engines, there being a lever 13, and pins 12, 14, for each of the two driving steam-cylinders; the driving-wheels will now revolve in the contrary direction, and the rakes will travel back towards the front of the furnace, carrying with them, as before described, a portion of the material. When this has been effected, the lever 31 on the shaft 10 (and which is now moving in a direction contrary to the arrow) will arrive in contact with the lever 19*, thereby causing the stop-tap 18 to be turned and the steam to be shut off; the motive power being thus arrested, the rakes will remain at the front and colder end of the furnace a sufficient time to cool, and that period is determined in the following manner:—It has been stated that the small cylinder 21 is constantly supplied with steam, and the train of gearing 23 to 28 is therefore constantly revolving, and the numbers of teeth are so arranged that when the rakes have been allowed to remain stationary a certain time, a pin 29 upon the wheel 28 arrives in contact with the lever 19, thereby turning the stop-tap so as to open it and admit steam to the cylinders 1, 2; when this is done, the tappet 11 will at the same time again arrive against the pins 12, but on the side thereof opposite to that above mentioned; the levers 13 will therefore be turned back into the position shown, thereby removing the pins 14 from the eccentric rods 15, and allowing them to fall, and again reverse the engine, so that the rakes will now be moved to the back of the furnace, and thus the operation continues. When the lever 37 turns back after having shut off the steam, the spring joint of the lever 19* allows it to pass.

Copper and Copper Ores; our ascertained positive knowledge respecting.—Atomic weight = 63; probable molecular weight = 63.

Pure copper is found in a state of nature, but the principal ore of this metal is a double sulphuret of copper and iron. This ore is subjected to the process of roasting, which transforms the sulphuret of iron into oxide of iron and sulphurous anhydrite. The oxide of iron passes off in the scoræ or slag in the form of fusible silicate. A repetition of the same process completes the

expulsion of the iron. A third roasting gives the copper in its raw state; the sulphuret of copper is, indeed, transformed into sulphurous anhydrite and oxide of copper, and this latter oxide reacts on the sulphuret not yet decomposed, thus producing copper and sulphurous anhydrite.

By roasting this raw copper in a silicious furnace, a certain quantity of oxide is formed by which the elimination of the sulphur is completed, and at the same time the oxides of the foreign metals, uniting with the silice of the furnace and forming silicates, pass away in the scoriae.

To free the copper from all oxide, it is melted, carbon is placed on its surface, and the mass stirred with green wood. The carbonated gases evolved from the wood by the action of heat are sufficient to reduce the oxide of copper in the metallic mass. These two latter are called refining processes.

Copper may be chemically obtained by reducing the oxide of this metal with hydrogen. For this purpose, pure oxide of copper is placed in a globular chamber blown in the middle of a glass tube; Fig. 2128; one end of this tube is made to communicate with an apparatus in which hydrogen is produced, through the medium of a desiccating tube, and the other end communicates freely with the atmosphere.

When the hydrogen has passed through during a time sufficiently long to ensure the expulsion of all the air, a precaution necessary to avoid an explosion, the oxide of copper is heated by means of a spirit-lamp; water is thus formed and the copper is liberated.

The process is complete when no more steam can be evolved.

Copper is of a red colour; it is sufficiently malleable to allow of being beaten out into transparent sheets; it is also very ductile and very tenacious.

It may be obtained artificially crystallized in cubes, and it is under this form that it is found in nature. The density of this metal is 8.85.

Copper, on being rubbed, emits a disagreeable odour. It melts at about 778° C. It does not become oxidized in dry air at an ordinary temperature; in a high temperature it becomes oxidized without incandescence. When exposed to damp air, it becomes covered with a layer of hydrated carbonate of copper (verdigris), but this layer preserves the metal from further change.

Azotic acid affects copper when cold, and sulphuric acid when heated. In the former case are produced bioxide of azote and azotate of copper; in the latter case, sulphate of copper and sulphurous anhydrite.

In the presence of acids, copper readily absorbs the oxygen of the atmosphere; it also becomes oxidized in the presence of ammonia, and is dissolved, producing a beautiful blue liquid.

Copper, previously heated, burns in chlorine, producing bichloride of copper. It combines directly with sulphur, phosphorus, arsenic, bromine, and most of the metals.

Copper forms two series of compounds. Being diatomic, it combines directly with two monatomic radicals, or with a diatomic radical like itself, and so becomes saturated. Thence we have a series of compounds which have received the name of maximum. These are;—

and the various oxygenated salts resulting from the substitution of radicals of acids for the hydrogen of the hydrite of copper.

By reason of the diatomic nature of copper, two atoms of this metal may unite, exchanging only a single atom between each other, and form the diatomic group Cu^{O} , as shown in the following

The group Cu^2 being diatomic, may combine quite as well as the atom Cu with chlorine, bromine, iodine, and so on; and as the combinations formed by it offer sufficient stability, we have a second series of compounds of copper, known by the name of minimum, and in which, instead of the single atom Cu , appears the group Cu^2 . These are;—

Protochloride	$\text{Cu}^2 \text{Cl}^2$	Protofluoride	$\text{Cu}^2 \text{Fl}^2$
Protobromide	$\text{Cu}^2 \text{Br}^2$	Suboxide	$\text{Cu}^2 \Theta$
Protoiodide	$\text{Cu}^2 \text{I}^2$	Subsulphuret	$\text{Cu}^2 \text{S}$

and the very unstable protosalts resulting from the substitution of the diatomic group Cu^2 for an even number of atoms of the hydrogen typical of the acids.

Besides these two series of compounds, copper forms with oxygen a bioxide $\text{Cu} \Theta^2$, and an acid the composition of which has not yet been exactly determined.

The diatomic nature of oxygen explains how several atoms of this body can unite with a single atom of copper: two atoms of oxygen may exchange each one atom with the copper and one between each other, as we see by the aid of the diagram.

We will consider more particularly bichloride, protosulphuret, protoxide, hydrate, sulphate, azotite, and the carbonates.

Bichloride of Copper, $\text{Cu}^2 \left\{ \begin{smallmatrix} \text{Cl} \\ \text{Cl} \end{smallmatrix} \right\}$.—This compound is formed by the direct action of chlorine upon copper; it is also produced by dissolving the protoxide of this metal in chlorhydric acid.

Bichloride of copper is soluble in water and in alcohol; its watery solution, concentrated when hot, deposits while cooling hydrated crystals, the formula of which is $\text{Cu}'' \text{Cl}^2 + 2 \text{aq}$. These crystals are in shape like long needles of a greenish-blue colour. The alcoholic solution of this salt burns with a bright green flame.

Protosulphuret of Copper, $\text{Cu}'' \text{S}$.—This substance does not exist alone in nature; it is obtained by sending a current of sulphurated hydrogen through the watery solution of a salt of copper, bichloride, for instance;—

It is precipitated under the form of a black mass, which converts itself into sulphate when exposed to the air, by attracting the oxygen.

Protosulphuret of copper loses half of its sulphur by being heated, and is transformed into subsulphuret.

Protoxide of Copper, $\text{Cu} \Theta$.—This oxide may be obtained; 1, by heating copper exposed to the air, when a layer of oxide easily detached is formed on the surface of the metal; 2, by calcining azotite of copper; 3, by heating hydrate of copper; to dishydrate this latter substance, it is sufficient to boil it with water.

Whatever process of preparation may be employed, with slight differences in the physical properties of the oxide, which may be more or less compact, this compound possesses the following properties;—

It is a black and amorphous powder, capable of supporting a very high temperature without being decomposed or melted. When, however, it is heated in too high a degree, the mass becomes a solid block, extremely hard, and, when pounded, of a yellowish colour. This oxide appears to be in a particular allotropic state. M. Kiehn has noticed that it then possesses the faculty of agglomerating at a lower temperature than when it has not been overheated. It loses this property when it has been heated several times at a temperature insufficient to cause it to agglomerate, and then allowed to cool.

Protoxide of copper is a basic anhydrite. It is much used in laboratories, where it is employed in making organic analyses.

Hydrate of Copper, $\text{Cu}'' \left\{ \begin{smallmatrix} \Theta'' \\ \text{H}^2 \end{smallmatrix} \right\} \Theta^2$.—This hydrate is obtained by precipitating the solution of bichloride, sulphate, or any other maximum salt of copper by an alkaline base. The precipitate so formed must be well washed and dried in an ordinary temperature; it is of a dirty blue colour.

Another way of preparing this compound is to dissolve suboxide of copper in boiling hydrochloric acid, and then to allow the liquid to cool, in the midst of which will be deposited the little colourless tetrahedrons of protochloride of copper.

It may also be obtained by heating perchloride of copper, which thus loses half its chlorine.

Chloride of copper minimum is a white substance hardly soluble in water, but soluble in hydrochloric acid and ammonia; it turns green when exposed to the air by absorbing oxygen and transforming itself into oxychloride, $\text{Cu}^2 \text{Cl}^2$. It also absorbs oxide of carbon, but it gives up this gas when its solution is made to boil. In an ammoniacal solution it gives, with the gaseous carburets of hydrogen of the series $\text{Cu}^2 \text{H}^{2n-2}$, explosible precipitates which, heated with hydrochloric acid, give out the hydrocarburet the elements of which it contains. This property has been utilized in organic chemistry.

Subsulphuret of Copper, $\text{Cu}^2 \text{S}$.—Subsulphuret of copper is found in a natural state under the form of beautiful crystals, belonging to the cubic system. They are of a black colour and sufficiently soft to be cut with a knife, and they melt in the flame of a candle. Their density is 5.0.

This substance is prepared artificially by calcining copper with an excess of sulphur; the excess of sulphur is evaporated during the process of calcination. To ensure the whole of the copper being acted upon, the product of this first operation is crushed and calcined a second time with sulphur.

When heated in the air, it gives a sulphate of copper, if the temperature is not too high; if not, it is transformed into oxide of copper and sulphurous anhydrite, by absorbing oxygen. Heated with oxide of copper, this sulphuret gives out sulphurous anhydrite, leaving a residue of metallic copper.

Suboxide of Copper, $\text{Cu}^2 \text{O}$.—This substance is found in a natural state. It is sometimes found in compact masses, and sometimes in octahedric crystals of a red colour; it may be obtained artificially in the form of a red powder, and in various ways.

If acetate of copper be boiled with glucine, a red crystalline powder is precipitated, which is suboxide of copper.

In the arts, this substance is commonly prepared by calcining a mixture of;—

	Parts.
Sulphate of copper	100
Dry carbonate of sodium	28
Copper filings	25

The produce of this operation must be well washed.

Suboxide of copper melts without undergoing change when heated unexposed to the air; when heated in the air it is transformed into protoxide.

Hydrochloric acid converts it into protochloride; this oxide is, therefore, a basic anhydrite.

Azotic acid gives up its oxygen to it, and causes it to pass into the state of a maximum azotate; strong acids decompose it into metallic copper and bioxide of copper, which, when in contact with these acids, gives a salt of copper;—

Ammonia dissolves this oxide without being discoloured; but the solution becomes blue by absorbing oxygen when exposed to the air.

Distinctive Properties of Salts of Copper.—Salts of copper are recognized in analyses by the following properties;—

1. A sheet of iron becomes covered with a perfectly-adhering layer of copper, when dipped into the saline solutions of this metal.

2. Hydrosulphuric acid causes in these solutions a precipitate insoluble in alkaline sulphurets; this precipitate is not produced in the presence of cyanide of potassium.

The maximum salts may be distinguished from the minimum;—

1. Potassium gives with the minimum salts a yellow precipitate insoluble in an excess of reactive, the maximum salts are precipitated by the same reactive, a dirty blue colour, and the precipitate becomes black on being boiled, if sufficient quantity of potassium has been added to wholly decompose the salt of copper.

2. Ammonia produces in the maximum and the minimum salts a precipitate soluble in an excess of reactive; but with the maximum salts the ammoniacal solution is of a beautiful blue colour, whilst with the minimum salts this solution is colourless and becomes blue only on contact with the air.

All the salts of copper are poisonous. The best means of counteracting this poison if accidentally swallowed is to take some white of egg, while waiting for an emetic. The albumine of the egg forms with the copper a compound almost insoluble, and by this means the absorption of the metal is prevented.

It has been proposed to substitute iron dust for albumine, which dust precipitates the copper in a metallic state, or sulphuret of iron, which will produce sulphuret of copper.

Figs. 2129 to 2131 are of the furnace, invented by Alfred Jenkin, of Zell, for the reduction and calcination of copper and lead ores.

This invention relates to a peculiar construction and arrangement of a double reverberatory furnace, to be employed in the reduction and calcination of copper and lead ores, whereby a great economy of fuel is effected. The principal feature in this improved furnace is, that one ordinary fire answers the double purpose of reducing and calcining the ore. The fire is contained in an ordinary fire-place, situated at one end of the double furnace.

The heat and flame from this fire pass through a lateral opening or flue into the reducing or flowing furnace, and after passing over the surface of the ore contained therein, it enters by another opening or openings into the calcining furnace, which is placed on the same level, or nearly so, with the flowing furnace. From the calcining furnace the heat passes off by a suitable flue or flues to the chimney. In the passage or passages which conduct from the flowing furnace to the calcining furnace there are placed suitable doors or dampers, which are so arranged that, by opening or closing certain of these doors or dampers, the heat and flame may either be directed into the

calcining furnace, or be entirely shut off from such furnace and be directed into a waste flue, which passes downwards to an underground flue communicating with the chimney. An air or a ventilating space is left between the calcining and flowing furnaces, for the purpose of preventing the bed of the latter furnace from becoming overheated, when the flame and heat are diverted down the waste or escape flue or flues, which flue or flues are formed in that side of the ventilating air-space farthest from the flowing furnace; so that, whether the calcining furnace be in operation or not, the bed of the flowing furnace will always remain at about the same temperature.

Fig. 2129 represents an exterior elevation of Jenkin's improved arrangement of a reducing and calcining furnace; Fig. 2130 is a longitudinal transverse section; and Fig. 2131 an horizontal section. A is the ordinary fire-place, the heat and flame from which pass through the lateral opening or flue B into the flowing furnace C, and after traversing over the surface of the ore contained therein enter by the passages D into the calcining furnace E, which is upon the same level with the floor of the flowing furnace. F are passages leading off to the main draught flue or chimney. When it is required to shut off the heat and flame from the calcining furnace, the two dampers G are closed, and the pair of dampers H are elevated, thereby shutting off the flow from the passages D, and diverting it into the descending or waste flue I, which conducts it underground to the main flue. An air or a ventilating space J is left between the flowing and calcining furnace, in order to prevent the latter from becoming overheated. The ore to be calcined is fed into the calcining furnace by the hopper K, and is removed when calcined through the aperture L in the bottom of the furnace. The flowing or reducing furnace is also provided with a similar hopper M, to supply the calcined ore to the flowing or reducing furnace. The small chimney N serves to carry off any dust or ashes arising from the fire when fresh fuel is supplied, or when the fire is otherwise agitated.

William Longmaid in 1842 proposed a method of treating ores. This method related to the treating of such descriptions of ores and minerals as contain sulphur; and had for its object the removal of the sulphur from such ores and minerals, in order to render the subsequent operations to which such ores are subjected more advantageous in obtaining products therefrom. Writing in 1842, Longmaid observes,—“I have discovered, after much experiment, that the use of common salt can only be generally and practically useful as a manufacture when the quantity of salt applied in respect to the ore or mineral treated considerably exceeds the quantity of sulphur contained in the ore or mineral. And I have found that when treating ores according to my plan with common salt, I obtain metallic oxides in a condition fit for metallurgical purposes; and by such means I am enabled more advantageously to obtain the metallic products of the ores treated than when operating on similar ores according to the means now practised, and with one great advantage, that in so treating ores and minerals containing sulphur, I take up the larger portion of the sulphur so contained in the ores or minerals, and convert common salt into sulphate of soda. Hence it will be understood that my invention consists of treating ores and minerals containing sulphur with such proportions of common salt that the ores are deprived of their sulphur, or nearly so; and the metallic products resulting from such process are rendered more suitable for subsequent processes for obtaining the metals therefrom, and at the same time the act of so treating the ores and the minerals will produce much larger quantities of sulphate of soda than has heretofore been obtained.

“I have found that any ore containing 15 to 20 per cent. of sulphur, and in some cases even less, may be usefully operated on according to my invention; and the treatment according to my invention may be usefully applied either before or after the ores have undergone any process of heat, provided a quantity of sulphur remains equal to the percentage above mentioned. The ores and minerals to be treated according to my invention are those containing sulphur, particularly mundics, or iron pyrites, copper ores, lead ores, tin ores, zinc ores; mundics, or iron pyrites, containing sulphur combined with copper or tin, or with both; copper ores, containing sulphur combined with iron or tin, or with both; lead ores, containing sulphur combined with copper; and tin ores containing sulphur combined with copper or iron, or with both. The process of treatment, according to my invention, is to be carried on in suitable furnaces. The one which I prefer is a reverberatory furnace, having four beds, each succeeding bed being on a somewhat higher level in proceeding from the fire towards the end of the furnace. At the same time I do not confine myself thereto, as the furnace employed may be varied without departing from my invention; and the ore or mineral, with salt, are to be introduced on the bed of the furnace most distant from the fire, in order that the sulphur given off at comparatively low temperature may be taken up by the salt; and as the ores operated on progressively require more heat to separate the sulphur, they will progressively be brought on to a hotter bed of the furnace.

“Figs. 2132, 2133, show a longitudinal section and plan of a furnace such as I prefer to use in carrying out my invention, and which I prefer to make about 60 ft. long, and 10 ft. from back to front in the clear, having several openings to allow of the matters under process being turned or stirred from time to time; and I find that the occasional admission of steam to the charge nearest the fire is attended with beneficial effects, promoting the oxidation of the minerals and the evolution of the muriatic acid, but this addition is not absolutely necessary.”

Description of the Process.—It is better that the ores should be crushed so as to pass through a sieve of four or more holes to the inch, though this is not always necessary. The salt should be dried previous to mixing with the mundics or other sulphur ores, by placing over a flue, so as to obtain the benefit of the otherwise waste heat. The object of this drying is to prevent its caking in the furnace. The quantity of sulphur contained in the ore having been ascertained by the analysis of a carefully-prepared sample, a given quantity of salt, say 1 ton, having been weighed out, a quantity of ore containing sulphur required for the conversion of the salt into salt cake should be added and intimately mixed. The quantity of sulphur required to convert a ton of salt into salt cake is, by calculation, about 5 cwt. 1 qr. 11 lbs.; but as all the sulphur cannot be taken by the salt, it is proper to have the sulphur in excess above that quantity. And although a beneficial working may be obtained by employing a much less quantity of salt in respect of the sulphur contained, yet

Longmaid found that in all cases the common salt should considerably exceed the known weight of sulphur contained in the ore or mineral under process. The mixture of about $\frac{3}{4}$ of the ore required for the salt used should be put upon the upper bed of the furnace, that is, the bed farthest removed

2132.

2133.

from the fire, and left until heated throughout. It should then be turned over from time to time, so as to allow of the successive contact of the mixture with the atmospheric air passing through the furnace. At about equal intervals and at several times during the time the mixture remains on the upper bed, the remaining quantity of ore should be added. By these means the rapidity and effectiveness of the operation is promoted, and some saving of fuel is produced. It is impossible to fix the exact quantity of ore required, as it must vary according to the quantity of sulphur contained in the ore employed, and depending, in some degree, on the nature of the substances associated with it. The less arsenic contained in the ore the better, although its presence is not an insurmountable objection, especially if associated with a small percentage of copper. A charge being drawn about every twenty-four hours from the front bed, each one of the three remaining charges will then be moved forward to the next lower bed, and a fresh charge put into the upper bed, each one of the charges being kept regularly raked in its turn. A brisk fire is to be kept up in the furnace during the whole time, and a damper is applied to the chimney to obtain regulation. As the decomposition of the salt and ore proceeds, the mixture is gradually fitted to bear the increase of temperature obtained by removal from the upper to the next lower bed, and so on, approaching the fire. The operation appears to proceed best when on the bed nearest the fire it has been brought to a semi-pasty condition, or when the mass has a tendency to agglomerate, and seems to be moist on the surface. By the increase of temperature to which it is here exposed, the charge soon begins to dry up, so that it is eventually drawn in a granular condition. The sulphate ash obtained contains sulphate of soda or salt cake, the chloride of sodium, oxides of iron, a soluble salt of copper, and oxide of tin, if any tin was present in the ore employed, provided the ores be mundic; and, if other ores are used, other products will be obtained. The ash being lixiviated with water, affords a solution containing the sulphate of soda, chloride of sodium, and salt of copper, the insoluble residue containing the oxides of iron and tin. If oxide of tin be contained in the ore employed, it may be separated from the residual matters by washing, the greater specific gravity of the oxide of tin rendering the separation comparatively easy. The copper may be separated from the solution, either with iron, as is well understood, or, as Longmaid prefers, by the addition of lime slacked in water, forming a milk of lime. Iron precipitates the copper in a metallic form; but the lime precipitates it as an oxide, associated with the slight excess of lime necessarily employed, and some small portion of sulphate of lime. This precipitate, by filtration, having been separated from the refined liquor, should be well washed, in order to the complete separation of sulphate of soda and chloride of sodium, the liquors obtained being employed in the lixiviation of fresh sulphate ash. This precipitate is bulky; but, by filtration and drying, its volume is very much diminished, and it is then obtained in a condition fit for reduction to the metallic state by the usual metallurgical process. The solution from which the copper has been separated may, if required, be concentrated by boiling, and set aside to crystallize in suitable vessels, very fine crystals of the sulphate of soda being obtainable. The mother liquor may be again concentrated and set aside to crystallize, or, if required, be employed for the manufacture of alkali by mixture with fresh lime in quantities bearing the proper proportions observed in the manufacture of black ash. If the salt cake be required only for the manufacture of alkali, the solutions obtained by lixiviation should be run off into a large tank, from which the quantity of liquor containing the desired quantity of salt cake may be run on its equivalent of newly-burnt lime, previously weighed out, by which means the water of solution is either solidified or expelled by the heat evolved in the course of the slacking. But should the solution be so weak that the heat evolved from the requisite quantity of lime would not be sufficient to expel the whole of the water, the lime, after being treated with sufficient of the liquor for slacking and converting into a very thick pasty condition, resembling a tough mortar, might be thrown either upon a flue at the end of a black ash furnace, by means of which the benefit of spare heat may be obtained, or upon the third bed of a black ash furnace, where, as evaporation proceeds, the remainder of the liquor required may be gradually added. By these means a more perfect mixture of the salt cake, with its equivalent of lime, is obtained than is the case by the usual process of mixing only the slacked lime and the dry

sulphate of soda or salt cake in powder. The mixture of sulphate of soda and lime treated with its requirements of carbonaceous matter previous to turning down to the lower bed of the black ash furnace is in the usual condition in which it is employed.

Longmaid, in 1844, stated that the great object of his method of 1842 was to obtain sulphate of soda, the metals obtained being considered a beneficial addition resulting from the process. But he afterwards observed that there were circumstances under which, and situations where, ores containing copper, tin, and zinc, with sulphur, may with advantage be treated with common salt for obtaining the metallic parts, without depending mainly on the profits derivable from the sulphate of soda. Longmaid's process of 1844 consists of an improvement in the manufacture of copper, tin, and zinc, by causing ores containing those metals to be treated with common salt below the relative quantities which he specified in 1842. In 1844 Longmaid stated that the more nearly the quantity of salt approaches sixty by weight to every forty by weight of the sulphur ascertained to be contained in the ores to be treated containing copper, tin, and zinc, the more effectually will the metallic portions of the copper and zinc become soluble in water; though the quantity of common salt may be reduced very considerably below sixty to forty of sulphur, and yet obtain very beneficial effects, particularly where the cost of common salt is comparatively great, and there is no ready sale for sulphate of soda at a price that will repay the manufacturer for using a larger proportion of common salt.

The salt to be used should be well dried, and the ores containing copper, tin, or zinc, with sulphur, to be broken to powder; and having ascertained the quantity of sulphur contained in any quantity of ore about to be treated, mix therewith a quantity of salt suitable for obtaining the metallic parts of the copper and zinc in such a state as to become readily soluble in water, using more salt when the cost thereof, coupled with the selling price and demand for sulphate of soda, do not restrict; but below the rate of sixty by weight of common salt to forty by weight of the ascertained quantity of sulphur, the object of this process being to obtain the metallic parts of the ore separate, without materially, and in some cases not at all, depending on the value of the sulphate of soda resulting from the process, this invention being useful only in those cases where the manufacturer, from local or other causes, does not desire to produce a quantity of sulphate of soda so large as would result from the sulphur contained in an ore if common salt were used in the manner described by Longmaid in 1842. The ore containing copper, tin, or zinc, mixed with the salt, is to be placed into a *suitable* furnace, similar to that to which Figs. 2132, 2133, appertain. The ore and salt mixed together are to be treated in the same manner as that described by Longmaid in 1842, except that, there being a reduced quantity of salt employed, the whole may be at once mixed before being introduced into the furnace. Each charge of ore and salt is to remain from twenty to twenty-four hours on each bed of the furnace, and to be drawn in about eighty to ninety-six hours, which the workman will judge of by the muriatic acid being driven off. And it should be stated that Longmaid found that some ores, when so treated with salt, are liable to flux. In such cases he applied about $\frac{1}{2}$ cwt. of small anthracite coal or other carbon mixed with a charge of a ton of mixed ore and salt, either when the same indicates fluxing in the furnace, or with all future charges of the same ore. The charge being drawn from the furnace, is then to be lixiviated with water in suitable vessels. The liquor obtained will contain metallic matters in solution, according to the nature of the ores operated on, together with sulphate of soda, muriate of soda, or chloride of sodium. The copper contained in any liquor obtained as above explained may be precipitated, as is well understood, by means of iron; and the milk of lime may be subsequently employed for separating the zinc, associated with an excess of lime and with some oxide of iron. Longmaid, in 1844, stated that the oxide of tin separates from the liquor by gravity, with residuary matters; and if they be not broken fine enough for the washing process to separate the oxide of tin, they are to be broken before washing to separate the tin in the ordinary manner (?). If the whole of the copper and zinc be not converted into the soluble form by the first operation, the insoluble residue may be treated with weak muriatic acid obtained by condensing (?) that product as it is evolved from the furnace where the ores are being treated with common salt, or weak muriatic acid otherwise obtained may be employed to dissolve the copper and zinc not before rendered soluble in water; and these metals may be separated from the solutions thus obtained, as above explained.

Longmaid, in 1851, says:—"In my processes, of 1842 and 1844, for treating ores and minerals, I have found considerable difficulty in condensing the gas and vapours arising therefrom, in consequence of the volatile carbonaceous matters contained in bituminous coal, which, when volatilized together with free carbon, have a tendency to choke the condenser, and thus retard the operations in the furnace, as well as hinder the condensation of the other volatile products of the process of calcination.

"In using coke in the decomposition of common salt and ores and minerals containing sulphur, I prefer having the fire-place of the furnace closed with a door, and the ash-pit supplied with water, which, being gradually converted into vapour, ascends through the fire, and promotes the combustion of the fuel.

"In using anthracite coal in the decomposition of ores and minerals and salt, I mix a small portion of (coking) bituminous coal, about $\frac{1}{4}$ part by weight of the anthracite coal, which has the effect of causing the mass to cohere on the application of heat. The opening to the fire-place I fit with an iron plate, about 2 ft. by 18 in., over which I turn an arch 15 in. high—that is, leaving the opening for charging the furnace with fuel 18 in. wide by 15 in. high in the clear. When the fire is well raised, I fill the opening with the mixed coal, and whilst in this position it becomes partially coked; when it is necessary to replenish the fire with more fuel, I move the partially coked coal on to the burning mass in the fire-place, and place a further quantity of coal on the plate, as before; I also apply water to the ash-pit, in a similar manner to that described when coke is the fuel used.

"The volatile products of the sulphating process possess great affinity for water, and their condensation is facilitated by the introduction of steam into the flue leading from the sulphating

furnace to the condenser at a convenient distance from the furnace; the object of the application of steam is, to obtain an intimate mixture of aqueous vapour with the volatilized matters, and thereby to promote their more perfect condensation.

"I have described processes for treating ores and minerals, and the manufacture of alkali, copper, and other products, by mixing such ores and minerals with common salt, and subjecting the mixture to heat in a furnace. In carrying these processes into practical operation, when treating ores and minerals containing silver and copper, these metals have been converted into a condition soluble in a solution of alkaline and metallic salts, being the product of some of these processes, and I have hitherto precipitated them by means of metallic iron, and then proceeded to oxidize the copper of such precipitate, and dissolve the oxide of copper so obtained with sulphuric acid, producing sulphate of copper in the well-known manner; the residual product, containing the silver, has hitherto been separated by the ordinary process of smelting silvery lead ores.

"I will now describe my improved processes for treating ores and minerals containing silver and copper, and the manner in which the same are performed. I treat ores and minerals containing sulphur in the manner described by me in 1842. I grind the ore and minerals containing sulphur, and mix with common salt, and calcine the mixed material, and obtain solutions therefrom, which I treat as hereinafter described; but if the minerals contain a considerable quantity of arsenic, antimony, or zinc, or any of them, I prefer to calcine such mineral, in order to drive off some or all of these volatile metals; I then mix the calcined material with ore or mineral rich in sulphur, so as to make the average quality about twenty to thirty of sulphur—that is, when one of my principal objects is to obtain sulphate of soda.

"If the ores or minerals be rich in sulphur, and I have none of the calcined ore, I prefer to reduce the percentage of sulphur by the addition of oxide of iron in a finely-divided condition; in all cases the process is best conducted when the sulphur in the mixed material is about 30 parts by weight to 100 parts of salt employed.

"If the primary object be to separate silver and copper from ores and minerals, it is sometimes convenient to calcine the material until the sulphur is nearly driven off, and then to add common salt to the charge, and subject it to further calcination; from eight to twelve hours will generally be found sufficient to convert the silver into the state of chloride.

"I usually grind the ores and minerals sufficiently fine to pass through a sieve of at least six holes to the inch; the richer the ores and minerals are in silver and copper, the finer I prefer to grind them, in order to ensure the whole or nearly the whole of the silver and copper being converted into a condition soluble in the sulphate liquor.

"I place the calcined mass, which I call sulphate ash, in a suitable vessel or vessels, and dissolve the soluble portions in water; the solution thus obtained consists of sulphate of soda, and soluble salts of silver and copper, and other matters; this solution I call sulphate liquor; I cause it to flow through a vessel or series of vessels furnished with metallic copper, the liquor coming into contact with the copper, the silver is precipitated, and an equivalent of the metallic copper is dissolved; when the silver is precipitated, I run the liquor into another vessel or set of vessels, in which the copper is precipitated by iron. If, however, the liquor be so rich in these metallic salts, that the whole of the silver or copper is not readily precipitated, I increase the number or size of the vats, or repeat the operation. Having carefully examined the liquor, to ascertain that the precipitation of the silver and copper is complete, I run the liquor into the alkali department of the works, to convert the sulphate of soda into carbonate. In order to dissolve the whole of the soluble portions of the sulphate ash, I repeat the washing until no more sulphate of soda or metallic salts are obtained; I preserve the weak liquor, and apply it to further portions of the sulphate ash; I convert the precipitate obtained by means of iron, above mentioned, and in fact any copper containing silver into regulus, by the well-known means. I prefer to granulate the regulus, in order to facilitate the further operations whereby the copper and silver are separated by common salt.

"In the manufacture of sulphate of copper, I find it convenient to convert the sulphide of copper into sulphate by calcining the regulus or other sulphide, being the product of my processes for precipitating silver and copper from thin solutions, by means of the compounds of sulphur, which I use for precipitating the sulphides of silver and copper, or the sulphides, carbonates, or oxides of these metals from their solutions at a low temperature with access of atmospheric air, and thus produce sulphate of copper and a soluble salt of silver; these I dissolve with water, precipitate the silver from this solution by means of metallic copper, and draw off and crystallize the liquor containing the sulphate of copper, the silver being obtained as a residual product. If the sulphate of copper be not wholly converted into sulphate, or if it be the mixed precipitate containing carbonate, or oxide, or both, I add sulphuric acid, and thereby dissolve the copper.

"I precipitate silver and copper from thin solutions by means of sulphide of calcium, such as alkali waste, which compound contains sulphide of calcium. I also precipitate silver and copper from thin solutions, by means of compounds containing alkaline and metallic sulphides and other alkaline salts, such as the third product (which I call green ash), which product contains sulphides of iron and sodium, carbonate of soda, caustic soda, and other matters, or one or more of these alkaline compounds; or I use solutions thereof. I also precipitate silver and copper from thin solutions by means of black ash or crude alkali, which contains sulphides of calcium and sodium, carbonate of soda, and caustic soda, or one or more of these alkaline compounds; or I use solutions thereof. When I use the earthy sulphides, or the alkali waste containing sulphide of calcium, I find it convenient to sift these substances through a sieve of six or more holes to the inch, in order to separate the coal and cinder and the larger aggregated masses of the alkaline earthy matters; having thus prepared a sufficient quantity, I place a layer in the bottom of the precipitating vessel; having previously provided means for filtering the liquor, I prefer to put a layer of straw, coke broken into fragments, or cinders, and on this I place the precipitant, and proceed to fill the vessel or vessels with the liquor containing the metals to be precipitated. Into a vessel or series of vessels about

15 to 20 ft. square and about 6 ft. deep, I put a layer of alkali waste or other earthy sulphide, about 18 in. deep, through which I cause the liquors to permeate slowly; the silver and copper during this operation combine with the sulphur of the sulphides and the chlorine or acid, and the oxygen in the latter case; and passing over from the metallic salts to the alkaline earthy matters, the metallic sulphides are precipitated, being insoluble in the sulphate liquor; or I allow the solution containing the metallic salts to remain in contact with the precipitant until the metals are precipitated. This operation will usually occupy only an hour or two, but it is desirable that sufficient time be allowed in order to obtain deposition of the precipitated matters; this will be ascertained on examining the liquors from time to time. When the precipitation and deposition are complete, the liquor is to be drawn off and the residual product fluxed to convert the silver and copper into regulus. The black or green ash, herein described, may be used in the solid form in a similar manner to that described when using alkaline earthy sulphide; but I prefer to make a strong and hot solution, and having ascertained the quantity of silver and copper in the sulphate solution, I run a quantity of the sulphide solution into a vessel or set of vessels, and then add the sulphate solution thereto. If the whole of the silver and copper are not precipitated, I add a further quantity of the precipitant. When the precipitate is fully subsided, I carefully draw off or filter the sulphate liquor which is to be used in the manufacture of sulphate of soda, and for the purposes to which sulphate of soda is usually applied. When the precipitate is sufficiently accumulated, I wash and dry it, and proceed to heat the precipitate, as herein described, to manufacture silver and sulphate of copper, or silver and copper, as the case may be.

"From such ores and minerals as are rich in silver, but containing little sulphur, with or without copper, I obtain solutions containing silver or silver and copper, as the case may be. I dilute the strong solutions with water; I heat the diluted solution by preference to boiling, and the silver is precipitated in the state of the chloride. I usually find this accomplished when Twaddle's hydrometer stands at 30 when applied to the diluted liquors. When the chloride of silver is fully subsided, I run the liquor, if it contain copper, into another vessel or set of vessels, and precipitate the copper, and I collect the chloride of silver and smelt it. I can treat such ores and minerals as are rich in silver, but with little sulphur, when containing copper, with common salt, and obtain solutions containing silver and copper. I produce a weak or diluted solution, and thereby precipitate the silver in the state of chloride on the residual matters of the ores or minerals. I mix the precipitate in this case with lead or lead ores, and smelt in the ordinary manner of smelting silvery lead ores; but if the silver has been precipitated separately by dilution, it may at once be smelted and metallic silver obtained. The copper solution I treat by any of the well-known methods for separating copper.

"In treating regulus containing silver and copper, I mix it with 5 or 10 per cent. of common salt by weight of the regulus, and grind it so as to pass through a sieve of 10 or more holes to the inch, and calcine the ground material in a furnace. As it is better to conduct this operation gradually, I prefer a furnace of three or more beds, each bed of about 12 ft. square, but a furnace with one or more beds may be used. I place the first charge on the bed farthest from the fire, and when it has remained about eight hours in the back bed I move it on to the next bed, and so on in rotation, occasionally stirring it and drawing the finished charge at the bed nearest the fire; the calcined material is put into vessels. When the soluble portions are dissolved, if the calcined material does not contain alkaline and metallic salts, I add strong and hot sulphate liquor, this solution having the property of dissolving chloride of silver; if, however, the whole of the chloride of silver is not dissolved by the first operation, I repeat it. In treating such ores, if the sulphate of soda be not an object of importance to the manufacturer, as will sometimes happen, I precipitate the chloride of silver by means of diluting the solution with water; having obtained the dilute solution, I heat it as before mentioned; this operation of heating causes the particles of chloride of silver to aggregate, and facilitates its deposition. I allow the liquor to rest until the chloride of silver has subsided, and then draw off the clear liquor; about forty-eight hours will generally be sufficient for its subsidence. I collect this precipitate and smelt it for silver.

"The ordinary regulus of the copper-smelter frequently contains a notable quantity of antimony; in this case having obtained solutions as before, I proceed to precipitate the silver and antimony together by the process of dilution with water; I collect and smelt the precipitate with lead, or a compound of lead, in the well-known manner of smelting silvery lead ores, and thereby obtain the antimony and silver. But if the ore or mineral treated be a sulphide of copper containing silver mixed with any compound of iron, I mix such material with common salt, calcine and dissolve the copper with hot water, taking care that the solution be so weak as not to dissolve the chloride of silver, which is obtained with the oxide of iron as a residual product, which I smelt with lead or compound of lead, as above described. If the ore or mineral I treat be a mixed mineral, such as sulphides of silver, lead, and copper, I proceed to mix such ore with common salt and calcine the mass, and dissolve the copper with water, and I prefer the use of a solution so dilute that the chlorides of silver and lead are not retained in the cold solution, but are deposited with the mass of the lead contained in the ore; the copper of the weak solution I precipitate. But if it be desired to produce chloride salts of lead, I dilute it, and thereby precipitate the silver; I draw off the hot solution and allow the chloride of lead to subside on cooling, after which I precipitate the copper as before. If the mineral I treat be regulus of copper, or the sulphide precipitate herein described, a portion of the copper only will be rendered soluble; this portion may be precipitated, but I prefer to use solution of black or green ash, and smelt the precipitate separately with great care; by this improvement I produce copper of a superior quality; the portion remaining undissolved I smelt. It is sometimes convenient to precipitate the silver and copper by means of other compounds of sulphur. To produce sulphides of silver and copper in all cases, I treat such sulphides as before explained, when describing my processes for treating such sulphides.

"Lastly, I select such product of the calcined ores and minerals as consist of oxide of iron; I separate the oxide of iron from the earthy matters by washing, and mix it with sufficient carbon to deoxidize the oxide of iron, and a small quantity of clay to cause it to cohere; I then mould the

mixture into balls, or other convenient shape, and subject it to a smelting process in a reverberatory furnace; the product is iron of fine quality. The carbon I use by preference to anthracite coal or charcoal, and in all cases the clay and carbon should be as free as possible from sulphur."

G. Hähner, in 1856, proposed to decompose certain metallic oxides at a high temperature in contact with alkaline chlorides, or other chlorides forming oxychlorides, or chlorides soluble in water, in avoiding the formation of free soda by the addition of a mineral acid, and lastly, separating the metals contained in the solution, and utilizing the residues.

For this purpose, the metallic ore is reduced to pieces and roasted, then pulverized, and again roasted with the admixture of coke, coal, or charcoal reduced to minute particles. After perfect oxidation of these matters, Hähner proposed to introduce into the furnace, to be mixed with the ore, a mixture of about two parts or more of chloride of sodium (common salt) or other alkaline chlorides, and three parts of ore already roasted to each part of metal to be extracted. When there was no longer any trace or smell of muriatic acid vapours, he introduced the roasted ore into vessels provided with filters, into which vessels water slightly acidulated was poured to wash the ore. According to this process, if the ore contains copper or silver, these metals will be found in the solution. The oxides of iron, tin, zinc, and so on, remain in the vessel; the oxide of tin is separated by washing, and the oxide of zinc by reducing it to metallic zinc. Gold remains also in the vessel, and is converted into chloride of gold by means of a stream of chlorine which is introduced into the vessel, and the chloride of gold dissolved in water. In certain cases, Hähner prefers to precipitate the copper by means of a stream of sulphuretted hydrogen, or by a solution of common ash, potash, or soda alone or mixed with lime.

Hähner further observes;—"To form the oxides I submit the ore to roasting either in the open air, or in kilns or furnaces for the purpose of expelling sulphur, arsenic, and other volatile substances, and render the ore more friable. If the metallic rock-gang contains calcareous substances, it must be burnt in a similar manner to lime, and dissolved in water; the oxides, and so on, of this ore will deposit at the bottom of the vessel in which the lime has been dissolved and driven off. Oxidized and other ores which do not contain sulphur or other mineralizing substances only require to be brought to a red heat. The ores treated as before described are then reduced to powder by the ordinary means, and again roasted in a reverberatory furnace, a small quantity of coke, charcoal, coal dust, or other combustible being added to facilitate the operation. To decompose metallic oxides obtained, and also other oxides, the red-hot ore remaining in the furnace after being completely roasted is mixed with an alkaline chloride (chloride of sodium being preferred on account of its low price) in the proportion of about two parts by weight (more or less, according to the nature of the ore) of chloride for each part by weight of metal to be extracted from the ore. To obtain a more perfect mixture, I add to the chloride, before its introduction, about an equal weight of ore already roasted, mixing them intimately, and moistening them if dry. The moistened chloride or mixture of chloride and roasted ore ought then to be incorporated as intimately as possible with the red-hot ore in the furnace, and kept in a continual movement, and at a red heat until the smell of muriatic acid becomes less perceptible, and the ore commences to adhere to the workman's tools; the ore is then withdrawn from the furnace, and a fresh charge added. It is advantageous to leave the red-hot ore thus withdrawn for some time in heaps, which renders the process still more perfect. If the ore contains no silica, it is requisite to add about 10 per cent. of this substance. The ores treated as before described are then submitted in a hot state, if possible, to lixiviation. I add to the water employed for the lixiviation of the roasted ore, about 5 parts by weight, more or less according to the nature of the ore, of sulphuric, muriatic, or other acid to 1000 parts by weight of ore, to render more soluble the oxychlorides or chlorides, and to decompose the free soda, silicates of soda, and so on, which may have been formed during the roasting, and which would cause a great loss of metal. The vessels in which the lixiviation is performed, may be of wood or masonry work, and may be of any form and dimension, according to circumstances; they should be furnished with an ordinary filter to allow the water to run off freely. The precipitation and purification of the metals contained in the solution, or the formation of other commercial products, can be effected by the usual processes. The copper, however, may be precipitated also by common ashes, lime water, and caustic water, and the products obtained may be used in the manufacture of different colours, salts, and so on, or reduced to the metallic state in ordinary furnaces, or by other known processes. The copper may also be precipitated in the state of arsenite or arseniate of copper for the formation of Schieles or Vienna green, by means of a solution of arsenite or arseniate of potash. The refuse wash waters which have served for the separation of the metals may be employed for moistening the roasted and pulverized ores, or for other purposes. After the lixiviation, there remains in the vessel the powdered metallic rock gold, oxides of iron, tin, zinc, and so on, if the ore contained such metals, which can be utilized by known means."

Other methods of treating ores containing copper, as well as those of Napier and Henderson, will be treated of hereafter. See ALLOYS. ARSENIC. ATOMIC WEIGHTS. CHIMNEY, p. 951. FURNACES. GOLD. IRON. CORK-CUTTING MACHINE. FR., *Bouchonnier*; GER., *Pfropfenschneidmaschine*; ITAL., *Macchina da turaccioli*; SPAN., *Máquina para cortar corchos*.

Figs. 2134 to 2139 relate to a peculiar construction and arrangement of a cork-cutting machine, invented by Hammer and Butz, of Philadelphia, U.S., whereby all the successive operations for transforming the bark of the cork-tree into any of the various descriptions of corks, may be conducted in such a manner, that the several operations can be simultaneously employed at different

manipulations upon the same machine, without hindrance to each other. This machine consists of an arrangement and combination of mechanism for cutting tapered corks from square or cylindrical blocks; of an improved arrangement for effecting the preliminary operation of cutting the raw bark into strips, and for subdividing these strips into parallel or tapered blocks of any required size, to be subsequently reduced to cylindrical or tapered corks in the first-mentioned part of the machine; and of mechanism combined with these arrangements for cutting flat and cylindrical corks by means of revolving crown cutters; the whole of these various subordinate combinations forming one complete machine, driven by one main driving belt. The main shaft of the machine carries a circular disc-cutter at each end, the edges of which are kept sharp by oil-stones fitted to the framing, and held in contact with the cutting edges as they revolve. One of these cutters, which is of larger diameter than the other, is for cutting tapered corks from square or cylindrical blocks; these blocks are contained in a tray or receptacle supported by a fixed bracket, and at the delivery mouth of this receptacle there is an adjustable gauge, against which the block is held by a blade spring until it is grasped between the adjoining ends of two rotating spindles. These spindles are contained in a sliding frame, and one of them, which may be termed the live spindle, receives a positive rotatory motion from an endless chain and chain pulley, the other being merely carried round by the frictional contact with the cork. A self-acting clutch and clutch-lever throw the chain-actuating pulley out of gear when the sliding frame is receding from the cutter, so that the spindles may be at rest when in the act of gripping the block, and, consequently, they take hold of it with greater certainty and accuracy. The grip is obtained by the aid of a spiral spring on one of the spindles. As the sliding frame approaches the cutter with the block of cork to be cut, the clutch is thrown into gear again, and the rotation of the spindles recommences. The cork being cut, and the sliding frame receding from the cutter, the spindles are separated, in order to allow the cut cork to fall into an inclined shoot below, which delivers it into a receptacle for the purpose. The clutch above referred to is thrown in or out of gear by a projection in the sliding frame coming in contact with the tail of the clutch-lever, as the slide moves to and fro. The separation of the spindles, in order to release the cut cork, is effected by a movable or spring incline, which acts upon the lower end of a lever, the upper end of which grasps a collar on the spindle to be slid back. This incline enables the lever to pass freely in one direction, namely, when approaching the cutter; but acts upon the lever and releases the cork when moving in the opposite direction, or receding from the cutter. The reciprocating motion of the sliding frame is obtained by means of a chain or cord attached to opposite ends of the slide, and passing under a drum or pulley to the periphery of which it is secured. By turning this drum or pulley in one direction or the other, by the aid of a lever handle, a reciprocating motion is imparted to the sliding frame. The apparatus for cutting the bark into strips consists of the smaller one of the two circular disc-cutters, in combination with a table and adjustable gauge. The bark is laid upon the table with its edge against the gauge, and the cutter, by revolving in the direction of the feed, draws in the bark as fast as it is cut, without any force being required to pass it through the machine. When subdividing these strips into blocks, a sliding saddle is fitted on to the table, and upon this saddle is placed a head-piece having a squaring strip thereon, against which one side of the strip of cork is held whilst being cut. This head-piece is pivoted to the saddle by a vertical centre pin, upon which it is free to turn slightly in an horizontal plane, so as to present itself, and the strip of cork upon it, at an horizontal angle with the plane of the cutting edge of the circular cutter. This angular movement is controlled by two screw pins passing through slots in the head-piece, which screws, when tightened, serve to hold the head-piece fixed in a position perfectly parallel to the cutter, when parallel blocks are to be cut. When tapered blocks are required, the head-piece is moved alternately from one strip to the other between the successive cuts, and hence in lieu of the strip of cork being cut across at right angles, which would produce parallel blocks, it is cut across alternately at two opposite angles, thereby producing tapered blocks. The apparatus for cutting flat and cylindrical ends consists of a vertical spindle, to the lower end of which are fitted different sized crown cutters, according to the diameter of the corks required. Beneath this spindle there is provided a table for supporting the cork to be operated upon. The vertical spindle is driven by a twisted strap, from a driving pulley on the main or disc-cutter shaft of the machine, such strap passing around a small fixed pulley on the vertical spindle. By having the usual fast and loose driving pulleys on the main-cutter shaft of the machine, and driving the same by a belt, the whole of the different operating parts receive motion simultaneously and in concert.

Fig. 2134 is a side view of this cork-cutting machine, combining the above-mentioned devices for effecting the several successive operations; Fig. 2135 is a front view of the machine; Fig. 2136 is a plan of that part of the machine in which the bark is first sliced and then cut into blocks; Fig. 2137 is a detached side view of the feed arrangement of the tapering machine for cylindrical blocks; Fig. 2138 is a plan thereof; Fig. 2139 is a detached plan view of part of the mechanism for cutting tapered corks; and Fig. 2140 a detached view of the feed-table of the tapering machine for square or bevelled blocks. A is the main shaft of the machine, provided with fast and loose driving pulleys a a^1 , and carrying at its extreme ends, outside of the adjustable bearing b b , the circular cutting discs or knives B and C, the larger one of which (B) serves to cut conical or cylindrical corks from blanks fed to it by means of the sliding spindle frame D. This frame—hereafter more fully described—is fastened in an adjustable manner to the slide E, reciprocating in a bed F. The feeding device for supplying cylindrical blocks to the spindles for transmittal to the knife B, is supported upon a stand c , and is constructed as follows:—Attached to the stand c , and vertically adjustable upon the same by means of a screw d , there is a rectangular piece d^1 ; on the top of the horizontal part of d^1 is placed the gauge e , which is adjustable lengthwise along d^1 , and secured by a screw and nut. A receptacle G for the corks to be fed to the spindles is provided on the top of e . The position in which the cork is placed for being grasped by the spindles J and J¹ is best understood from Fig. 2137; resting upon the inwardly projecting end of d^1 , the cork is lightly pressed against the gauge e by a spring pad f , swinging upon a small rock-shaft g , which pad is

CORK-CUTTING MACHINE.

sufficiently yielding to allow the cork to be removed horizontally towards the cutting disc. A sliding movement of the spindle frame D, for alternately carrying the corks to the knife and returning to the feed-table for a next one, is given by means of a cord or band *h*, so attached to the opposite ends of the slide E, and to the periphery of a pulley H, that by means of a hand-lever H¹ on the pulley-shaft *i*, motion is transmitted to E by the cord *h* in either direction. The outward movement of the slide E is arrested by a fixed stop I on the plate F, while a screw I¹ serves as an adjustable stop for the movement of E in the opposite direction; by varying the position of this screw, the finished diameter of the screw is regulated with accuracy. The spindle J, for rotating the cork as it is presented to the cutting edge of the circular knife B, is driven by means of a chain *j* passing over the pulleys *j*¹ and *j*², the latter being the driver, and receiving motion through the bevel-wheels *j*³ and belt *j*⁴ from the main shaft A. *j*² is provided with a clutch, and

so actuated by a clutch-lever *k* and arm *k*¹ projecting from the slide E, that the spindle J ceases to rotate as it recedes towards the feed-table, and is in turn thrown into action when approach-

ing the cutting disc. The spindles being thus at rest when grasping the blank to be conducted to the knife, will be much more certain to take accurate hold of the blank than if they were revolving at the time. A rocking arm K, actuated during the sliding motion of E by an inclined plane i^1 , and by a spiral spring i^2 , on the spindle J^1 , serves to give the requisite sliding movements to that spindle for alternately grasping and releasing the corks as they pass through the machine. Although this sliding motion of one spindle only is ordinarily sufficient, it may in some cases be advantageously given to both spindles. The arrangement of the inclined plane i^1 , and the manner in which it actuates the double-armed lever K through the spindle J^1 , will be best understood upon reference to Fig. 2139, where it will be seen that i^1 is attached to a plate L in the following peculiar manner;—It has a limited vibrating movement upon a central axis l , between two small stops 2 and 3, the axis l being confined in an oblong opening in the plate L; a light coiled spring 4 bears against one end of i^1 , and brings its other end in contact with the pin 3.

The operation of the whole is as follows;—The lever K, while holding the cork to the knife, occupies the position represented in Fig. 2135, and as it recedes towards the feed-table, its small friction-roller 5 brings up against i^1 , as shown in dotted lines at Fig. 2139; by yielding to the inclined plane the lower arm of K is drawn inward, and by a consequent movement of its upper end in an outward direction, the cork just finished is released from between the two spindles, and falls down; in this separated position the spindles remain during the whole outward movement, until at the instant of the slide E, bringing up against the stop I, the friction-roller 5 is liberated from the inclined plane; the spiral spring i^2 , being thus freed from its previous compression, suddenly pushes the spindle J^1 inward, to make it grasp the blank on the feed-table. The roller 5 on the arm K is now in the position shown in dotted lines, Fig. 2139; and as upon the advance of E toward the knife, this roller comes in contact with the inclined plane i^1 on the opposite side, the latter will yield to it in the oblong bearing of its axis l , so as not to disturb the spindles in their hold upon the cork to be cut; in returning from the knife the described routine of movements is repeated. By an arrangement of hoppers or inclined planes, shown in Fig. 2134, the chips are separated from the finished corks; the former, curling up on the inner side of the knife, fall into the large hopper M, and are heaped up under the frame of the machine; while the corks as they leave the spindles are carried over two inclined planes m and n into a separate receptacle. N and N^1 are small oil-stones, so attached to their supports as to press lightly against opposite sides of the cutting edge of the knife, thus keeping it uniformly sharp. The mechanism for cutting the bark into strips consists, in addition to the small circular knife C, of a table O and gauge O^1 ; the end of the piece of bark to be cut into slices is held against the gauge O^1 , and then laterally advanced toward the edge of the revolving circular knife C, the direction of motion of which is such as to draw the bark through without the least application of force on the part of the workman. For the subsequent operation of reducing these strips into blocks, a sliding saddle P is employed in addition to the gauge O^1 , which saddle has a vibrating head-piece Q. When required for cutting blocks with parallel sides, this head-piece is permanently fastened upon the sliding saddle P, in the position shown in the engraving, Fig. 2136; but the same parts are in a very simple and efficient manner adapted to cutting blocks with tapering sides, from which tapered corks can be cut most economically. To this end, the head-piece Q is made to vibrate upon an axis p , this movement being limited between adjustable stops q ; the strip of cork is laid upon the front part of the head Q against the squaring strip Q^1 , and between successive cuts of the knife the head is moved alternately from one stop to the other, so that the cork blocks become tapered by thus reversing the angle for each successive cut. In addition to the above mechanism, the machine is provided with a frame R, carrying in bearings S S the hollow cutter-spindle T, for cutting cylindrical and flat corks of any required diameter and thickness, by means of changeable cutters set into the lower end of the spindle. U is the table upon which rests the slice of cork to be operated on by the revolving cutter, and V is the lever for actuating the cutter-spindle; the latter is driven from a pulley on the main shaft A by means of a half-twist belt running over a small pulley W.

CORROSION. FR., *Corrosion*; GER., *Zerfressung-Corrosion*; ITAL., *Corrosione*; SPAN., *Corrosion*.

With the exception of Robert Mallet's extensive experiments on the action of air and water upon iron and steel, *corrosion* and *anti-corrosion* have not received that amount of attention on the part of scientific men—chemists in particular—that their industrial importance demands.

Malleable iron undergoes no change in dry air, or in water free from air; but in moist air, or water containing air, it gradually becomes oxidized or rusted from the surface inwards, until eventually the entire mass is converted into oxide. The carbonic acid present in atmospheric air appears to contribute largely to the production of this change. The presence of saline substances in water also facilitates the oxidation of iron, while alkalies and oily or resinous substances retard it. Contact with more highly electro-positive metals, such as zinc, also hinders the oxidation of iron within a certain distance around the point of contact. Caustic alkalies or alkaline carbonates act as preventatives. There is a theory that, so soon as the first thin coating of oxide has formed upon the surface of the metal, a galvanic action sets in, whereby the process of oxidation is greatly accelerated, the iron acting as a positive agent, the oxide as a negative one. Brass and copper are attacked by ammonia, for which no efficient preventive is known.

Corrosion of Steam Boilers.—The process of corrosion is very similar to that of the combustion of

fuel, the only difference being that in corrosion the metal unites with the corrosive agent slowly, while in combustion the fuel unites rapidly with the supporter of combustion.

The external corrosion of a boiler is due to simple oxidation, caused principally by atmospheric exposure.

In the boilers of sea-going vessels it is also caused by the contact of the bottom of the boiler with bilge-water, and by the exposure of the top to leakage from the deck. The best means of preventing this is to cover the top with felt and sheet lead soldered at the joints, and to keep the bottom thoroughly painted. The internal corrosion is due to simple oxidation, and to the galvanic action taking place whenever two different metals or a metal under different conditions are either wholly or partially immersed in a fluid in which either of them would be oxidized—that is, united with the oxygen of the corrosive agent, and which has the effect of confining the corrosion principally and sometimes wholly to one of the two metals in contact. The sheets are eaten away around the rivets before the rivet is injured, on account of the iron in the rivet being in a different condition from that in the sheet, owing to its being more dense from being hammered until cold, and, consequently, producing a galvanic action by which the sheet is corroded. Tube-sheets are apt to leak, when the sheets and tubes are composed of different metals, from the effect of the galvanic action produced by them.

The hot brine or sea-water contained in marine boilers is a most powerful corrosive agent of wrought iron. Hence the stays are corroded, and the pins or bolts which hold the stays are eaten and loosened. A very thin film of scale is the best protection against this kind of corrosion. The corrosion of the steam drum is caused by the high temperature of the uptake, about 600° Fahr. for natural draft, thereby superheating the steam, and oxidizing the iron in a similar manner to the making of hydrogen gas, by sending steam over red-hot iron.

Boilers not in use are liable to corrosion on the fire side of the heating surface as well as on the water and steam side. To prevent this, the smoke-stack should be covered over to keep out rain and moisture; the man-hole plates taken off, so as to allow a free circulation of air inside; and a light fire of shavings should be built occasionally to dispel all moisture.

Corrosion of High-pressure Boilers.—Speaking on the explosion of locomotive and other high-pressure boilers, William Kirtley, of Derby, in a paper printed in the Proceedings of the I. M. E. (1866), observed that in the large majority of exploded locomotive boilers it has been found that the explosion has arisen from the plates of the boiler having become weakened by corrosion at particular places. In the paper referred to it was the writer's object to describe the nature and extent of this corrosion, and to endeavour to show the causes of its occurrence, together with the means of prevention.

In the present ordinary construction of locomotive boilers with lap-joints, as shown in Figs. 2141, 2142, the wear by corrosion of the plates is found principally round the smoke-box end of the boiler barrel, in the interior, opposite to the edge of the outside angle-iron as shown at A A in Figs. 2143 to 2145, where an annular groove is found to be eaten out of the plates by corrosion. This grooving extends sometimes so deep into the plate that only a thin shell of metal is left on the outside at the bottom of the groove, as shown in Fig. 2145, which is a full-size section of an actual case of the grooving; and the corrosion takes place so rapidly in many cases that the plates require renewal after only a few years' work. A similar grooving also takes place along the edge of the inside lap at the longitudinal joints, as at D and E in Fig. 2146, and also at the transverse circular joints, as at B B in Figs. 2147, 2148; but in the latter case the grooving does not occur so frequently, nor is the extent of corrosion so great, as at the smoke-box end and at the longitudinal joints.

It may be remarked first that this grooving is only found below the water-line, showing that it must be due to the chemical action of the water on the plates; and the special point to be inquired into is the cause of this action being so remarkably concentrated at the particular lines where the grooving takes place. It was evident from the specimens shown Kirtley, which were taken from locomotive boilers that had been at work for various periods of from three years to as much as nineteen years, that some corrosion also takes place over the general surface of the plates; but this is very limited in extent compared to the grooving at the seams, and it occurs very irregularly, being apparently influenced by some irregularities in the structure of the plates, causing them to be pitted irregularly by the corrosion.

In the ordinary construction of locomotive boilers with lap-joints, as shown in Figs. 2141, 2142, the barrel of the boiler is constructed of three rings, each ring formed by two plates of $\frac{7}{16}$ in. thickness, riveted with lap-joints FF and H H. The general amount of lap is $2\frac{1}{4}$ in. for single-riveted and $3\frac{1}{2}$ in. for double-riveted joints. The smoke-box and fire-box are each united to the barrel of the boiler by an angle-iron K K, Fig. 2142, 3 in. or $3\frac{1}{2}$ in. wide, welded into a ring. General experience has shown that after five or six years' wear of these boilers the grooving action that has been described is developed at the joints and at the edge of the angle-iron rings.

Now the longitudinal strain upon the joints of boilers constructed in this manner tends to spring and bend the plates at the joints, when under pressure, into the form shown exaggerated in Fig. 2149, in consequence of the plates not being originally in the line of strain, as shown by the dotted line S S in Fig. 2142, which, it will be seen, runs along the outer face of one plate and the inner face of the next. Also, in the longitudinal joints of the barrel, shown at FF in Fig. 2141, a similar mechanical action takes place, the strain acting in the true circle shown by the dotted line S S, springing and bending the plates at the edge of the joints, as shown at G G, each time that the boiler is under pressure. The continued alternation of expansion and contraction in the boiler causes the scale that is deposited upon the plates from the water to be continually broken off at the edge of the joints by the mechanical action of this springing and bending of the plates at the lines of the joints; and the plates are thereby laid bare at those parts, and kept continually exposed to the corroding action of the water, instead of being protected from the action of the water by the deposited scale remaining attached to them.

It must be noticed that the pressure under which the locomotive boilers are worked is much higher than in the case of stationary boilers, and the injurious action caused by the springing of the plates at the joints is therefore proportionately increased; and taking the pressures at 35 lbs. the inch for the stationary boiler and 140 lbs. for the locomotive, this makes the action four times greater in the locomotive boiler from this cause, taking the increase to be only at the same rate as the increase in pressure. Hence as the action is six times greater from the previous cause, a total is given of twenty-four times as great an extent of injurious action in the locomotive boiler as in the stationary boiler in the same length of time. As an illustration of the effects of increased pressure in increasing the corroding action, it may be mentioned that this grooving of the plates has been found to be materially increased in amount since the working pressure of locomotives has been increased from 100 lbs. up to the present 140 lbs. the inch.

In some of the older classes of locomotive engines Kirtley found that there is an increased local action of serious amount caused in the boilers by the rigid points of attachment to the boiler barrel, such as frame-stays, brackets, and so on, which offer special points of resistance to the expansion of the boiler when under pressure. A specimen of this grooving, taken from No. 187 engine in the preceding Table, is shown at C C in Figs. 2147, 2148, caused by the rigid attachment of the spectacle bracket M to the boiler barrel. The result is made worse when the fire-box is rigidly fixed to the frames, or not allowed full freedom for expansion by the provision of a sliding bracket; as a great additional strain is thereby thrown on the tube-plate, springing the angle-irons round the ends of the boiler. The expansion of a 10 ft. 6 in. or 11 ft. boiler barrel being about $\frac{3}{8}$ in. at a pressure of 140 lbs. the inch, an attachment to the frame at any other place besides the fixing of the cylinders and tube-plate at the front end must subject the boiler to a bending strain at the points of attachment, causing a risk of corrosion at these points. In the Midland Railway engines all the other attachments except the smoke-box angle-iron are now removed, including that of the motion-plate which carries the inner ends of the slide bars; and the boiler is allowed in expanding to slide freely throughout upon the frames.

In the longitudinal joints of the boiler the grooving from corrosion is generally found to be more marked when the inside edge of the lap faces upwards, as at E in Fig. 2146, than when it is turned downwards, as at D. In the former case it may be considered that the deposit will collect upon the projecting ledge in larger quantities, forming a thickness of deposit sufficient to be detached bodily by the springing of the plate under pressure; and it will consequently leave the bare plate more frequently and extensively exposed to the direct action of the water, than when the edge of the plate faces downwards, as at D, because in the latter case the thinner film of deposit will not be so readily and frequently detached from the plate by the same action. It must be borne in mind that the earthy deposit itself, being chemically neutral, cannot have any injurious action upon the plate; except in the case of a stationary boiler heated from an external flue, where undue heating and expansion of the plate are caused wherever its inner surface is separated from the water by any considerable thickness of non-conducting deposit.

In the preceding Table are given the particulars of seventeen locomotives on the Midland Railway, from which the specimens of corroded plates were taken; showing the length of time of working, and the mileage and consumption of water before the plates had become so defective as to require removal. The average result is, $10\frac{1}{4}$ years' working, 255,645 miles run, and 7,618,778 gallons of water consumed by each engine.

In the case of the boilers constructed in the ordinary manner, as already described, the plates cut out show the grooving action of the corrosion below the water-line, while they are comparatively clean above. In No. 235 engine the tube-plate was flanged and riveted inside the boiler barrel; and the result of working shows the advantage of this mode of construction over the ordinary angle-iron joint, since the plates at the smoke-box end are not grooved along the edge of the flange, as they would have been with an external angle-iron.

From the foregoing consideration of the subject, observes Kirtley, it therefore appears that the special corrosion of the plates at the joints is to be attributed to the combined operation of chemical and mechanical causes, the chemical action of the water in the boiler being concentrated upon those particular parts in consequence of the mechanical action produced at those parts by the strain upon the plates. That the combination of these two causes is requisite for producing this effect is shown by the middle of the plates being free from it, where they are exposed to the chemical action alone, without the mechanical action; and further by the joints in the upper part of the boiler above the water-line being also free from it, where exposed to the mechanical action alone, without the chemical action. The removal of one of these causes will therefore be sufficient; and in the locomotive boilers now to be described this object has been aimed at by removing the mechanical cause which produced the springing of the plates at the joints.

From the particulars already given of the corrosion which takes place in locomotive boilers, it appears that the greatest injury takes place at the smoke-box end of the barrel, where there is not only a great and sudden change in the thickness and rigidity of the plates at the edge of the angle-iron, as at J in Fig. 2142, but also a leverage for the springing of the plate from the outer line of rivets, as at L in Fig. 2149. The consequence is the bending of the plate at the point J, as in Fig. 2149, each time of being under pressure of steam, owing to the outer line of rivets L being entirely outside of the line of strain S of the boiler-plates. There is also a great tendency to injury of the angle-iron, by this action tending to split it between the rivet-holes at the outer line of rivets L.

The present plan adopted on the Midland Railway is found to obviate the injury previously experienced from corrosion; and this is accomplished by the use of plates rolled with thickened edges, as shown in section in Fig. 2150, and shown exaggerated in thickness in Figs. 2151, 2152. The ordinary thickness of $\frac{7}{16}$ in. is preserved in the body of the plate, and the edges are thickened to $\frac{3}{4}$ in., with a long gradual taper in the thickness from I to I, Fig. 2150, about 4 in. long. The effect of this long taper is that, when the plate is flanged, as at N, in order to do away with the angle-iron,

the taper ensures a gradual springing of the plate, distributed over all that length, instead of the sudden bending concentrated at one point, as at J in Fig. 2149.

A similar section of thick-edge plate is also used at the transverse circular joints, as shown in Figs. 2151, 2152, causing a gradual springing of the plates over a considerable length when under pressure, as in Fig. 2152, instead of the former sudden bending at one point, as in Fig. 2149. There is also an increased strength gained by this mode of construction, as the increased thickness of the plates between the rivet-holes compensates for the loss of section by the holes.

The practical working of the thick-edge plates is shown by the specimen No. 306 engine in the preceding Table. The original boiler of this engine, constructed in the ordinary manner, was removed after 11½ years' working, as the plates were much grooved and pitted; and a new boiler, constructed with the thick-edge plates, was substituted, which has continued at work 6½ years. It was then found that the plates were free from grooving, although they were badly pitted.

A consideration of the ordinary construction of locomotive boilers and their defects shows that their construction admits of important improvement in the barrel, by removing the injurious strains resulting from the employment of lap-joints, which throw the plates out of the line of strain, and by making the barrel truly cylindrical and circular throughout. These objects are effected by welding the longitudinal joints of the three rings forming the boiler barrel, and making these rings all exactly the same diameter, uniting them to one another with flush butt-joints. This plan is now carried out upon the Midland Railway, as shown in Figs. 2153 to 2155, and exaggerated in thickness in Fig. 2156. The meeting ends of each ring are turned in a lathe, and united by covering strips OO, formed of welded flush rings, shrunk on over the joints and double-riveted. Strengthening hoops PP are also shrunk on the centre of each of the plates, crossing the longitudinal welded joints, and are secured by a few rivets. These hoops and covering strips for the joints are carefully blocked before being shrunk on, and the whole of the rivet-holes are drilled after the hoops are in their places.

These boilers are consequently truly cylindrical at all parts, and no strain to which they are subjected has any tendency to change their circular form. The effect of the longitudinal strain upon the transverse circular joints, as in Fig. 2157, is found to be altogether inappreciable in practice, because the covering rings OO could not yield to it without contracting in circumference in the form of a double cone, Fig. 2157; and on this account, together with their greater thickness, they offer a greatly increased resistance as compared with simple lap-joints. All possible effect of the longitudinal strain might indeed be entirely got rid of, if desired, by the further addition

of inside covering strips at the butt-joints, as shown in Figs. 2158, 2159. At present the circular plates of these welded boilers are in two semicircular segments for the circumference of the boiler, and therefore require two welds; but Kirtley thinks the barrel of the boiler would be improved if

each length were made of one plate only, whereby only one longitudinal weld would be necessary.

A remarkable corroboration of the correctness of this mode of construction is given by the samples, No. 658 engine, the boiler of which was constructed with butt-joints all flush throughout, the transverse joints being covered by external hoops and the longitudinal joints by internal strips. This boiler has been at work nearly nineteen years, having been started in 1847; but the engine being of smaller size than those now used with trains, has only been employed as a spare engine for some years past. The plates of the boiler, which are the original ones and have never been repaired at any part, are all good, and the grooving has not taken place at the butt-joints, a little irregular pitting alone being visible on the inside of the plates. The boiler has now been cut up only on account of the engine being abandoned from the great length of time it has been worked. The remarkable contrast shown by the freedom of the butt-joints in this boiler from the grooving so universal with the lap-joints in the ordinary boilers appears only to admit of being accounted for by the difference of construction of the joints in the two cases. In another engine of the same class, which was last broken up, after attaining the maximum mileage of 343,000 miles, the boiler-plates were very badly grooved at the angle-iron joint at the smoke-box end, showing that this part of the boiler remained as defective as in the ordinary boilers, the construction being the same as regarded this joint; while the rest of the joints being butt-joints were free from the grooving.

The flanging, bending, and welding of the thick-edge plates for forming the boiler barrel are performed by the aid of machines specially designed for the purpose, which are shown in Figs. 2160 to 2172.

The Flanging Machine is shown in Figs. 2160 to 2162. It consists of a horizontal table A, on which the thick-edge plate, shown black, having been previously heated, is laid and secured by

clamps, being pushed forwards against the adjustable stop B, Figs. 2161, 2162, so that the thick edge projects beyond the edge of the table to the required extent for forming the flange. The

roller C is then brought down with a slow motion by the eccentrics D, as shown in Fig. 2161, being firmly held by guides E at each end in the frame of the machine; and the edge of the plate is thus gradually bent down to form the flange. The table A is made to slide upon the bed F of the machine, and is set up by adjusting screws G to the required amount of clearance from the bending roller B, according to the thickness of the plate to be flanged. The front edge of the table is faced with a separate wrought-iron or cast-iron edge-piece I, which can be removed and changed for another having a different curve for the edge, according to the curve that is desired in the neck of the flange. The holding-down bar H is screwed down tight upon the plate, immediately behind the edge of the table, so as to hold the plate down flat on the table while the flange is being bent by the roller. The working speed of this machine is seven double strokes per minute.

The Bending Machine, for bending the thick-edge plates into the semicircle to form the boiler barrel, is shown in Figs. 2163, 2164. It consists of three horizontal rollers, of which the two lower ones

2163.

2164.

A A are carried in fixed bearings at each end in the frame of the machine; while the third roller B slides vertically in the frame, and is lowered by the screws C C at each time of passing the plate through the rolls, to give the required degree of curvature to the plate. The screws C C were at first worked by hand, but are now driven by gearing from the main shaft. As the thickness of the body of the plate is only $\frac{7}{16}$ in., while the thickness of the edges is $\frac{5}{8}$ in., a liner-plate, $\frac{3}{8}$ in. thick, is laid over the body of the boiler-plate in the bending process, in order to make up the same thickness of $\frac{5}{8}$ in. throughout for passing through the rolls; and the liner-plate is afterwards flattened again ready for subsequent use. At one end of each of the lower rollers A A is a groove D to receive the flange of the plate; this groove is shown enlarged in Fig. 2165, and is formed by a glut-piece or ring E, screwed upon the roller-spindle F and tightened by a set screw G, by means of which the width of the groove can be increased or diminished according to the thickness of the flange of the plate. A corresponding groove is provided at the opposite end of the upper roller B, to allow of bending plates with the flange inside instead of outside. In order to obtain a sufficient hold upon the plate to pass it through the rolls, the surfaces of all the rollers are fluted longitudinally with shallow flutes at $1\frac{1}{4}$ in. pitch, as shown in Fig. 2165, and enlarged to half full size

2165.

2166.

in the section, Fig. 2166. The lower rollers only are driven by gearing, the upper roller being merely a pressing roller for giving the required curvature to the plates, and weighing about 25 cwt. The working speed of the rollers is three revolutions a minute, or about 12 ft. a minute speed of surface.

The two semicircular plates are then welded together into a single ring, to form one length of the boiler barrel. The edges to be welded are first heated in the fire at A, Fig. 2167, and upset sufficiently to give the required thickness of metal for forming the scarf weld. A welding heat is then taken on a short length of the joint of the plates, and the plates B are welded together along the joint upon the welding anvil, shown in Figs. 2167, 2168. The anvil-face C is shaped to the internal diameter of the boiler barrel, and is separate from the pedestal D of the anvil, so that it can be exchanged for other sizes of face, according to the diameter of the boiler. During the heating and welding, the plates B are held in the circular frame E, in which they are securely clamped; and the frame E being slung from a crane, the plates are readily handled. The two ends of the joint are first tacked together by welding, to secure the correct diameter of barrel, and the joint is then welded in short lengths from the centre towards each end.

The rings of the boiler barrel, when welded up, are blocked, to test them by stretching and bring them to the diameter of the boiler. For this purpose the rings are first heated in the

blocking furnace shown in Figs. 2169, 2170, having the fire-grate A under the centre, with six chimney-flues C C round the circumference. The ring B to be heated is put in from the top, and placed on end, with the heat from the fire passing up through the inside of the ring and then down all round the outside to the flues, so as to give a uniform heat to the ring.

The ring is then put on the blocking press, shown in Figs. 2171, 2172; which is an ordinary hydraulic wheel-tire blocking press, worked by a centre cone D forcing out the blocking segments

E E. These blocking segments are carried up for the purpose and strengthened by brackets, as shown in the drawing. One half of the height of the ring B is blocked at once; and the ring is then turned over for blocking the other half.

The welded joints of these boilers have been tested by a series of experiments upon the tensile strength of strips of plate cut out across the weld, which were taken from several boilers from the

opening cut out for the steam dome R, Fig. 2153. Three sets of strips were tested, of 1, 1 $\frac{1}{8}$, and 1 $\frac{1}{2}$ in. width respectively, and each 7 $\frac{1}{2}$ in. length, cut out of the plate transversely to the weld, which was in the middle of each piece. The following was found to be the average breaking strength a sq. in. of these strips;—

EXPERIMENTS TO TEST STRENGTH OF WELDED JOINTS.

Width of Strips.	No. of Strips tested.	Broke in Weld.	Broke in Solid.	Breaking Strength per square inch.		
				Least.	Greatest.	Average.
inch.				tons.	tons.	tons.
1	15	8	7	16·5	23·8	20·2
1 $\frac{1}{8}$	4	2	2	19·6	22·2	21·0
1 $\frac{1}{2}$	4	1	3	18·1	23·5	21·7
Total .. 23		11	12	16·5	23·8	20·6
Also .. 11 Strips of the same plates }		unwelded }		20·7	25·8	23·6

From these results it appears that more than half of the strips broke in the solid and not at the weld, and the average breaking strength of the twenty-three welded plates was within one-eighth of the full strength of the eleven unwelded plates; while the worst pieces, including some cases of as extremely defective weld as are at all likely to occur in practice, had more than two-thirds of the full strength of the unwelded plates.

In reference to the cost of construction of the welded boilers in comparison with the ordinary class of lap-jointed single-riveted boilers with angle-iron ends, it has to be noted that there is an increase of weight of 1 $\frac{1}{4}$ ton in the new boilers, the weight of the 11-ft. boilers, 3 ft. 11 in. diameter, being 7 $\frac{1}{2}$ tons as compared with 6 $\frac{1}{2}$ tons in the old class of boilers of the same dimensions. This increase arises from the thick-edge plates, and from the hoops and joint strips, which weigh about 2 $\frac{1}{2}$ cwt. each; and the joints, instead of being single-riveted, are double-riveted on each side of the joint, making four rows of rivets.

There have, says Kirtley, been nineteen of these welded boilers in constant use upon the Midland Railway for the last 6 $\frac{1}{2}$ years, and the result has proved so thoroughly satisfactory that this construction has now been permanently adopted for the engines of this line. Up to the present time (1866) all these nineteen boilers have been examined once, and have been found in good condition; the mileage of each during the 6 $\frac{1}{2}$ years that they have been running has been equal to about 175,000 miles, and each boiler has had one set of tubes worn out.

Anti-corrosive Paints.—Tarr and Wenson's *anti-corrosive paint* for ships' bottoms consists of a composition made by reducing an alloy of zinc, tin, iron, and quicksilver to powder, and adding to the mass 20 per cent. of white arsenic. This is mixed with a composition of 40 gallons of wood tar, 30 gallons of coal naphtha, and $\frac{3}{4}$ lb. oxide of iron.

G. W. Morse's paint for ships' bottoms is composed of antimony, 80 parts; lead, 15; cement—copper, 5; naphtha, 1; benzine, 1; and tar, 2.

John Platt, of Oldham, in a paper printed in the Proceedings of the I. M. E., observes that the process of spinning involves three essential and distinct operations;—

1st. *Drawing*, in which the fibres of the raw material are drawn out longitudinally, so as to lay them all parallel with one another, and overlapping at the ends; as is done by the fingers of the hand spinner for forming a continuous sliver out of the short fibres lying irregularly in the bundle that is tied upon the distaff.

2nd. *Twisting*, in which the sliver previously formed is twisted into a roving or thread, for giving it longitudinal tenacity by increasing the lateral friction between the fibres; as is done by the hand spinner by twirling the bobbin on which the portion of thread already twisted has been wound.

3rd. *Winding*, in which each portion of the thread, after it has been sufficiently twisted, is wound upon the bobbin.

In the application of machinery to the performance of these operations, the great difficulties experienced have arisen from the irregular character of the cotton fibre on the one hand, and on the other from the unyielding action of machinery, which has to take the place of the delicate feeling of the fingers in hand spinning, whereby the spinner is enabled to accommodate the action continually to the variations in the material. It is a point of special mechanical interest, however, to note at how early a period in the application of machinery correct ideas were developed as to the principles of action in the important successive steps; so correct indeed that they have

remained unaltered in principle to the present time, although many highly ingenious improvements in detail have subsequently been effected.

In Paul's first machine the raw cotton was passed through a succession of pairs of rollers, each pair running faster than the preceding, so as to draw out the sliver of cotton longitudinally to any degree of fineness required. The machine thus accomplished only the drawing process, leaving the sliver so formed to be twisted and wound afterwards by hand. The great feature of this invention was that the important principle of drawing by rollers running at different speeds was thus established at the outset, to supersede drawing by the fingers in hand spinning; and this mode of drawing has been adhered to ever since as the fundamental principle in the preparation of fibrous materials for spinning.

Paul invented, also, a carding machine, for carding or combing the raw cotton in preparation for the drawing rollers. It consisted of a number of flat parallel cards fixed upon a table with spaces between them; and the teeth of the cards being all bent in the same direction, the cotton was carded by being drawn over them by hand by means of an upper flat carding board set with teeth bent in the opposite direction. In another arrangement this flat upper card was replaced by a horizontal carding cylinder, made to revolve by hand; and the lower carding table was made concave to fit the under-side of the cylinder. When the cotton was sufficiently carded, it was taken off each card separately by hand by a needle-stick, and then connected into one entire roll or lap.

Paul improved his original machine, in 1758, by rendering it capable of performing the two other processes of twisting and winding requisite to complete the operation of spinning by machinery; and he constructed a spinning machine having a circular frame containing fifty spindles. The cotton was drawn by rollers, as in his previous machine, and the sliver was delivered from the rollers to a bobbin upon each spindle, by means of an arm or flier fixed upon the spindle; and the spindle being so contrived as to go faster than the bobbin, the sliver was thus twisted into thread by the flier, before being wound upon the bobbin.

Although the two mechanical principles which have formed the basis of all subsequent spinning machinery—namely, the drawing rollers, running at different speeds, and the differential motion of the flier and bobbin—were thus originated by Paul, it does not appear that his machines were ever practically successful; and Arkwright's spinning machine, in 1769, appears to have the merit of being the first that was brought into successful operation. This machine cannot be called more than an improvement in detail upon Paul's, as the principles of the two were the same; and it is difficult to imagine that Arkwright had not seen Paul's machine. The success of the later machine may be attributed to its superiority both in workmanship and in the material employed, the earlier machine having been composed almost entirely of wood.

In 1770 Hargreaves invented the Spinning Jenny, shown in Fig. 2173, the principle of which is identical with that of the present spinning machinery. It thus presents a remarkable instance

of a correct perception respecting the best mode of working having been attained at so early a stage in the application of machinery to a new purpose. The operation of spinning into threads the rovings produced by the machines of Paul or Arkwright, or by the modern improved machines similar in principle, comprises the two processes of twisting and elongating the roving to form it into a thread, and then winding the spun thread into the form of a cop upon the same spindle by which the spinning or twisting has been performed. These two processes still continue to be effected in essentially the same manner as in Hargreaves' spinning jenny.

The twisting of the thread is effected by causing the spindles G, Fig. 2173, to revolve, as though

for winding up the thread, but allowing the thread to slip off the free end of the spindle once in each revolution. For this purpose the thread is led off from the top end of the spindle at an angle so much greater than a right angle that its tendency to wind in a spiral brings it to the top extremity of the spindle in each revolution, causing it to slip off the end of the spindle at each successive revolution; and the top of the spindle is shaped conical to facilitate the slipping of the thread off the end. The result is that the thread is twisted one turn by each revolution of the spindle, without disturbing or interfering with the portion of spun thread already wound up into a cop on the lower part of the spindle. The cross-bar J, carrying the guiding eyes through which the several threads pass, rests at each end on a carriage that runs along the side framing of the machine; and before the commencement of the spinning by the spindles G, the cross-bar is first drawn backwards from the spindles by hand through about one-third the length of the machine, drawing off a continuous supply of roving from the bobbins K below, which are free to turn on their bearings. The clasp H is then pressed down tight upon the cross-bar J, holding the rovings fast, and the spindles G are set in motion, twisting the lengths of thread between the spindles and the cross-bar; and during the twisting the cross-bar is gradually drawn backwards by hand to the end of the machine, thus producing the required elongation of the threads by tension during the spinning, as is done in the case of hand spinning by the weight of the bobbin or spindle hanging from the twisting thread. The spindles G receive their motion from the drum M driven by the driving pulley L, which is turned with the right hand by the handle N, while the left hand draws back the cross-bar J by means of the handle upon the clasp H.

When the cross-bar J has been drawn back to the extreme end of the machine and the spinning of the threads has been completed, they are then wound up on the spindles by depressing them all simultaneously to the lower portion of the spindles by means of the faller wire O, which is brought down upon the threads by the rotation of the discs P P in the direction of the arrow. The rotation of the discs is effected by tightening the cord R which runs along the side of the machine, and they are turned back again by a counterbalance weight for raising the faller wire when the cord is released; the cord passes round three horizontal pulleys on the top of the carriage S, and is tightened for depressing the faller wire by a transverse sliding movement being given to the middle pulley by means of a hand lever, which is worked by the left hand whilst holding the clasp on the cross-bar J. The threads being depressed by the faller wire, the further rotation of the spindles now causes the threads to be wound up in cops upon the spindles, the sliding cross-bar J being pushed forwards gradually by hand as the winding proceeds, until it again reaches the spindles, when it is ready for beginning the spinning of a fresh length of rovings. During the winding of the threads already spun between the spindles and the cross-bar J, this length of the threads is secured and separated from the untwisted rovings beyond the cross-bar by the pressure of the clasp H, which is kept pressed down tight upon the threads.

On the completion of the spinning, however, of each length of the threads, and before the change can take place from spinning to winding, it is necessary first to unwind the short spiral of thread extending up from the top of the cop previously wound to the top extremity of the spindle. This spiral is unavoidably formed at the commencement of the twisting, before the thread can reach the point where it ceases to wind and begins slipping off the end of the spindle at each revolution; but if this portion of thread were not entirely removed before the faller wire O is lowered at each time of changing from twisting to winding, an irregular and loose accumulation of thread would take place upon the upper end of the spindle, spoiling the form of the cop and interfering with the proper slipping-off action in twisting. The motion of the spindles has therefore to be stopped and reversed for a few turns when the twisting is finished, to unwind these few spiral coils; and this was done in the spinning jenny by the spinner stopping the driving wheel L, and then giving it a partial turn backwards by hand, for backing off the thread before driving forwards again for winding the thread on the spindles.

This backing-off motion and the faller wire are identical with those now in use in the modern spinning machines, the only difference being that they are now made self-acting. In winding the cop each successive layer of thread is so regulated that a conical form is given to each end of the finished cop, in order to prevent the thread from getting loosened upon it at the ends in subsequent handling; while at the same time the crossing of the thread in the alternate spiral layers gives firmness to the cop, and still allows the thread to be afterwards drawn off it, when required for use, either by slipping off the end as in a shuttle, or by unwinding the cop on a spindle. In the spinning jenny this shape of cop was obtained by regulating the winding of the thread by means of the cord R acting upon the discs P P, raising and lowering the faller wire O during the winding so as to guide the thread upon the spindle as required for producing the desired shape of cop. The same shape of cop and mode of guiding the thread on are still adhered to in the present spinning machines; but the whole of the movements are now effected entirely by self-acting machinery.

Further improvements in the preparatory processes of carding and roving were introduced by Arkwright in 1775, which may be said to include the principal features contained in the carding and roving machines now used. The cotton delivered from the preliminary machine was formed into a roll or lap, for supplying a continuous fleece of cotton to the carding cylinders, the carding operation being repeated until the irregular mass of fibres in the raw material had been combed straight and laid parallel in the fleece of cotton with a sufficient degree of uniformity to allow of proceeding to the subsequent operations. Comb-plates worked backwards and forwards by cranks were also added for combing off the cotton in a continuous fleece from the doffer or taking-off cylinder of each of the carding machines. The sliver delivered from the last carding process was passed between a pair of rollers for the purpose of consolidating it by the pressure of the rollers after the loosening action of the doffing comb-plate; and it was then coiled down into a can.

The doubling and drawing process employed at this stage of the manufacture was also introduced by Arkwright at the same time, the object being to intermingle the fibres more completely in the sliver, and thereby render it more uniform in quality, ready for twisting into a roving. For

this purpose two or generally more of the slivers from the carding engine are passed side by side through a series of pairs of drawing rollers, each pair in succession being made to run faster than the preceding; and the last pair of rollers runs as many times faster than the first pair as there are slivers doubled together, so that the single combined sliver delivered from the rollers is drawn down to the same size or weight a foot as one of the original slivers. The doubling and drawing operation is usually repeated three times, and the ultimate sliver so prepared is then ready for the roving frame, in which it is again drawn and twisted and wound upon a bobbin.

In the roving frame Arkwright now effected an important advance upon his previous machine, by introducing the new principle, which has since been adhered to, of driving the bobbin and the spindle independently by separate motions, instead of letting the bobbin be simply dragged round by the thread. At the same time he also introduced the conical regulating drum, for reducing the speed of the bobbin in proportion as its diameter was increased by the thickness of the coils of roving wound upon it, so as to avoid increasing the tension upon the roving, as would be the case if the speed of the bobbin were uniform, since the spindle and flier are driven always at a constant speed. This mode of regulating the speed of the bobbin by a conical drum is the same that is still employed in the modern machinery, with modifications only in the mode of application.

Opening.—The first process in the preparation of the raw cotton was known as willowing, and took its name from the willow switches formerly used for beating or opening the tufts of cotton by hand. A number of small parallel cords were stretched tight and close together on a horizontal frame, so as to form a sort of table, upon which the cotton to be opened was laid; and the cotton being then beaten with switches made of willow rods kept smooth for the purpose, the fibres of the cotton remained on the cords, whilst the sand and seeds fell through between. Some of the best descriptions of sea-island cotton are still batted in this way, for the finest counts of yarn. Several attempts were made to work the willow-beaters by machinery, but they have all been superseded by opening and scutching machines on the modern

principle, having revolving cylinders to act as beaters. The most primitive of these is known as the Oldham Willow, and has a revolving cylinder about 36 in. diameter, set with spikes placed in parallel rows, and revolving against a grid of bars set with similar spikes; the cotton is fed upon the grid, and beaten for a longer or shorter time, according to its condition, and an exhausting fan is employed for taking away the sand and bits of dried leaves beaten out. This machine is now used only for separating hard lumps of cotton in bales packed too tightly, and for cleaning cotton waste and the refuse cast out by other cleaning machines.

Fig. 2174 shows a section of the Cotton Opener in use at the present time for the purpose of opening out the fibres of the cotton after it has been pressed in the bales, and for extracting the sand, dried leaves, and other impurities imported with it, the object being to do this without entangling or injuring the fibre. The crude cotton from the bales is spread by hand upon the endless travelling lattice A, which conveys it underneath the iron guide-roller B with longitudinal ribs on its surface to the pair of fluted feed-rollers C. These are pressed together by the weighted lever D, and deliver the cotton to the picker-cylinder E, set with twelve rows of teeth, which are spaced so that the teeth follow one another spirally round the cylinder, as shown in the plan, Fig. 2175. The tufts of cotton being gripped tight between the rollers C are caught by the tips of the teeth on the cylinder revolving in the direction of the arrow, and are thus torn open and dashed by the teeth against the circular grid F, formed of angular bars set with spaces between them, which allow the dirt disengaged by the beating action to fall through. A perforated plate G forms the remainder of the casing of the cylinder on the under-side, allowing the dust to drop through while the cotton passes over it. The picker-cylinder delivers the cotton against the teeth of the beater H, which has four rows of teeth, similar to those on the picker E. Here the cotton is further beaten and passed over a circular grid and perforated plate; and the beater-cylinders being covered in at the top by a sheet-iron casing, the current of air produced by their revolution wafts the light fleece of cotton forwards over the straight grid J. It is whilst the cotton is thus floating in the air that the heavier impurities, loosened by the beaters, drop out and fall through the grid J into the dust-box. The cotton then passes between the two wire-gauze cylinders K, which serve as fine sieves, the interior of the cylinders being exhausted by the fan L; by this means the more minute particles of dust remaining in the cotton are sifted out, and discharged by the fan through the aperture M, thereby keeping the rooms where the machines are at work perfectly free from dust. There is thus a continual deposit of impurities taking place throughout the whole passage of the cotton through the machine, from the feed-rollers C to the wire cylinders K. In the drawing, only two beater-cylinders E and H are shown; but the machines are more generally made with four cylinders, for cleansing the cotton more effectually, the two additional beaters being provided with four rows of teeth, the same as the second cylinder H. From the wire cylinders the loose cotton is collected again and consolidated into a fleece by the fluted stripping rollers I, running close to the cylinders K, but not touching; and these deliver it to the travelling lattice N, which discharges it ready to be taken to the next process of scutching, a lap machine being sometimes attached, so as to form the fleece into a lap or roll for supplying the scutcher. The beater-cylinders E and H run at about 1000 revolutions a minute; the feeding lattice A travels at 6 ft. a minute, which is also the surface speed of the feed-rollers C; and the surface speed of the wire cylinders K, the stripping rollers I, and the delivery lattice N, is 60 ft. a minute.

Scutching.—The Scutching Machine now in use for further beating and cleansing the cotton delivered from the opener is shown in Fig. 2176, having also combined with it the Lap Machine for forming the fleece of cotton delivered from the scutcher into a roll or lap. The cotton from the opener is supplied to the scutcher upon the travelling feeding lattice A, and in order to produce a uniform fleece for the further processes, it is necessary at this stage to regulate the quantity fed into the scutcher, which is effected in two ways. In feeding by hand the tedious method of weighing the cotton supplied has to be resorted to, so as to distribute a uniform weight of cotton over each foot of length of the feeding lattice, which together with the feed-rollers C is driven at a uniform speed. But in the improved mode of feeding by laps B, supplied from a lap machine in connection with the opener, the top feed-roller is allowed to rise and fall, according to the variations in the thickness of cotton fed in, and the amount of its vertical movement multiplied by means of levers is employed to regulate by a self-acting arrangement the speed at which the feeding lattice and rollers are driven. By this means an almost uniform supply of cotton is fed to the beater H, which is composed of three plain bars, as shown in the plan, Fig. 2177, and is driven at about 1250 revolutions a minute. The cotton is beaten, as before, against the circular grid F and perforated plate G, and the current of air from the beater wafts it forwards over the straight grid J to the wire cylinders K, exhausted by the fan L, the action being exactly the same as in the opening machine. The rollers I, which strip the dust-cylinders, deliver the fleece to a set of four callender rollers O, placed over one another, so that the cotton in passing through them receives three compressions, which consolidate it into a kind of felt; the surfaces of the callender rollers are kept clean by rubbers of iron covered with flannel, which are pressed in contact with them.

The Lap Machine, for coiling the fleece into a roll or lap, has two fluted driving rollers P P running in the same direction, as shown by the arrows; and the lap, resting in the channel between them, is driven by contact, and wound upon the iron rod R, guided in a vertical groove at each end. For tightening and closing the coils of the lap, the rod R was weighted in the former machines by a heavy weight suspended from the ends of the rod, and it was then necessary to lift the whole of this weight at each time of changing the lap; but this is now effected by the friction brake S pressing against a friction wheel on the shaft T, on which are pinions gearing into the vertical racks U, and these racks carry rollers at the top, bearing down upon the ends of the rod R in the lap. By this means, as each successive coil is wound upon the lap, the brake S slips and allows the lap to rise; and when the lap is completed, the brake is released by a treadle, and the

racks are lifted clear by the hand-wheel on the shaft T, so as to allow the finished lap to be removed. The driving pinion V, from which the callender rollers O receive their motion, is held up in gear by the lever W supported by a catch; and when the lap is finished this catch is released by a tappet upon the pinion X, which is driven from the bottom callender roller, the speed of the pinion being so reduced that one revolution of it corresponds to the size of lap required to be made. The catch being released allows the driving pinion V to fall out of gear, whereby the callender rollers O are stopped; and the lap-rollers P continuing to revolve, break off the fleece, ready for removing the finished lap from the machine. By changing the pinion X, carrying the tappet, the size of lap made by the machine can be varied as desired.

The scutcher shown in Fig. 2176 is a single machine, and it is usual to pass the cotton first through a double scutcher of similar construction, but having a second set of feed-rollers with beater and wire cylinders, running at a higher speed; the second pair of wire cylinders and stripping rollers are driven three times as fast as the first pair, so that they deliver a fleece of one third the thickness first supplied to the machine. Three of the laps from this double scutcher are then fed into the single scutcher shown in the drawing, as at B B B, Fig. 2176, being spread upon the surface of the feeding lattice A in three layers on the top of one another, so as to present to the feed-rollers a uniform fleece equal in thickness to that fed into the first scutcher. By thus doubling the laps the fibres are more thoroughly mixed, and the fleece is thereby made more uniform in thickness.

Scutching machines having a revolving beater, composed of two plain bars describing a circle of about 14 in. diameter, were introduced about 1810; and these machines contained also a travelling feed-lattice, two pairs of feed-rollers, and a second travelling lattice for conveying the beaten cotton underneath a perforated revolving cylinder, the interior of which was exhausted by a fan. The cotton passing through this machine was delivered in a loose fleece, and a few years later a lap machine was added for coiling the fleece into a lap. Other improvements have gradually been introduced up to the present time, as regards both design and workmanship; the cylinders and beaters have been put in perfect

balance so as to revolve steadily at the high speed required, and the forms of teeth on the cylinders have been arranged for greater strength and greater facility of construction; stronger and simpler gearing has been employed, improvements have been made in the form and construction of the bearings of the beaters and other quick revolving shafts, so as to ensure more efficient lubrication,

and air-tight dust boxes have been added with movable doors for facility of cleaning; and the self-acting arrangements have been introduced for stopping the machine when a given length of fleece has been delivered, and for regulating the rate of feed according to the thickness of the cotton supplied, so as to dispense with the previous plan of weighing the cotton in feeding. Thus by successive improvements through a long series of years the difficulties which originally presented themselves in the successful adaptation of machinery to cotton cleaning have been overcome.

Carding.—In the carding process the felted fleece delivered by the lap machine of the scutcher, with its fibres crossed in all directions, is combed out a great number of times so as to straighten the fibres; and the light impurities still adhering to it are taken out, such as short fibres and bits of the moss-like covering of the seeds, which if allowed to remain in the sliver produced by this operation would give a roughness to the yarn. For making coarse yarns one carding process only is employed; but for finer yarns the fleece is first passed through a breaker carding engine, which performs the first rough carding, and the slivers delivered by this are then doubled by laying together a large number of slivers, side by side and overlapping one another, into a new fleece, so as to obtain sufficient thickness and breadth of material to allow of a further carding; and the lap formed of this new fleece is then fed into a second or finisher carding engine. As many as ninety-six slivers from the breaker card, each drawn out of a separate can, are laid together by the doubling machine into a single fleece for the supply of the finisher, in order that the mixing of the cotton may be more thoroughly effected, and more perfect uniformity ensured in the sliver delivered by the finisher. For the finest qualities of yarn the finisher card is itself used as a breaker, and the sliver delivered by it is afterwards combed by a combing machine.

The Roller and Clearer Carding Machine employed at the present time as a breaker card for performing the first carding of the fleece is shown in section in Fig. 2178, and consists of a main carding cylinder A, round which are arranged a series of pairs of carding rollers or workers B B and clearing rollers or strippers C C. The surfaces of all these are covered with cards, and they are made to revolve so close together as to allow the tips of the card teeth just to clear one another. The cards are a kind of wire brush with inclined teeth, as shown full size in Fig. 2179, and are made of staples D of fine steel or iron wire, each about $\frac{3}{8}$ in. long and $\frac{3}{16}$ in. wide, with a side bend in the middle of their length. These are fixed close together into a strip of webbing about $1\frac{1}{2}$ in. wide, which is wound tight round the cylindrical rollers in a continuous spiral, keeping the staples pressed home in the cloth by the surface of the cylinder, so that they have an elastic firmness which keeps their points up to the work.

The working width of the machine is about 40 in. on the card teeth, corresponding with the breadth of the fleece in the lap E by which the carding engine is fed. The unlapping of the fleece is performed by the rollers F on which the lap rests, and the fleece is then drawn forwards under the feed-roller G, and delivered to the taker-in roller H revolving in the direction of the arrow. At this point the carding or combing action commences, the fleece being held by the feed-roller G travelling at the slow speed of only about $\frac{2}{3}$ ft. of surface a minute, while the taker-in H runs much faster, at about 800 ft. a minute surface speed; and the carding teeth on the taker-in being bent forwards in the direction of motion, the points of the teeth strike down into the fleece held by the feed-roller, and comb out the fibres, while the impurities separated fall to the ground. The fibrous tufts of cotton are carried round on the under-side of the taker-in to the main carding cylinder A, which revolves in the same surface direction with a speed of about 1600 ft. a minute. The teeth of the carding cylinder being bent forwards in the direction of motion sweep off the cotton from the taker-in teeth inclined in the same direction but running at only half the speed, and carry it forwards to the dirt-roller J, the teeth of which face those of the carding cylinder, and travel with a very slow motion of only about 16 ft. a minute. The dirt-roller thus assists in combing out the fibres, and holds in the interstices of its wires any impurities that it receives from the cotton, which are carried forwards and stripped from it by a vibrating comb, so that they accumulate in a roll on the upper surface of the dirt-roller, to be taken away by hand at intervals.

The carding cylinder then carries the cotton forwards to the several pairs of workers and strippers, one of which is shown to a larger scale in Fig. 2180; and at each pair in succession the fibres undergo a further combing out and straightening. The motion of the teeth of all these pairs of rollers is in the same direction as that of the adjacent teeth on the main carding cylinder, as shown by the arrows in Fig. 2180, but at a much slower speed; and the teeth of the strippers C are inclined forwards in the direction of motion, while those of the workers B are set the opposite way so as to present the points of the teeth facing those on the carding cylinder A. The cotton on the carding cylinder is therefore carried past the stripper C without being caught by its teeth, and is caught upon the teeth of the worker B running at only about 20 ft. a minute, so that a combing action for straightening the fibres and dividing the tufts of cotton is obtained by the excess of speed in the carding cylinder running at the high velocity of 1600 ft. a minute. All fibres failing to pass the worker B are carried round upon its teeth to the stripper C, which runs at a surface speed of about 400 ft. a minute, being thus intermediate in speed between the slow worker B and the quick carding cylinder A; the teeth of the stripper therefore sweep off the cotton from the worker, and are themselves stripped in the same way by the carding cylinder running at the higher speed. After passing the six pairs of workers and strippers, the fleece of straightened fibres is taken off in a continuous sheet from the carding cylinder A by the doffer K, the teeth of which face those of the cylinder and move in the same direction but at a much slower speed of only about 65 ft. a minute; the fleece thus receives a further straightening and stretching in quitting the carding cylinder, and is carried round on the under-side of the doffer to the vibrating comb L, which describes a short arc of $1\frac{1}{4}$ in. vertical motion and is driven by balanced cranks at about 800 double vibrations a minute. This comb strips the fleece from the face of the doffer in its down-stroke and clears itself in rising; and the thin fleece, of the full width of the machine, 40 in., is then gathered in by lateral guides to a width of 6 in., and finally into a smooth bell-mouthed round funnel L, having a hole only $\frac{1}{2}$ in.

diameter, through which the contracted ribbon or sliver is drawn by the two pairs of drawing rollers M, the second pair running one-half faster than the first, whence it passes to the coiler N and can O.

The coiler consists of a revolving plate N having an eccentric aperture, through which the

sliver is passed from the pair of rollers P above the plate, so that it is delivered into the can in circular coils. The can O, however, is also made to revolve with a slow motion in the opposite direction to the coiler, and the centre line of the coiler N is eccentric to the axis of the can, whereby the sliver delivered from the coiler describes a succession of hypocycloid curves in the can, the circles of sliver being laid into the can so that the outsides of the coils touch the inside of the can.

The sliver thus forms coils continually crossing one another, so that the can is filled up solid throughout, and when taken to the doubling frame the coils of sliver come out again without adhering to one another.

The Flat Carding Machine employed at the present time as a finisher card for performing the second carding operation is shown in Fig. 2181; and consists of a main carding cylinder A, as in the breaker card, but the pairs of workers and strippers employed in the first carding are here re-

placed by a series of flat cards D D, connected together by links so as to form an endless travelling lattice. The lap E, formed of a number of slivers from the breaker card laid together into a fleece by the doubling machine, is supplied to the carding cylinder A by the feed-roller G and taker-in H, in the same way as in the breaker card; and the carding cylinder A is driven at the same speed of about 1600 ft. of surface a minute. A single worker B, called the fancy roller, with a stripper C, is placed immediately beyond the taker-in H, running in the same direction as the adjacent surface of the carding cylinder A; but in this case the teeth of the fancy roller B are bent forwards in the

direction of motion, and it therefore requires to be driven at a higher velocity than the carding cylinder, and has accordingly a surface speed of 2000 ft. a minute. It thus seizes the cotton from off the teeth of the main carding cylinder A, and throws it against the teeth of the stripper C facing those of the fancy roller; and the fibres having thus been subjected to a preliminary carding are again swept off the teeth of the stripper, moving at only 400 ft. a minute, by the higher speed of the main carding cylinder A.

The cotton is then carried forwards by the carding cylinder to the series of flat cards D D, Fig. 2182, which are made of cast-iron bars faced with card teeth, as shown to a larger scale in Figs. 2183, 2184; these extend the entire width of the machine, and rest at each end upon a cir-

cular guide on the top of the side frames of the machine, which is concentric with the main carding cylinder A, so that the teeth of the flats are kept in close proximity to the teeth of the carding cylinder during the whole of their forward traverse. The teeth of the flats D are set to face those of the carding cylinder A, and travel forwards in the same direction as the surface of the cylinder, but at a very slow rate of only 1 in. a minute: and the cotton thus undergoes a very thorough carding and straightening in passing the twenty-one cards that are always in contact with the top of the carding cylinder. The flats are arranged to work at a slight inclination to the surface of the carding cylinder, so that the delivering side of each flat is closer to the cylinder, and a wider space is left at the entering side between the flat and the cylinder for the cotton, to enter, as shown half full size in Fig. 2184. The angle thus formed is called the bevel of the flat, and the correct adjustment of this inclination is a point of great importance and delicacy; the bevel is obtained by cutting a bevel groove Q in each end of the flat at the part where it is to rest upon the circular guide on each side of the machine, as shown enlarged in Figs. 2183, 2184, where the dotted circle X X represents the edge of the guide on which the flat travels, and the dotted circle Y Y indicates the surface of the main carding cylinder A.

The endless lattice of flats D D is carried over the three shafts P P P, and on quitting the carding cylinder A, each flat in turn is stripped of any fibres or impurities adhering to it by the vibrating comb R, which describes an arc of 1 in., and is driven at the rate of forty double strokes a minute by the cam S, Fig. 2185. The flats are further cleaned by the brush T, shown in plan in Fig. 2186, running at a surface speed of 50 ft. a minute; and they are then passed over a guide U, which holds them up against an emery wheel V, running at the high speed of 550 ft. a minute, and traversing across the machine along the length of the flats, whereby the faces of all the cards are successively ground to a true surface whilst at work, and the points of the wires sharpened. The same mode of grinding is also employed for keeping true the surfaces of the carding cylinder and doffer. The fleece of straightened fibres is taken off in a continuous sheet from the carding cylinder by the doffer K and vibrating comb I, and is contracted into a sliver and coiled down into the can O in the same manner as previously described.

The stripping by hand labour, however, was an unhealthy and a disagreeable process; and bad work and spoiled cotton were the consequences whenever it was not done regularly and thoroughly. Many arrangements have been introduced from time to time for stripping the flats mechanically. Within the last few years a simple mechanism for this work has been introduced by Mr. Wellman, an American, the application of which has received a great stimulus from the difficulty of obtaining men to perform the stripping by hand; and it is now extensively used. Metal flats were introduced by Smith, of Deanston, and these were linked together in the form of an endless lattice, which was made to travel slowly forwards over the carding cylinder; and each flat was adjusted to the proper bevel by two screws at each end, which travelled over two circular guides concentric with the carding cylinder. Another short flat guide at the back of the flats brought them into contact with a stripping brush, which was cleaned by a comb, and the comb teeth were scraped clear by a tin knife. These flats were used in several of the Scotch mills, but few of them were introduced into Lancashire. The flat carding machine was further improved by Mr. Evan Leigh, by cutting the bevel on the ends of the flats, as shown at Q Q, Fig. 2183, and making the circular guides over which they travel adjustable for wear; at the same time a second face was formed on the back of the flats, to work over the guides U, Fig. 2182, which hold them up in the right position for being ground by the emery wheel V; and the vibrating comb R was also added for stripping the flats before they are finally cleaned by the brush T, instead of the brush alone being used for the purpose.

The finisher carding machine until recently was constructed without the taker-in roller H, Fig. 2181, the main cylinder taking the fleece direct from the feeding roller G. This caused the fibres to clog the cards, and any impurities passing the feed-roller damaged the teeth of the main cylinder, which was of serious importance on the large extent of surface of the cylinder. By using the taker-in, however, these evils are prevented, the fibres being delivered to the carding cylinder in a more divided state, and more equally distributed over its surface. Carding machines are also sometimes made, which are a combination of the breaker and finisher card, having rollers and clearers on the side of the cylinder next the feeder, and flats on the side next the doffer.

The practical difficulty originally experienced with the carding engine consisted in getting the cards to work sufficiently near to one another without occasionally coming in contact, which destroyed the carding points. The surfaces on which the cards were fixed were generally constructed of wood, and therefore varied with every change of the atmosphere from the shrinking or swelling of the wood, so that the faces of the cards had to be made true each time by grinding down the points of the wires at the full parts. Moreover, the cylinders and rollers were not carefully constructed so as to run with a steady motion; and the fixings for carrying the different journals were not capable of a fine adjustment, nor were they steady after being set. These defects are now overcome by using iron instead of wood, and by the aid of machinery and tools adapted for making all the parts accurately; fine adjustments are provided, and the adjustable portions are made as firm when set as if fixed. These improvements cause less grinding and stripping to be required, as the finer and truer the points of the wires can be maintained, the clearer the cards continue in working.

Drawing.—The slivers from the finisher card are next taken to the Drawing Frame, shown in section in Fig. 2187, which contains generally four pairs of drawing rollers A, each pair running faster than the preceding, and the front pair running at six times the surface speed of the back pair. Six slivers B in separate cans from the carding engine are fed up together to the back pair of drawing rollers, being combined together by passing between two guide-pins C; and after being laid together and drawn out to six times the original length, the single sliver so produced is passed through a funnel to the pair of callender rollers D, by which it is delivered to the coiler E, and coiled down into the can F in the same manner as in the carding machines. This combined sliver, having

been doubled six times and drawn six times, is the same weight a foot as each of the original slivers fed up to the back pair of rollers; and the object sought in the doubling and drawing process is to equalize the distribution of the cotton fibres and produce slivers of more uniform strength and texture by the combination. The process is repeated three times in this machine, and the extent of combination or intermixture obtained in the ultimate slivers is therefore represented by the cube of six, or 216 times, in comparison with each of the original slivers first supplied to the machine.

In order to ensure the drawing rollers being always supplied with the full number of six slivers, each of the slivers fed up to the rollers is passed over a guide G, turning on a centre pin and nearly balanced, so as to turn with a slight pressure; and during the working of the machine this guide is depressed by the weight of the sliver into the position shown by the full lines. But in the event of the sliver breaking or running out, the tail of the guide, being overweighted, drops into the position shown by the dotted lines, and catches the vibrating finger J, which is worked by an eccentric on the shaft H running at 70 revolutions a minute. This shaft is driven at the end

by a small crown ratchet-clutch, held in gear by a spiral spring behind and driving by the inclined faces; so that whenever the shaft H is stopped by the tail of a guide G catching one of the vibrating fingers J and the ratchet is consequently held stationary, the clutch is thrown out of the ratchet by the inclination of the teeth, and the end-motion thus produced releases a catch which holds the strap-fork of the machine; the fork is then reversed by a spring always acting upon it to throw off the strap from the fast to the loose pulley, thus stopping the machine. After the sliver run out has been renewed or the broken sliver joined up by the attendant, the machine is set in motion again by moving the starting rod I, which extends the whole length of the drawing frame.

The improvements made in the drawing frame since its introduction include, amongst other details, the construction of the roller-supports so as to be easily set and adjusted to the different distances required to suit the different lengths of cotton fibre worked; the addition of the self-acting stop-motion, for stopping the machine when any one of the slivers breaks or runs out; a simpler mode of suspending the weights from the top rollers; and the use of an endless travelling cloth over the surfaces of the top rollers, as shown in Fig. 2187, for cleaning off the waste or fly from the

rollers. The top rollers are also made with dead spindles and loose bosses, the bosses being driven by independent motions. In drawing frames used to prepare slivers for the finer counts of yarn, an additional stop-apparatus is provided for stopping the machine whenever a breakage of the sliver occurs between the front pair of drawing rollers and the callender rollers D, Fig. 2187, or when the can F is full or a given length of sliver has been delivered; this stop-action is worked from the same shaft H as that employed for breakages of the supply slivers.

Slubbing, Intermediate, and Roving.—The slivers delivered from the drawing frame are conveyed to the Slubbing Frame, into which they are fed either single or double, passing over a guide, like that in the drawing frame, to a set of three pairs of drawing rollers; the last pair runs at five times the speed of the first, so that the sliver is again increased in length five times in passing through the rollers. From the drawing rollers the sliver, now called slubbing, passes to a revolving flier carried upon a vertical spindle, by which it is twisted and then wound upon a bobbin revolving loose upon the same spindle. The flier runs at a constant speed, while the bobbin is driven by means of a differential motion at a speed varying according to its increasing diameter as the slubbing is wound on; and the lifting movement, for raising and lowering the bobbin upon the spindle so as to wind on the slubbing in regular coils, is also worked by the same differential motion. The speed of the flier is 500 revolutions a minute, and the slubbing is delivered from the drawing rollers at the rate of 50 ft. a minute, so that the number of twists put into it in this machine is $\frac{1}{8}$ twist an inch of length.

The bobbins from the slubbing frame are next supplied in pairs to the Intermediate Frame, in which the slubbings are doubled by passing two of them together through a set of three pairs of drawing rollers, and then twisting them into one by means of a flier, and winding on a bobbin in the same manner as in the slubbing machine. In this process, intermediate between the slubbing and roving, the amount of drawing produced by the rollers is five times, and $1\frac{1}{2}$ twists are put into the doubled slubbing by the flier an inch of length delivered from the rollers.

In the Roving Frame, shown in Fig. 2188, the contents of two bobbins A A from the intermediate frame are again doubled, drawn, and twisted as before; and the cotton, now called roving, is wound upon bobbins ready for being finally spun into thread.

The extent of drawing in the three pairs of drawing rollers B is six times, and the front pair runs at a surface speed of 29 ft. a minute; the flier C is driven at 900 revolutions a minute, and thus puts $2\frac{1}{2}$ twists an inch into the roving. The bobbins A A supplying the cotton for the rovings are fitted upon wood spindles called skewers, pointed at the lower end where they rest upon their bearings, which are shallow cups made of glazed earthenware; these

bobbin-pinion N makes eighteen revolutions for every sixteen of the flier-pinion M. Hence the ratio of speed of the bobbin-pinion to the flier-pinion is 32 to 24 in the first case and 27 to 24 in the second; and the total reduction of speed of the bobbins, whilst the strap travels along the entire 30 in. length of the cones, is $\frac{3}{8}$, or 16 per cent. of their original speed, which is the range of variation required to allow for the increasing diameter of the bobbins in winding.

The differential motion affords the means of obtaining this delicacy of adjustment with a compact and easily-worked apparatus; and by virtually magnifying the range of variation required avoids the use of cones with too small a taper for good working. The arrangement shown in Fig. 2189 is for the case of the bobbin running in advance of the flier, when the speed of the bobbin has to be reduced as its diameter increases in winding; and the action of the differential motion is exactly similar in the converse case of the bobbin following the flier, the only difference being that the disc wheel Q must then be made to rotate in the same direction as the driving shaft K, instead of in the contrary direction. As the advance of the driving strap T along the cones is a uniform amount at each reciprocation of the bobbin-lifter, the driving cone R requires to be shaped with a concave outline and the driven cone S with a corresponding convex outline; since the absolute increase made in the diameter of the bobbin by each successive layer of roving bears a continually diminishing ratio to the increasing diameter of the bobbin, requiring the variation of speed therefore to be effected also in a continually diminishing ratio.

Houldsworth's differential motion requires only a single rack and pinion of uniform pitch, with ratchet-wheels of varied pitches for giving motion to the rack-pinion; so that for a change in the fineness of the roving it is only necessary to change the ratchet-wheel, which is readily effected and is much more convenient than having to change the rack. When this form of the differential motion was first applied, one cone drum only was used, with counter-pulleys and a weighted pulley for keeping the strap tight; but latterly the two cone drums shown in Fig. 2189 have been used instead, made with corresponding concave and convex surfaces, so that the strap continues equally tight in all positions.

Spinning.—In the practical working of Arkwright's spinning machine and Hargreaves' spinning jenny, it was found that the rovings and threads produced were both coarse and uneven, only fit for the manufacture of quiltings, and poorly adapted even for that purpose. A great improvement in this respect was effected in 1779 by Samuel Crompton's spinning machine or mule, which was a combination of Paul's or Arkwright's spinning machine and Hargreaves' jenny, combining the drawing-roller arrangement in the former with a modification of the sliding cross-bar and spinning spindles in the latter. In this machine the spindles were placed in a movable carriage, which had a stretch or run of about 54 in.; and the rovings delivered from the drawing rollers in a soft state were further drawn by the spinner in pulling the carriage backwards from the rollers, and completely twisted by the receding spindles, ready for being wound upon the spindles during the run-in or return traverse of the carriage and spindles. In the spinning jenny each successive length of the rovings was held by the clasp on the sliding cross-bar, and the stretching of the rovings was done entirely by drawing back the cross-bar by hand from the spindles; and in Arkwright's machine the stretching was performed entirely by the rollers; but in Crompton's mule the stretching was accomplished partially by the drawing rollers, when the carriage and spindles began to recede from the roller-beam, and partially by the continued run-out of the carriage after the rollers had been stopped. The rollers were stopped when the carriage had receded nearly the length of its run, and they then acted as a clasp to hold the threads during the completion of the stretching and twisting.

Crompton's first mule contained about thirty spindles; and the threads spun by it were far superior in regularity, strength, and fineness to any ever spun before. They realized about double the prices obtained in 1743 for the same counts of yarn spun by other machines, and must therefore have been very superior in quality, having been produced much more cheaply; and in order to show what could be done with the mule, small quantities were spun as fine as No. 80, which is such a quality of thread that 80 hanks of 840 yards each weigh together 1 lb. The adoption of these mules extended so rapidly that in 1811, thirty-two years after the first was made, there were 600 mills containing 4,209,000 spindles working on this plan, and only 310,500 spindles on Arkwright's plan, and 155,900 spindles on the spinning-jenny plan.

Many of the principal movements, however, in the working of Crompton's mule still required to be performed by hand by the spinner, the same as in the previous machines. This was the case with the backing-off motion, and with the working of the two faller wires, a second or counter-faller having now been added underneath the threads, which was lifted for the purpose of taking up the slack in the threads after the backing off, the first faller being depressed for guiding the threads upon the cops during the winding. The speed of the spindles also required regulating by hand during winding, so as to correspond with the increasing diameter of the cops formed on the spindles, and to suit the conical-shaped ends of the cops. Great skill was therefore necessary on the part of the spinner, in order to make the cops regular in shape, size, and hardness, suitable for transport and for being uncoiled without waste. To supersede this skilled labour and render the mule self-acting was therefore the great aim in the subsequent improvements.

In 1818 the entire operation of winding up the spun threads into cops on the spindles was rendered altogether self-acting by William Eaton. This involved both a self-acting method of performing the backing off, which has to be done at the conclusion of the twisting of each stretch, before the winding begins; and also a self-acting arrangement in connection with the faller wire, for guiding the threads regularly upon the cops during the winding, and a self-acting contrivance for regulating the speed of the spindles according to the increasing size of the cops.

The arrangement of Eaton's Backing-Off Motion is shown in Figs. 2190, 2191. The main shaft or rim shaft A, from which the driving motion of the spindles in the travelling carriage is derived, is itself driven in the forward direction during the twisting, and again during the winding, by the driving strap running on the fast pulley B, as shown by the dotted lines in Fig. 2191. The loose

pulley C communicates a slow motion through intermediate pinions to the wheel D revolving loose upon the shaft A, but in the contrary direction; and at the other end of the shaft A is a corresponding wheel E fast upon the shaft. The two toothed sectors F F are keyed upon a shaft G, which is carried in the rocking frame H; and the weight K on the rocking frame is constantly acting to draw the sectors back, out of gear with the wheels D and E; while the sectors themselves are only partly counterbalanced by the second weight L, and are ready to fall down into gear with the wheels as soon as the catch I, by which they are held up out of gear, is released. When the twisting of the threads is completed, the driving strap is shifted to the loose pulley C, and the forward motion remaining in the shaft A is arrested by a friction brake carrying a ratchet-wheel, which is caught by a hook falling into gear at the moment of reversing the strap. The pull upon this hook extends a spiral spring, the recoil of which is made to release the catch I; and the sectors F falling into gear with the wheels D and E, a backward motion is then communicated to the shaft A from the loose pulley C running forwards, whereby the spindles are made to turn backwards through the few revolutions necessary for backing off the spiral coils of thread at the top of the spindles, preparatory to winding. As the form of cop employed was a simple cone, increasing in height at the same time as in diameter, as shown in Fig. 2192, the length of the spiral coils that require backing off at the top of the spindles becomes less with the increasing height of the cops on the spindles, and the number of backward turns in the backing off has therefore to be gradually diminished as the cops approach completion; this is effected by an adjustable stop underneath the sectors F, which is gradually elevated in proportion to the increasing height of the cops. This stop is connected with a lever catching against a stud at the lower extremity of the arm H of the rocking frame; and the downward movement of the sectors F, while in gear with the wheels D and E, depresses the stop until at length the arm H is liberated; the weight K then withdraws the sectors out of gear, whereby the backward motion of the shaft A is stopped. By then shifting the driving strap to the fast pulley B, the shaft A is again driven in the forward direction, and the threads previously spun are wound up on the spindles as the carriage runs inwards. The pin J fixed upon the carriage, travelling inwards in the direction of the arrow, now comes in contact with the tail of the lever M, and lifts the sectors up again into their highest position, in which they are retained as before by the catch I at the other end of the lever M; and when the run-in of the carriage is nearly completed, the same pin J comes in contact with the tail of a second lever N, bearing against the extremity of the arm H of the rocking frame, whereby the sectors are thrown forwards again in readiness for the next time of backing off.

Eaton's Faller Motion is shown in Fig. 2192, and was almost identical with that in use at the present time, the difference being that the faller wire A was depressed by a weight B, instead of, as in the present mules, by a chain passing round a pulley upon the faller shaft C. The direction of the run-in of the carriage D carrying the spindles and cops E is shown by the arrows; and during the run-out in the opposite direction the weight B is held up in the position shown, by the catch F holding the tail of the lever G. This catch is withdrawn by the downward movement of the sectors in the backing-off motion, and the weight B then brings the front end of the lever G down upon an arm on the front side of the faller shaft C, depressing the faller wire A upon the threads H. The roller I, carried upon an arm on the back of the faller shaft, is thus brought up against the pin J fixed in the parallel-motion bar K, and is locked by the latch L; so that by the vertical movement of the bar K the faller wire A is raised and lowered during the winding of the threads, for guiding them upon the cops from end to end. The reciprocation of the bar K is obtained by its bottom end resting upon the shaper fusee or long tapered cam M, which is driven by the pinion N from the toothed wheel O travelling along a rack P fixed upon the floor. As soon as the carriage has begun to run in, the weight B is lifted off the faller and raised again to its original position by the tail R of the lever coming in contact with a fixed stop S. When the carriage arrives at the end of its run-in, the sliding bolt T coming against a fixed stop pushes

back the latch L, and unlocks the roller I; and a balance weight upon the back of the faller shaft C raises the faller wire A clear off the threads into the extreme position shown by the dotted lines. For regulating the shape of the cop as its size increases, the shaper fusee M is gradually traversed endways along its shaft N by the rack and pinion U driven by a worm wheel from the ratchet V, which is turned round one tooth at a time by the lever W coming against a stop X fixed on the floor at each end of the run of the carriage.

Further improvements were introduced by Maurice de Jongh, the backing-off motion being driven by a rack instead of by sectors; and with the backing off was combined the process of putting down the faller wire to the required part of the cops for the commencement of the winding. The working of the faller for guiding the threads during winding was effected by an arm on the back of the faller shaft, carrying a roller, which travelled along a template or copping rail extending the whole length of the stretch. The upper edge of this copping rail was shaped according to the form of cop required, and the entire rail was gradually lowered by a regulating screw at each end as the cop was built up. The winding of the threads on the cops was done by employing a slack strap or friction strap for driving the main shaft or rim shaft of the mule, during the run-in of the carriage; and this strap was tightened by a weight and two friction pulleys pressing against it, the weight being adjusted so as to make the strap drive or slip as required for keeping the threads in proper tension.

Richard Roberts' Self-Acting Mule is the form of self-acting mule almost universally employed at the present time for spinning cotton. In this mule the faller wire was for the first time put down by the agency of the rim shaft, or main driving shaft of the machine, during the time that the shaft is turning the reverse way for backing off.

The arrangement of Faller-Wire Motion, as employed in the present spinning mules, is shown in Figs. 2193 to 2196. A is the top-faller arm, which is made of the sickle shape shown in the drawing for the purpose of enabling it to put down the faller wire to the bottom of the cops J, without the arm itself being required to pass down between the cops, so as to save room in the length of the mule. On the front of the faller shaft I is keyed the sector C, and a chain D attached to the sector passes round the pulley E to a snail F upon the shaft of the tin roller, which is a long hollow cylinder made of tin, and driving by separate cords the whole row of spindles T. The snail F is geared to the tin roller by a ratchet-clutch, with the teeth set so as to engage only when the tin roller is driven the reverse way for backing off, as shown by the arrow in Fig. 2194. Whilst the tin roller is running forwards during the spinning, and again during the winding, in the direction shown by the arrow in Fig. 2193, the snail F is not in action; but as soon as the carriage G of the mule has run out to the end of the stretch, as shown in Fig. 2194, the tin roller is turned through part of a revolution in the reverse direction, as indicated by the arrow, sufficiently for unwinding the coils in backing off; and the snail F then comes into action and winds up the chain D, thereby bringing the top-faller wire A down upon the threads W and depressing them towards the bottom of the cops. On the back of the faller shaft I is fixed the curved arm B, against which bears the vertical locking bar H; and when the arm B is lifted by the depression of the faller A, its extremity is caught by the recess in the bar H, which is thrown forwards by the bell-crank lever K, as shown by Fig. 2195; the tail of this lever having been brought, by the run-out of the carriage G, under the corresponding bell-crank L fixed in the end frame of the mule, has previously extended the spiral spring attached to the bell-crank L, Fig. 2194, the recoil of which throws the locking bar H forwards as soon as the arm B is sufficiently raised, Fig. 2195. The pulley E is carried on a rocking lever R, the tail of which presses against the stop S in the end frame of the mule during the time that the chain D is depressing the faller, Fig. 2194; but at the moment when the locking bar H is thrown forwards to lock the faller arm B, the stop S is lowered, as shown in Fig. 2195, clear of the tail of the lever R, allowing the pulley E to yield to the further

pull of the chain D until the reverse motion of the tin roller in backing off is stopped; by this means the snail F, Fig. 2194, is prevented from depressing the faller wire A beyond the required distance down the height of the cop.

2193.

The faller being thus locked, the carriage G begins to run in, in the opposite direction to that indicated by the arrows in Fig. 2193; and while the spindles wind up the threads on the cops, the

faller wire is gradually allowed to rise by the locking bar H running down the inclined coping rail M, the curved arm B being kept constantly pressed home in the notch of the locking bar, by a counter-balance weight or spring acting on the back of the faller shaft I to raise the faller A. The length of the stretch or run-in of the carriage G is 63 in., which is therefore the length of thread to be wound upon the cop J at each time of winding; and this whole length of 63 in. of spun thread in each stretch is wound upon the cop during each stroke of the faller wire. The mode of building up the cop in successive stages is shown half full size in Fig. 2197; and in order to allow for the increasing diameter of the cop, the successive layers of thread are wound upon it in more open coils as the size increases, as indicated by the dotted lines, which is effected by gradually increasing the range of the faller wire; at the same time the ends of the cop are made of the conical form shown in the drawing. The length of range or chase of the faller wire at the commencement of the cop upon the bare spindles is only from A to B; but this is gradually increased until the cop has attained its full diameter C C, when the length of range is from C to D; after which the range is

slightly diminished again to the length EF in finishing the cop. For the purpose of obtaining the requisite motion of the faller wire for giving these successive shapes to the cop during the winding, the extremities of the coping rail M, Fig. 2193, are supported on the two sliding wedges N and O, which are kept at an invariable distance apart by a connecting rod. In

commencing the winding of a set of cops upon the bare spindles, as shown at A B in Fig. 2197, the copping rail is set at the top of the wedges and is at its smallest inclination; and after each successive layer has been wound on, the two wedges are slid from under the rail by a traversing screw worked by a ratchet-wheel, which is advanced one or more teeth during each run-out of the carriage G, Fig. 2193. By this means the copping rail M is gradually increased by the outer wedge N being made with a rather smaller angle at the top than the inner wedge O, for the purpose of forming the cop with a more gradual taper at the top than at the bottom, as shown in Fig. 2197. This increase of inclination continues until the cop has attained its full diameter CC and has assumed the shape A C D; after which the inclination slightly decreases again until the cop is completed to the finished shape A O E F, by the latter part of the outer wedge N being made slightly steeper than the corresponding portion of the inner wedge O, as shown in Fig. 2193. The inner end of the copping rail being the lowest, the winding of each stretch leaves off at the top; and at the commencement of winding each stretch the faller wire puts down the thread to the point at which the winding of the new layer is to be started, about three coils being wound on during the descent of the faller, as indicated by the spiral dotted line from F to E in Fig. 2198, and the remainder during the rise of the faller. When the spindles arrive at the rollers P, as shown in Fig. 2196, having wound up the 63-in. stretch of threads, the stop U pushes back the locking bar H, thereby releasing the faller A, which immediately rises clear of the threads W.

The counter-faller wire is carried by the arm V from a second shaft behind the top-faller shaft I, and during the winding it bears up constantly against the underside of the threads W, as shown in Figs. 2194 and 2195, with a slight pressure from a counter-balance weight or spring acting on the shaft, so as to ensure keeping the threads in proper tension; during the spinning the counter-faller is held up just beneath the threads, but without touching them, as shown in Fig. 2193. The arm V of the counter-faller is curved as shown in the drawing, so as to reach

over the shaft I of the top faller, and also to avoid passing down between the cops; and the curved arm B on the back of the top-faller shaft I is shaped so as to clear the shaft of the counter-faller. The height of the counter-faller wire is employed as a means of regulating the speed of the spindles in

2197.

2199.

winding, in the manner afterwards explained, so as to avoid the occurrence of any slack in the threads.

Roberts' Backing-Off Motion as employed in the present mules is shown in Fig. 2199, which is a plan of the main driving shaft or rim shaft A of the machine, carrying the large rim-wheel Z or double-grooved pulley driving the whole of the mule-spindles by the endless cords X X, Fig. 2193, passing round the pulleys Y Y. On the boss of the loose pulley B is a pinion C, which, through a train of intermediate wheels D D, drives in the reverse direction and at the required slower speed the spur wheel and friction cone E, also running loose upon the shaft A and sliding longitudinally upon it. This friction cone engages in a corresponding hollow cone inside the fast pulley F; and when the driving strap is shifted from the fast pulley F to the loose pulley B for the purpose of backing off, the friction cone is also brought up against the fast pulley, thereby first arresting by friction the forward motion of the driving shaft A, and then giving it the reverse motion for backing off.

Roberts' Winding Quadrant, for regulating the winding of the threads by diminishing the speed of the spindles in proportion as the diameter of the cops increases, is shown in Fig. 2200. This very ingenious contrivance has never been superseded, and is employed in almost every self-acting mule at the present day. The quadrant A turns upon a fixed centre C in the frame of the mule, and a pinion B gears into it, which is driven by a band and pulley receiving motion from the traverse of the carriage G, the arrows indicating the direction of motion during the run-in of the carriage. The grooved arm D of the quadrant contains a double-threaded screw, by which the sliding nut E is traversed outwards from the centre of motion C towards the extremity of the arm D. When the carriage is at the outer end of its stretch, the arm D stands inclined 12° outwards from the vertical, as shown by the dotted lines; and during the run-in of the carriage it turns inwards through an arc of 90° . A chain F, attached to the nut E, is coiled round a drum H inside the carriage G, and as the carriage recedes from the quadrant arm during the run-in the chain thus causes the drum to rotate, and thereby drives the spindles T through the intervention of the tin roller I geared to the drum H. At the commencement of a set of cops, the nut E is at the bottom of the quadrant arm D, nearest to the centre of motion C, as shown dotted; and the number of revolutions then given to the drum H by the uncoiling of the chain during the run-in of the carriage is nearly as many as if the end of the chain at the nut were held stationary, and is sufficient to wind up on the bare spindles the length of threads spun in one stretch.

As the cops increase in diameter from their original size AB to their full diameter CC, Fig. 2197, the nut E is gradually advanced outwards along the quadrant arm D, Fig. 2200, so as to increase its arc of motion and thereby diminish the number of revolutions of the drum H and the speed of the spindles T. This advance of the nut is obtained from the counter-faller V bearing against the under-side of the threads W during the winding. The depression of the counter-faller towards the lower part of the cop J brings down the end of a governing lever upon a horizontal strap, which passes round a pulley on the headstock of the mule and round another on the centre shaft C of the quadrant; and on this shaft is a bevel pinion gearing into a second bevel pinion on the end of the double-threaded traversing screw in the arm D; so that when the governing lever is depressed upon the strap by the counter-faller, the forward motion of the lever as the carriage runs in drags the strap along with it by friction and turns the shaft C forwards, sliding the nut E outwards towards the circumference of the quadrant. At the moment when the backing-off motion has ceased and the carriage begins to run in for winding up the stretch of thread spun, as shown in Fig. 2195, the counter-faller wire V is at its highest working position, compensating for the

additional length of thread that has been uncoiled from the top of the spindle in backing off after the spinning of the stretch was completed. The nut E, however, Fig. 2200, is still at the same distance from the centre C of the quadrant as it was at the conclusion of winding the previous stretch; and, therefore, as the diameter of the cop is now greater by winding the new layer of thread outside the previous one, the winding of the new stretch commences rather too fast, and begins at once to take up the length of thread given out in the backing off. The counter-faller V is thus depressed, and by means of the governing lever slides the nut E farther out from the centre C, until the speed of winding is sufficiently diminished to allow the counter-faller to rise again high enough for lifting the governing lever off the strap. It will be seen that, in consequence of the arm D describing the quadrant of a circle, the horizontal motion of the nut E in the winding of each stretch is greatest at the commencement of the winding, and gradually diminishes as the carriage runs in; and the effect of this is that the speed of winding is gradually increased towards the end of each stretch. By this means the threads are wound uniformly upon the cops, with an equal degree of tightness throughout.

The whole mule is driven by a strap $3\frac{3}{4}$ in. broad, running over the fast pulley F, Fig. 2199, on the rim shaft A, and travelling at about 1670 ft. a minute, or about 19 miles an hour. The driving power required is about 1 indicated horse-power the 230 spindles, or $4\frac{1}{4}$ horse-power for each mule containing 1000 spindles. The speed of the endless cord X passing round the rim wheel Z, Fig. 2193, is 2640 ft. a minute, or about 33 miles an hour. The carriage of the mule makes 3 to $3\frac{1}{2}$ double journeys out and home a minute, the length of stretch being 63 in.; but the velocity varies at different parts of the traverse, the carriage being taken in by a pair of scrolls in the centre of the machine, and drawn out by three spiral grooved pulleys keyed upon a shaft running the entire length of the mule, one pulley being in the middle of the shaft and one at each end. The length of the carriage being upwards of 100 feet, a parallel motion is required for keeping the carriage straight; and this is obtained by a horizontal traversing pulley at each end of the carriage, traversing along fixed cords and thereby made to revolve; and these two pulleys being also coupled together by a crossed cord, are compelled to revolve at the same rate, and consequently cause each end of the carriage to travel at the same rate. There are three pairs of drawing rollers P, Fig. 2193, by which the rovings are drawn about eight times before being delivered for spinning. The last pair of rollers delivers the rovings at a speed of 26 ft. a minute, until the carriage G has run out the 63-in. length of stretch, when the rollers are stopped, and hold the threads fast during the winding up as the carriage runs in again. The actual length of roving delivered by the last pair of rollers for each stretch of 63 in. is about 61 in.

The spindles make about 1260 revolutions in twisting each stretch of 63 in., thus putting about 20 twists an in. into the threads; and the total time occupied is about $12\frac{1}{2}$ seconds. In winding up the threads, as the total length to be wound up remains constant, namely 63 in., the number of revolutions is diminished in each successive stretch according to the increasing size of the cop, from about 70 revolutions at the commencement to 23 revolutions at the full diameter of the cop, with cops of an average size winding an average number of yarn, such as No. 32, which is such a quality that 32 hanks of 840 yards each weigh together 1 lb.; the time of winding each stretch is about $3\frac{1}{2}$ seconds. The velocity of the spindles is about 390 revolutions a minute in winding, and in twisting the speed ranges from 8000 down to 3000 for coarse work, a common average being about 6500 to 7000 revolutions a minute. In backing off, the velocity of revolution is about $\frac{1}{10}$ of that in twisting. The direction of rotation of the spindles is the same in twisting and in winding, and the thread is wound on in a right-handed spiral when spinning twist, and left-handed when spinning weft. Fig. 2198 shows full size the conical form of the top of the spindles for the purpose of letting the thread slip off freely at each revolution in twisting; and the two lines G and H show the extreme inclinations of the thread to the spindles during the twisting. The larger angle shown by the dotted line G, when the spindles are nearest to the drawing rollers, is about 145° ; and the smaller angle shown by the full line H is about 105° , when the spindles are at the outer extremity of the stretch. The spindles themselves are inclined inwards towards the drawing rollers at an angle of about 12° from the vertical, as shown in the drawing.

Cotton Gin.—For the purpose of ginning cotton, or separating the cotton fibres from the seed, the roller gins, as they are called, are of the most primitive construction, simply and ingeniously made, and are of Indian origin. Fig. 2201 shows a section of a roller gin of modern construction. It is formed of two small rollers about $\frac{3}{4}$ in. diameter and from 6 to 9 in. long, made to revolve in opposite directions, as shown by the arrows, by means of toothed wheels. The bottom roller turns on fixed bearings, and the upper roller is kept in close contact with it by means of a lever and screw. The cotton seeds are fed forwards between the rollers from the table in front, a space being left between the edge of the table and the bottom roller, to allow the seeds to drop down as they become cleaned of the cotton fibres by the revolving action of the rollers. A brush is fixed underneath the bottom roller to brush off any cotton fibres adhering to its surface. It is necessary that gins acting in this way should have rollers of small diameter, say from $\frac{3}{4}$ to $\frac{3}{8}$ in., because the smaller the rollers the more obtuse is the angle they present to the seed which is being cleaned, and the seeds are thereby better prevented from being drawn in between the rollers and crushed and mixed up with the cotton fibre. It is evident from Fig. 2202 that large rollers present an acuter angle to the seed, and with such rollers the seed would unavoidably be drawn in and crushed

and mixed with the fibre. The object to be attained in ginning cotton is to get it free from all impurities; and it is found that the smaller the rollers and the slower their motion, the cleaner is the cotton fibre separated from the seeds; for if the rollers are above an inch in diameter, and if they revolve very rapidly, they draw in soft, small, and false seeds, crushing them in their passage, and straining and otherwise injuring the cotton fibre.

The most improved gin of the roller class is given Fig. 2203, and is constructed with one large roller covered with leather and having small spiral grooves formed round it both right and left. A guard-plate A is fixed near the surface of the roller, having a grating along its bottom edge just wide enough for the seeds to pass through to the roller; and between it and the roller a thin steel striker blade B vibrates a short distance up and down with a rapid motion. By this means the seeds are shaken and turned round in contact with the surface of the roller revolving in the direction of the arrow, and the cotton fibres are drawn between the blade B and the roller, while the stripped seeds are rejected and drop down through the space between the blade B and the edge of the feed-table, having been thus cleaned of their fibres in a most thorough manner.

In 1793 Whitney invented a machine, Fig. 2204, known by the name of Whitney's saw gin. It consists of a wooden cylinder with a series of circular saws C, about 8 in. diameter, fixed upon it at regular distances. The edges of the saws project a short distance through a grid, the divisions of which are too narrow to permit the seeds to pass through. Care is taken that the saws revolve in the middle of the grid spaces, for if they rubbed against the bars they would tear the cotton filaments to pieces. A cylinder with brushes D, the tips of which touch the saw teeth, sweeps off the adhering cotton wool from the teeth of the saws by revolving in the opposite direction to the saw roller. The cotton seed as picked from the pods is thrown into the hopper E, and the saws in turning round snatch the filaments from the seed which remains against the grid, and drag them inwards and upwards. The stripped seeds, being too large to pass through the grid, accumulate at the bottom of the hopper E, and are let out at intervals.

The Carding Engine of Curtis, Parr, and Madeley, of Manchester, Fig. 2205, is constructed on the roller-and-clearer principle. Its dimensions are as follows, namely;—

- | | |
|---|--|
| 1 large or main cylinder, | 50 in. diameter, and 40 in. on the wire; |
| 1 doffer | 22 in. " " |
| 7 rollers | 4½ in. " " |
| 7 clearers | 3½ in. " " |
| 1 dirt-roller | 6¾ in. " " |
| 1 licker-in | 8 in. " " |
| 1 second licker-in | 8 in. " " |
| 5 knives placed horizontally across the main cylinder between the clearer and roller; | |
| 6 boxes or receivers, placed across the main cylinder, behind the clearer; | |
| 1 revolving shaft, placed inside the boxes or receivers, working horizontally. | |

It is obvious that the main operations of carding, on the roller-and-clearer carding engine, take place between the roller and main cylinder. The novelty of this carding engine consists in the application of a knife between each pair of rollers and clearers, combined with a box, behind the clearer, to receive all the short-fibre cotton, fly, and shell-dirt liberated through the action of the knife and thrown into the box by the centrifugal force of the clearer. The action of the knife is almost equal to that of a combing machine; for the cotton, being held on the roller, cannot pass in fleeces to the clearer, as is the case when no knife is used, but is drawn by the roller under the edge of the knife, and by this means the fibre is more evenly laid and combed. All extraneous matter is thus liberated and immediately thrown into the box or receiver, and there retained by means of the small revolving shaft. By this principle a better quality of carding can be produced than by the ordinary common roller-and-clearer principle, without the knife and box.

2206.

The Roller A is worked in various ways. Sometimes it is set to work into the cylinder as an ordinary roller; at other times it runs one-fourth quicker on the surface than the surface of the cylinder, A is then called a fancy; at other times it works into the licker-in and cylinder, in this case A runs a little quicker than the licker-in.

A *crowbar* is a bar of iron sharpened at one end, and used as a lever for raising heavy bodies.

Hydraulic Crow, Figs. 2206, 2207.—In this tool hydraulic power is employed, it being a hydraulic

crow, for straightening or setting rails, designed by J. M. Budge. The construction of this tool consists of a small hydraulic press cylinder, 2½-in. bore, having hinged to it a pair of arms by which the rail which is to be straightened or set is held. On the top of the press cylinder is screwed a casting, which forms an oil tank, and which contains a small brass pump of the kind used in Tangye's hydraulic lifting jacks; this pump, which has a ½-in. ram, being worked by means of a rocking shaft, which projects through the casting and is furnished with a lever handle outside.

The whole arrangement is very compact and convenient, and it dispenses with the necessity of using the long awkward levers required with the ordinary screw crows.

CRUCIBLES. FR., *Creusets*; GER., *Schmelztiegel*; ITAL., *Crogiuoli*; SPAN., *Crisoles*.

Vessels used for the fusion of metals, and generally for all other chemical purposes in which intense heat is employed.

The use of the crucible appears to have originated with the old alchemists, who were in the habit of marking them with the sign of the cross before commencing their operations; whence the derivation of the name. The principal requisites of a good crucible are, that it should be capable of enduring the strongest heat without becoming soft or losing much of its substance; that it should not crack on being exposed to sudden alternations of temperature; that it should withstand the corrosive effect of the substance fused in it; and lastly, that it should be sufficiently strong to support the weight of the molten metal when lifted from the furnace. In the present day the consumption of crucibles is very large; they are extensively employed by the brass-founder, the gold and silver refiner, the manufacturers of cast steel and gun-metal, as well as in the melting of zinc and copper, in the various operations of the analytical chemist, assayer, and in the production of the coinage of different countries. The crucibles in most common use in Birmingham and its neighbourhood, as well as in Sheffield, are made of a fire-clay found near Stourbridge, which is generally mixed with some other substance, such as powdered coke, in order to lessen its tendency to contract when strongly heated. These Stourbridge clay crucibles, or casting pots, are not burnt until required for use, when they are put into the furnace first with the mouth downward, and when red hot are taken out, and put in again with the mouth upward.

The material from which the most refractory crucibles are now made is plumbago, or, as it is used to be called, black-lead. This is one of the various forms assumed by carbon, and in its pure state is nearly identical in composition with the diamond, although so very different in its structure and physical character. Until a few years ago the use of black-lead, Plumbago, pots was exclusively confined to the melters of precious metals, but they are now employed for melting all descriptions of metal; and large numbers of Morgan's far-famed crucibles, which are composed of plumbago, are used by the brass-founders and others in Birmingham. Immense quantities of these crucibles are annually manufactured by the Plumbago Crucible Company, whose works cover a large space of ground at Battersea, near London; and the manufacture as at present carried on at the Battersea works, presents a striking illustration of the rise and progress of a branch of industry comparatively unknown a quarter of a century ago.

In making the crucibles, the materials are first ground to powder and sifted, after which they are mixed with certain proportions of various constituents, so as to give a sufficient degree of coherence and plasticity. Formerly, crucibles were made by hand, common wooden moulds being employed, but those of Morgan are made by machinery, thus securing an exactness of form and uniformity of weight which could never be attained under the old processes. Morgan's Plumbago Crucibles, shown in the Exhibition of 1862, had been used for respectively 80, 90, and 100 pourings—a vast improvement on the ordinary clay pot, which is considered to have done a fair average of work if it lasts throughout the day.

The advantage, indeed, of using plumbago crucibles wherever durability is required is now so apparent, that although comparatively expensive at first, they are ultimately found to be the cheapest that can be used. They effect a great saving of time, labour, and fuel (as much as 1½ ton of the latter being saved to every ton of steel fused), and are consequently gradually superseding all others in steel foundries.

Crucibles are made of various forms and sizes, according to the kind of work for which they are intended; those used for assaying are scarcely larger than a lady's thimble, whilst others made for zining shot will hold as much as 800 lbs. of molten zinc. Some are nearly cylindrical, others triangular, and others skittle-shaped. They are generally numbered according to their capacity; thus, No. 30 will contain 30 kilogrammes, or something more than 60 English pounds, and so on, the adoption of French weights being found useful to Continental consumers.

Cornish crucibles are principally used for assaying copper; they are made of a clay found in some parts of Cornwall, and the smaller sizes are capable of resisting sudden alternations of temperature (a quality which is probably due to the large proportion of silica mixed with the clay), but they are rapidly corroded by melted oxide of lead.

Hessian crucibles were formerly employed to a much greater extent in metallurgical operations than they are at present. They are made principally from a clay found at Gross-Almerode, and in their composition resemble very closely the Cornish crucibles. The form is triangular, and they are generally packed in nests of six; the smaller sizes fitting into the larger. These crucibles are tolerably lasting at moderate temperatures, but are apt to fuse when exposed to very great heat.

Several kinds of *French crucibles* are manufactured, some of which are of very excellent quality, especially those of Beaufay, called the *creusets de Paris*, and those of Deyeux, termed *creusets de Saveignies*. Both kinds, however, contain a large percentage of oxide of iron, which renders them objectionable for some purposes.

London crucibles are of a reddish-brown tint, very close grained, and capable of resisting the corrosive action of oxide of lead, but liable to crack when suddenly heated. Of late years white fluxing pots, manufactured by the Plumbago Crucible Company, Battersen, have been very much employed on account of their smooth surface, and their power of resisting the action of fluxes. They are made in various sizes, from 2½ in. up to 8½ in. in height.

The large crucibles used in the manufacture of glass, glass-house pots, are made of the best Stourbridge clay, mixed with about ¼ its weight of cement of old pots ground to fine powder.

For special metallurgical or chemical purposes, crucibles are sometimes made of platinum, lime, bone dust, magnesia, pure carbon, and other materials.

Pressure of Water.—Let $L F B D$, Fig. 2208, be a vessel of any form whatever, filled with water, ab any portion of the surface $F K C B$ in contact with the water, G the centre of gravity of ab , $G R$ the perpendicular depth of G below the surface of the water; then if $R G = 10$ ft., and the area of the surface $ab = 3$ sq. ft., the lbs. pressure on this surface will be $= 3 \times 10 \times 62.5 = 1875$ lbs. 1875 lbs. is the weight of a column of water whose base is the area ab , and perpendicular height the depth of the centre of gravity of ab .

If the area of ce on the bottom of the vessel $= 5$ sq. ft., and $Q G_1 = 14$ ft. the perpendicular depth of the centre of gravity G_1 below the surface of the water; then the lbs. pressure on the area $ce = 5 \times 14 \times 62.5 = 4375$ lbs.

Again, if the area of the surface hf , on the slanting face $A L = 4$ sq. ft., $P G_2 = 11$ ft., G_2 being the centre of gravity of the area hf ; then the pressure on this slanting surface will be $4 \times 11 \times 62.5 = 2750$ lbs.

As in former cases, the weight of a cubic of water is taken $= 62\frac{1}{2}$ lbs. It may be further observed that the positions or inclinations of the surfaces ab , ce , hf , are not taken into account, but merely their areas and the perpendicular distances of the centres of gravity from the horizontal surface of the fluid. On this simple principle rests that department of mechanics termed *hydrostatics*; it is easily demonstrated, as gravity acts on all the particles of the fluid, and each particle presses on that next below it, and, further, because, from the peculiar property of the fluid, this pressure is transmitted in all directions equally.

Ques. Find the lbs. pressure on a floodgate whose breadth is 9 ft. and depth 7 ft.

$7 \times 9 = 63$ sq. ft. area, depth of centre of gravity $= \frac{7}{2} = 3.4$ ft. $\therefore 63 \times \frac{7}{2} \times 62\frac{1}{2} = 13781.25$ lbs.

Ques. What is the pressure upon 10 ft. length of an embankment, the depth of the water pressing against it being 11 ft.

$$10 \times 11 \times \frac{11}{2} \times 62.5 = 37812.5 \text{ lbs.}$$

Ques. Required the relation of the pressure upon the four sides of a cubical vessel filled with water, and the pressure on the bottom which is horizontal.

Put n = the length of the side of the cube in feet, $n^3 \times 62.5$ = pressure on the base; $n \times n \times \frac{n}{2} \times 62.5$ = pressure on one of the sides, $\therefore 2n^3 \times 62.5$ = pressure on the four sides.

Then $n^3 \times 62.5 : 2n^3 \times 62.5 :: 1 : 2$; that is, the pressure on the sides is = to twice the pressure on the base. In these calculations the fluid is supposed to be at rest, and acted on only by gravity.

Let $ABCD$ be a vessel filled with water, the pressure Q on any point n , in the side AD , Fig. 2209, is due to the perpendicular depth $A n$. If in the base DC produced we take $D F = D A$, the perpendicular depth of the water, then the pressure upon the point D will be due to the pressure of a column of the fluid, whose height is $= D F$. Draw $F A$, and from any point n draw $m n$ perpendicular to $A D$; hence $m n = A n$, and the pressure Q on the point n will be due to a column whose height is $m n$; the same reasoning applies to any other point in the side of the vessel.

Let us take an example and compare this method of viewing the subject with the one previously enunciated and illustrated.

Ques. What is the pressure on an embankment whose length is 21 ft. and depth of the water $A D = 12$ ft.

The whole pressure upon the side of the embankment is equivalent to the pressure or weight of a mass of fluid of the form of a wedge, $A F D$, Fig. 2209.

Area of the triangle $A D F = 12 \times \frac{12}{2} = 72$ sq. ft., $\therefore 72 \times 21 = 1512$ cub. ft. content of the wedge. $\therefore 1512 \times 62.5 = 94500$ lbs. pressure.

Before it was stated that the pressure in lbs. on the side is equal to a column of water whose base is the area of the surface, and perpendicular height the depth of the centre of gravity.

It is evident, since the side of the embankment is a parallelogram, the depth of its centre of

gravity = $\frac{12}{2} = 6$ ft., area of the surface = $12 \times 21 = 252$ sq. ft. $\therefore 252 \times 6 \times 62.5 = 94500$ lbs., the pressure before found.

It may be easily perceived that there is a certain point in the side A D of an embankment or vessel filled with water, where a single pressure will counterbalance the pressure of the water against the whole side. This point is called the *centre of pressure*.

The *centre of pressure* must evidently lie in the line P G passing through the centre of gravity, G, of the *wedge of pressures*, of which the plane A F D is a cross-section.

Bisect F D in E, and D A in H, draw A E and F H; these lines cut one another in the centre of gravity G. D P = $\frac{1}{3}$ D A, that is, the centre of pressure, P, in this case lies at $\frac{1}{3}$ of D A, from the bottom.

Ques. Required the pressure on the staves of a cylindrical vessel filled with water, the diameter of the base being 10 ft. and the perpendicular height 8 ft.

$3.1416 \times 10 = 31.416$ ft. the circumference of the cylinder,

$$\therefore 31.416 \times \frac{8}{2} \times 8 \times 62.5 = 62832 \text{ lbs. pressure.}$$

If the staves of this barrel are to be kept together by a single hoop, that hoop should be $\frac{10}{3} = 3\frac{1}{3}$ ft. from the bottom.

Ques. An embankment H D, Fig. 2210, resists a pressure of water whose *centre of pressure* is at P; it is required to determine by construction the conditions of equilibrium, supposing when the pressure is sufficient to overturn the embankment it will turn upon A, as a centre.

Let F O C be the vertical line drawn through G, the centre of gravity of the embankment. Draw P L perpendicular to F C, intersecting F C in O. Make O n = the lbs. pressure in the embankment, and O m = the pressure of the water, complete the parallelogram O m p n, then if the diagonal O p or O p produced falls as at B inside the base, the embankment will stand, but if the diagonal cuts outside of A, embankment will fall by turning over upon O.

Otherwise, since the pressure of the water P, in pounds multiplied by the length of A L in feet, gives the moment of the water tending to turn the embankment, H D, on A as a centre; and the product of the weight of the embankment, H D, in pounds by the length of A C in feet, gives the momentum of the embankment that acts against the pressure of the water; consequently, when these moments are equal the embankment, A H E D, is upon the point of turning over the point A; if the moment of the water be the greater of the two, the structure will fall, but if it be the lesser of the two, it will stand.

Ques. Suppose 10 ft. to be the length of an embankment whose height, D E, from the surface of the water at E, is 28 ft., A D = 6 ft., will the embankment stand or fall when a cubic foot of the material of which it is composed = 160 lbs.

Surface upon which the water presses = $28 \times 10 = 280$ sq. ft. Pressure of the water = $280 \times \frac{28}{2} \times 62.5 = 245000$ lbs. $\frac{28}{3} = D P = A L$ = the distance of the centre of pressure P,

from the bottom A D. $\therefore 245000 \times \frac{28}{3} = 2286666\frac{2}{3}$ the moment of the water. Weight of the embankment = $28 \times 10 \times 6 \times 160 = 268800$ lbs. Moment of the embankment

$$= 268800 \times \frac{6}{2} = 806400.$$

This structure must fall, since the moment of the water is greater than the moment of the embankment.

Ques. What must be the height of the water in the last question, so that the embankment may be upon the point of overturning.

Putting x for the required height, then the moment of the water will be

$$x \times 10 \times \frac{x}{2} \times 62.5 \times \frac{x}{3} = \frac{x^3}{6} \times 625. \therefore \frac{x^3}{6} \times 625 = 806400. \therefore x = 20.59967 \text{ ft., height required.}$$

Ques. Required the thickness of a rectangular embankment that supports a pressure of water rising its full height of 16 ft. when the structure is upon the point of turning over; the weight of a cubic foot of the material, of which the embankment is composed, 128 lbs.

We may take the length of the embankment = 1 ft., for if it stands for 1 ft. of length, it will stand for any other length. $1 \times 16 \times \frac{16}{2} \times 62.5 = 8000$ lbs., the pressure of the water.

$$\therefore 8000 \times \frac{16}{3} = \text{the moment of the water.}$$

If x be put for the thickness of the embankment, its moment will be

$$16 \times x \times 1 \times 128 \times \frac{x}{2} = x^2 \times 8 \times 128.$$

Putting $8 \times 128 \times x^2 = 8000 \times \frac{16}{3}$, gives $x^2 = \frac{125}{3}$; $\therefore x = 6.45497$ ft.

Ques. Let the cross-section of the embankment, $ABCD$, Fig. 2211, have the form of a trapezoid, where $AE = 6$ ft., $EB = 5$ ft., $BC = 15$ ft., and the weight of a cubic foot of the material = 120 lbs.; as in former cases, the cubic foot of water is supposed to weigh $62\frac{1}{2}$ lbs.

Let us consider the circumstances with respect to 8 ft. length of embankment, and suppose the cross-section, $ABCD$, to be divided into two parts, namely, the rectangular part, $BCDE$, and the triangular part, AED . It has been before shown that a vertical line, g L , passing through the centre of gravity, g , of the triangular part, cuts the base, AL , supposed to be horizontal; so that $AL = \frac{2}{3}$ of $AE = 4$ ft. The vertical line, GF , passing through the centre of gravity, G , of the parallelogram, $EDCB$, cuts the base at F ; so that $AF = AE + \frac{1}{2} EB = 8.5$ ft.

It is supposed that the pressure, P , of the water tends to turn the embankment over a horizontal line passing through A , perpendicular to the plane of the paper. $\frac{6 \times 1}{2} \times 8 \times 120 = 43200$ lbs. weight of the part of which ADE is a cross-section; the moment of this part will be = $43200 \times 4 = 172800$.

Weight of $BCDE = 15 \times 5 \times 8 \times 120 = 72000$ lbs. Moment of this part = $72000 \times 8.5 = 612000$. $\therefore 612000 + 172800 = 784800$, the moment of 8 ft. length of embankment.

Since the moment of the water will be $15 \times 8 \times \frac{15}{2} \times 62.5 \times \frac{15}{3} = 281250$, it follows that the embankment will stand.

Ques. The breadth of a floodgate is 12 ft.; the depth $AB = 8$ ft.; the centre of the hinge, Q , is 18 in. from the bottom A , and the hinge, R , is 18 in. from the surface, B ; the pressure on Q , Fig. 2212, is required.

Since one-half the pressure of the water on the gate only acts on the hinges Q and R , that Pressure in lbs. will be = $8 \times 6 \times \frac{8}{2} \times 62.5 = 12000$ lbs.

Let P be the centre of pressure of the water, then $AP = \frac{8}{3}$; $QR = 8 - 3 = 5$ ft.;

$$PR = PB - BR = \frac{8}{3} \times 2 - 1\frac{1}{2} = 3\frac{5}{6} \text{ ft.}$$

Because the pressure of the water at P is supported by the hinges at Q and R , then, on the principle of the lever, supposing R to be the fulcrum, $\therefore$ putting x for the pressure on Q , $x \times QR = P \times PR$, that is $x \times 5 = 12000 \times 3\frac{5}{6}$; $\therefore x = 9200$ lbs.

Ques. If one side of an equilateral triangle, immersed in a fluid, be perpendicular to the surface of the fluid, find the relation of the pressures on the three sides.

Let the side, AB , be perpendicular to the surface of the fluid LN , Fig. 2213. From F and G , the points of bisection, and therefore the centres of gravity of AC , CB , draw EF , DC , HG , perpendicular to AB .

It is evident that the perpendicular depths, $MF = AE$, AD , $MG = AH$, of the centres of gravity of the sides, AC , AB , BC , are as $1 : 2 : 3$. Hence the pressure on the side BC is equal to the sum of the pressures on AB , AC .

Geometrical Proposition.—If from any of the angles of a triangle, ABC , Fig. 2214, a line, Am , be drawn to m , the middle of opposite side, CB , the point G is the centre of gravity of the triangle if $mG = \frac{1}{3}$ of mA .

Draw Bn , bisecting AC , join m, n , then it is evident that all lines, as pq , parallel to CB are bisected by Am ; hence the centre of gravity of the triangle must lie in Am . In the same manner it may be shown that Bn bisects all lines, as rs , parallel to CA ; therefore the centre of gravity is also in Bn ; consequently the point G , where Am and Bn intersect, is the centre of gravity of the triangle ABC .

But $mn = \frac{1}{2} AB$, and is also parallel to AB : and because the triangles $m n G$ and $G A B$ are similar, $mG = \frac{1}{3} GA$, whence $mG = \frac{1}{3} mA$.

As the knowledge of the position of the centre of gravity of a body is of much importance in

almost every department of mechanics, and to save the trouble of distinct investigations in cases that often occur, we have thought it proper, in this place, to add the succeeding results.

The centre of gravity, G, of a trapezium, A B C D, Fig. 2215.—Let L be the centre of gravity of the triangle A D C, H of A B C, E of A B D, F of B D C; join H L and E F; these lines cut in G, the centre of gravity of A B C D.

To find the centre of gravity, G, of a quadrilateral, A B C D, when two sides, A D, B C, are parallel, Fig. 2216. $a = A L = L D$, and $B K = K C = b$; $K L = 3c$. $KG = c \frac{b+2a}{b+a}$.

To find the centre of gravity, G, of any triangular pyramid, A B C D, Fig. 2217.—Put $AB = a$, $AC = b$, $AD = c$, and $BC = d$, $BD = e$, $CD = f$; then $AG = \frac{1}{3} \sqrt{3(a^2 + b^2 + c^2) - (d^2 + e^2 + f^2)}$.
Or, bisect BC in F , draw FD , FA ; make $EF = \frac{1}{3}$ of FD , and $HF = \frac{1}{3}$ of AF , and draw HD , AE . The triangles HGE , GAD are similar. $\therefore HG = \frac{1}{3} GD = \frac{1}{3} HD$; $EG = \frac{1}{3} GA = \frac{1}{3} EA$.

Case 2.—When $BC = CD = DB$. Then $AG^2 = \frac{3}{16}(a^2 + b^2 + c^2 - d^2)$.

Case 3.—When $BC = CD = DB$, and also $AB = AC = AD$. Then $AG^2 = \frac{3}{16}(3a^2 - d^2)$.

Case 4.—If all the edges are equal, $ABCD$ becomes a regular tetrahedron. Then $AG = \frac{1}{4} a \sqrt{6}$.

To find the centre of gravity of a pyramid whose base is any polygon.—The centre of gravity will be on the line drawn from the vertex to the centre of gravity of the base, and at the distance of $\frac{3}{4}$ of its length from the vertex.

The centres of gravity of the surface of a cylinder, of a cone, and of a conic frustum, are respectively the centres of gravity of the parallelogram, triangle, and trapezoid, which are vertical sections of the respective solids.

The centre of the surface of a spherical segment is at the middle of its versed sine, or height.

In the cone, as well as in the pyramid, the distance of the centre of gravity from the vertex is $\frac{3}{4}$ of the axis.

In a conical frustum, the distance of the centre of gravity, measured on the axis from the centre of the less end = $\frac{h}{4} \frac{3R^2 + 2Rr + r^2}{R^2 + Rr + r^2}$, h = the height; R, r , the radii of the greater and lesser ends.

The last theorem will apply for the frustum of any regular pyramid, taking R and r for the sides of the two ends.

In a paraboloid, the distance of the centre of gravity from the vertex = $\frac{3}{8}$ of the axis.

In the frustum of a paraboloid, the distance of the centre of gravity from the centre of the lesser end, along the axis = $\frac{h}{3} \frac{2R^2 + r^2}{R^2 + r^2}$; h denotes the height, R and r the radii of the greater and lesser ends.

To find the centre of gravity, G, of a circular arc, M A m, Fig. 2218.—From the middle point of the arc A , draw AO to O , the centre of the circle; put $x = AP$, $y = MP = Pm$, radius $AO = r$; z = the length of the half-arc, or $MA = z = Am$. Then $OG = \frac{ry}{z}$.

When the arc is a semicircle, then $y = 1$; and $z = \frac{1}{2} \pi = 1.57079$, or $\frac{y}{z} = \frac{1}{1.57079} = .63662$; and then $OG = .63662 r$.

To find the centre of gravity, G, of a circular segment, M A m, Fig. 2219.— $OG = \frac{MP^3}{3 \text{ area of } AMP}$.

When the circular segment becomes a semicircle.

$$OG = \frac{r^3}{(3 \text{ quadrants}) \text{ radius } r} = \frac{r^3}{2 \cdot 356194 r^2} = \frac{r}{2 \cdot 356194} = .42441 r.$$

In a circular sector, O B A C, Fig. 2220, the distance from the centre of the circle to the centre of gravity, or O G, $= \frac{2cr}{3a}$; in which $r = OA$; $c = BC$; $a =$ the length of the arc B A C.

To find the centre of gravity of a common parabola, Fig. 2221. $AG = \frac{3}{8} AC$.

To find the centre of gravity, g , of the semi-parabola, C A D, Fig. 2221, take $Gg = \frac{3}{8} CD$.

To find the centre of gravity, G , of the sector of a sphere, O D A B, Fig. 2222.—Let $AC = x$, $OD = r$, then $AG = \frac{1}{8} (2r + 3x)$. When $x = r$, the sector becomes a hemisphere, then $AG = \frac{3}{8} r$.

To find the centre of gravity, G , of the segment of a spheroid.—Let A be the vertex of the fixed axis a , putting c for the length of the revolving axis, then $AG = \frac{4a - 3x}{6a - 4x} x$.

When the segment becomes a hemispheroid, then $x = \frac{a}{2}$ and $\frac{4a - 3x}{6a - 4x} x = \frac{5}{8} x$, for the distance of the centre of gravity from the vertex, $\therefore \frac{3}{8} x$ is its distance from the centre of the base.

If $c = a$, the spheroid becomes a sphere, and, as the theorem is independent of c , it is alike applicable to both solids and their corresponding segments.

To find the centre of gravity of a hyperboloid.—Putting $g =$ the distance of the centre of gravity G , from the vertex A , and taking $y^2 = \frac{c^2}{a^2} (ax + x^2)$; $g = \frac{4a + 3x}{6a + 4x} x$.

The position of the centre of gravity, G , of any irregular body, A B C, may be determined when balanced in the manner represented in Fig. 2223, and applying the proportion, $W : w :: a : z = RQ$.

$\therefore z = \frac{aw}{W}$. RS is put $= a$, and is horizontal. KL, QG, ST are perpendicular to SR .

Ques. Let the shores, a, c , Fig. 2224, support the wall, A C B, that sustains a pressure of water up to the top A; the stay delivers its thrust opposite the centre of pressure, P , of the water; the thrust on the stays is required, when the embankment is upon the point of turning over. Suppose $AB = 15$ ft.; $CD = 3$ ft.; the weight of a cubic foot of the material of which the wall is composed 120 lbs.; $ad = PB = 5$ ft.

We will estimate for 8 ft. length of wall, but any other length may be selected. Weight of wall $3 \times 15 \times 120 = 43200$ lbs. Moment of the wall $= 43200 \times \frac{3}{8} = 64800$.

Let bd be perpendicular to ac ; $\therefore bd = \sqrt{\frac{25}{2}} = \frac{5}{2} \sqrt{2} = 3.5355$.

Put x for the thrust on the stays, a, c , that prop 8 ft. length of wall; the moment of this thrust will be $x \times 3.5355$.

When the pressure on AC is equal to the pressure on CF, then

$$x^2 = b^2 - x^2 \therefore 2x^2 = b^2; \text{ or } x = \frac{b}{\sqrt{2}}. \quad \text{Or } 1 : \sqrt{2} :: x : b.$$

If the pressure on ABCD is to be to the pressure on DCEF, 5 to 7, then

$$x^2 : b^2 - x^2 :: 5 : 7 \therefore 7x^2 = 5b^2 - 5x^2 \therefore x = \sqrt{\frac{5}{12}} b.$$

Let ACDF, Fig. 2229, be a rectangular parallelogram immersed in water, the side AC coinciding with the surface, AB = a; AF = b. FBD is the inscribed parabola; find the ratio of the pressure on the parallelogram and the pressure on the parabola.

If G be the centre of gravity of ACDF, then BG = $\frac{b}{2}$ and the pressure

$$= ab \times \frac{b}{2} \times 62\frac{1}{2} = \frac{ab}{2} \times 62\frac{1}{2}.$$

The area of the parabola = $\frac{2}{3}$ of the parallelogram; Bg = $\frac{2}{3}b$, if g be the centre of gravity of the parabola; $\therefore \frac{2ab}{3} \times \frac{3b}{5} \times 62\frac{1}{2} = \frac{2ab^2}{5} \times 62\frac{1}{2}$ = the pressure on the parabola.

$$\therefore \frac{ab}{2} \times 62\frac{1}{2} : \frac{2ab^2}{5} \times 62\frac{1}{2} :: \frac{1}{2} : \frac{2}{3}$$

$\therefore 5 : 4$, is the ratio of the pressure on the parallelogram to the pressure on the parabola.

Show that if a hollow sphere be filled with a fluid, whose specific gravity is s, that the whole pressure against the internal surface is three times the weight of the contained fluid.

Let r = the radius; then $4\pi r^2 \times$ internal surface, π as usual = 3.14159265. $\therefore$ the pressure = $4\pi r^2 \times r \times s = 4\pi r^3 s$; the solid content of the sphere = $\frac{4}{3}\pi r^3$, and its weight = $\frac{4}{3}\pi r^3 s$. $4\pi r^3 s : \frac{4}{3}\pi r^3 s :: 1 : \frac{1}{3}$ or 3 : 1.

Let G be the centre of gravity of a trapezoid ABCO, Fig. 2230, AB = a, and parallel to OC = b; BC = c, and perpendicular to both AB and OC. The straight line OY is drawn perpendicular to OCX, it is required to find general expressions for the perpendicular co-ordinates x = mG = On, and Y = nG = Om.

Let p be the centre of gravity of the rectangle ABCD, $pQ = \frac{c}{2}$ and $QO = b - \frac{a}{2} = \frac{2p - a}{2}$.

If t be the centre of gravity of the triangle OAD, then the co-ordinates of t will be

$$tR = \frac{1}{3}AD = \frac{1}{3}BC = \frac{c}{3}. \quad OR = \frac{2}{3} \text{ of } OD = \frac{2(b-a)}{3}.$$

Area of ABCO $\times Gn$ = area of ABCD $\times pQ$ + area of AOD $\times tR$; that is,

$$c \frac{a+b}{2} y = ac \times \frac{c}{2} + \frac{(b-a)c}{2} \times \frac{c}{3} \therefore y = \frac{c}{3} \left(1 + \frac{a}{a+b} \right).$$

Again the area OABC $\times Gm$ = area of ABCD $\times OQ$ + area of AOD $\times RO$; that is,

$$c \frac{b+a}{2} x = ac \times \frac{2b-a}{2} + \frac{c(b-a)}{2} \times \frac{2(b-a)}{3} \therefore \frac{b+a}{2} x = a \frac{2b-a}{2} + \frac{(b-a)^2}{3} \\ \therefore x = \frac{2b}{3} - \frac{a^2}{3(a+b)}.$$

Ques. Given in ABCO, Fig. 2231, which represents the cross-section of an embankment made of brickwork, a cubic foot of which weighs 112 lbs.; AB = 1 ft., parallel to OC = 2 ft.; find the height, BC (which is perpendicular to both AB and OC), when the embankment is upon the point of overturning upon the edge at O by the pressure of the water which stands at the brim, E.

Put v = BC, the required height, then the pressure of the water on 1 ft. length of embankment

$$= v \times 1 \times \frac{v}{2} \times 62.5 = \frac{v^2}{2} \times 62.5. \quad \text{Moment of the water} = \frac{v^2}{2} \times 62.5 \times \frac{v}{3} = \frac{v^3}{6} \times 62.5.$$

If G be the centre of gravity of the trapezoid ABCO, then by the last proposition,

$$OD = \frac{2}{3} \times 2 - \frac{1}{3(1+2)} = \frac{11}{9}.$$

Pressure of a length of 1 foot of the embankment = $\frac{1+2}{2} v \times 112 = 168 v$ lbs.; moment of embankment = $168 v \times \frac{11}{9}$. $\therefore \frac{v^3}{6} \times 62.5 = 168 v \times \frac{11}{9}$; $\therefore v = \sqrt{19.712} = 4.439821$. Weight of embankment = $168 v = 745.89$ lbs.

Ques. Let the embankment A B C O, Fig. 2232, be the same as in the previous question; now if the embankment be raised until H L = 3 ft., what must be the perpendicular depth B L, so that when the part A B C O be upon the point of overturning at O, at the same time the whole embankment, A B L H, will be upon the point of turning over the edge through H.

$$E L = D C = 2 - \frac{11}{9} = \frac{7}{9} \quad \therefore H E = 3 - \frac{7}{9} = \frac{20}{9}$$

$\therefore$ the moment of O A B C round the point H, will be $745.89 \times \frac{20}{9}$. If g be the centre of gravity of O C L H, then

$$H F = \frac{2}{3} \times 3 - \frac{4}{3(2+3)} = \frac{26}{15};$$

putting z for B L, the moment of the part O C L H round H as a fulcrum will be $\frac{2+3}{2} (z-v) (112) \times \frac{26}{15}$.

The moment of the water acting in opposition will be $z \times 1 \times \frac{z}{2} \times 62.5 \times \frac{z}{3} = \frac{z^3}{6} \times 62.5$
 $\therefore \frac{z^3}{6} (62.5) = \frac{2+3}{2} (z-v) (112) \times \frac{26}{15} + 745.89 + \frac{20}{9}$.

$$\therefore z^3 - 46.592 z = -47.73689344;$$

[β]

$$\therefore z = 6 \downarrow 0.4, 0.5'1'9''9.5 = 6.24037812.$$

By dual arithmetic in any cubic equation the value of the unknown quantity, as in [β], may be found, in a few minutes under an endless variety of forms, but each corresponding form can be reduced to one or other of the roots; in the present case z may be found under the form

$$z = 6 \downarrow 0.3, 9.4, 3.4, 8.5, \text{ which is also } = 6.24037812$$

z may be found under the form $5 \downarrow 2.3, 1.1, 3.2, 0.1, = 6.24037812$.

When we assume z of the form $n \downarrow u_1 u_2 u_3 \dots$ a convenient value for n is readily found by supposing A B H L a trapezoid, then B L must be greater than 6, hence n was put = 6; but we might assume $n = 4, 5, 6$, or 7, and yet determine $z = 6.24037812$.

The height and dimensions of any number of trapezoids forming an embankment like A L H, of equal strength, can be found in a similar way. A B, O C, H L, &c., may be given any common difference. The labour and difficulty experienced in finding the roots of equations higher than a quadratic, before Oliver Byrne, the editor and compiler of this Dictionary, invented the art and science of Dual Arithmetic, prevented writers on practical mathematics from introducing problems involving cubic or higher equations. The student should pay particular attention to the following remarks;—

In solving equation [β] we put it under the form $z^3 + \frac{47.73689344}{z} = 46.592$.

Because, in the dual calculus, z^2 and $\frac{1}{z}$ become known at one and the same time. This arrangement being made, it is soon found that $z = 6 \downarrow 0.4, 0.5' u_1' u_2' u_3'$.

In supposing w in [1] to have a continuous range of numerical values, no new result is obtained by imagining v to be a proper fraction of the form $\frac{1}{z}$; for then [1] becomes [2].

$$v + \frac{1}{v} = w; \quad [1]$$

$$z + \frac{1}{z} = w. \quad [2]$$

Hence it is unnecessary to suppose v in [1] to have a value less than 1, for the same resulting value of w may be obtained by giving to v its corresponding value greater than 1. If w is negative then v and $\frac{1}{v}$ must be negative; and [3] becomes [4].

$$v + \frac{1}{v} = -w; \quad [3]$$

$$-v - \frac{1}{v} = -w. \quad [4]$$

Consequently the value of v in [3] is the same as the value of v in [1], numerically, but negative. And, consequently, no whole number or fraction, positive or negative, substituted for v in [1] will render $v + \frac{1}{v}$ numerically less than +2 or -2. Therefore, all such equations as $v + \frac{1}{v} = \pm w$, may be put under the form [1], in which v may be always considered greater than unity, without interfering with the continuity of the numerical values of w . From [1] we obtain [5],

$$1 + \frac{1}{v^2} = w \frac{1}{v}. \quad [5]$$

Since v is a positive number greater than 1 , the left-hand member of [5] is always greater than 1 but less than 2 ; whence the right-hand member of [5], that is, $w \frac{1}{v}$, must have a value existing between the same limits, but not beyond.

In supposing w in [6] to have a continuous range of numerical values, no new result is obtained in supposing v to be a proper fraction of the form $-\frac{1}{z}$; for then [6] becomes [7].

$$v - \frac{1}{v} = w; \quad [6] \qquad -\frac{1}{z} + z = w. \quad [7]$$

It is therefore unnecessary to suppose v in [6] to have a value less than (-1) ; for the same resulting value of w may be obtained by giving to v its corresponding positive value z greater than 1 . Nor can v in [6] be a negative whole number, for then $v - \frac{1}{v}$ would become negative; and equal to w which is supposed to be positive. If $\frac{1}{z}$ be substituted for v in [6] it becomes $\frac{1}{z} - z = w$,

$$\text{or } z - \frac{1}{z} = -w. \quad [8]$$

Whence, if the value of v be known in [6], the value of z in [8] becomes known, for z in [8] is equal to $\frac{1}{v}$ in [6]. v cannot be $= +1$ or -1 in [6], for then $v - \frac{1}{v} = 0$, which is absurd, for v is always $=$ the whole number w ; w being positive in [6], v must be a positive whole number, for if it be a proper fraction $+\frac{1}{z}$, it assumes the form [8], in which w is negative. And if v be a negative fraction $-\frac{1}{z}$, [6] assumes the identical form [7], in which z is a whole positive number.

Therefore all such equations as $v - \frac{1}{v} = \pm w$, may be solved by solving [6], in which v may be always considered greater than unity, without interfering with the continuity of the numerical values of $+w$.

From [6] we obtain [9],

$$1 - \frac{1}{v^2} = w \frac{1}{v}. \quad [9]$$

Since v in all cases is a positive number greater than 1 , the left-hand member of [9] is always greater than 0 , but less than 1 ; whence the right-hand member of [9], that is $w \frac{1}{v}$, must have a value existing between the same limits 0 and 1 , but not beyond.

When w is not considered as standing for all possible numbers between its known limits, but has a particular value n , greater than 2 ; that is, $v + \frac{1}{v} = n$; then if $a = v$ or $a + \frac{1}{a} = n$, also will $\frac{1}{a} = v$; for $\frac{1}{a} + \frac{1}{\frac{1}{a}} = \frac{1}{a} + a = n$.

Again in $v - \frac{1}{v} = m$, then if $v = b$, or $b - \frac{1}{b} = m$; v also $= -\frac{1}{b}$; for

$$-\frac{1}{b} - \left(\frac{1}{-\frac{1}{b}} \right) = -\frac{1}{b} + b = m.$$

Lemma I.—If f be put for any decimal fraction as $\cdot 34567888$, and $f_1 = 3456788 \cdot 8$, $f_2 = 345678 \cdot 88$, $f_3 = 34567 \cdot 888$; &c.

Then, for dual numbers of not more than eight consecutive dual digits, we have

$$\begin{array}{l|l} \downarrow, (1 + f \downarrow u_8) = \downarrow, (1 + f) + \frac{f_8 u_8}{1 + f} & \downarrow, (1 + f \downarrow u_8) = \downarrow, (1 + f) + \frac{f_6 u_6}{1 + f} \\ \downarrow, (1 + f \downarrow u_7) = \downarrow, (1 + f) + \frac{f_7 u_7}{1 + f} & \downarrow, (1 + f \downarrow u_5) = \downarrow, (1 + f) + \frac{f_5 u_5}{1 + f} \end{array}$$

All of which are true to the required degree of accuracy. $f_8 = \cdot 34567888$; $f_7 = 3 \cdot 4567888$; $f_6 = 34 \cdot 567888$; $f_5 = 345 \cdot 67888$. $\downarrow, u_1 = 9531018, \times u_1$; $\downarrow, u_2 = 995033, \times u_2$; $\downarrow, u_3 = 99950, \times u_3$; $\downarrow, u_4 = 10000, \times u_4$; &c.

$$\begin{array}{l|l} \downarrow, (1 + f \downarrow u_8) = \downarrow, (1 + f) - \frac{f_8 u_8}{1 + f} & \downarrow, (1 + f \downarrow u_6) = \downarrow, (1 + f) - \frac{f_6 u_6}{1 + f} \\ \downarrow, (1 + f \downarrow u_7) = \downarrow, (1 + f) - \frac{f_7 u_7}{1 + f} & \downarrow, (1 + f \downarrow u_5) = \downarrow, (1 + f) - \frac{f_5 u_5}{1 + f} \end{array}$$

Within the designed degree of accuracy, which may be as great as we please, these equations

hold exactly true, while the places of figures of the whole number f are not greater than half the places in $1 + f$;

Example.

$$1 + \cdot 50000000 \\ 16539$$

$$1 + \cdot 50016539 \text{ Sum.}$$

$$1 + \cdot 49983461 \text{ Diff.}$$

$$\downarrow, (1 + \cdot 50000000) + \frac{16539}{1 \cdot 5} = \downarrow, (1 \cdot 50016539)$$

$$\downarrow, (1 + \cdot 50000000) - \frac{16539}{1 \cdot 5} = \downarrow, (1 \cdot 49983461)$$

Proof.

$$\left. \begin{aligned} \downarrow, (1 \cdot 50016539) &= 40557538, \\ \downarrow, (1 \cdot 50000000) &= 40546512, \\ \downarrow, (1 \cdot 49983461) &= 40535484, \end{aligned} \right\} \begin{array}{l} 11028, \\ \text{Differences} \\ 11028, \end{array}$$

$$\frac{16539}{1 \cdot 5} = 11026.$$

Here it may be observed that, in the process hereafter established, to find the roots of equations of all degrees, the digits of the development $\downarrow u_1, u_2, u_3, \dots$ or of $\downarrow u_1, u_2, u_3, \dots$ may be determined in numbers not greater than 5, or 5.

In continuation,

$$\downarrow, (1 + f \downarrow u_1) \text{ nearly equal to, but greater than } \downarrow, (1 + f) + \frac{f_1 u_1}{1 + f};$$

$$\downarrow, (1 + f \downarrow u_2) \quad " \quad " \quad \downarrow, (1 + f) + \frac{f_2 u_2}{1 + f};$$

$$\downarrow, (1 + f \downarrow u_3) \quad " \quad " \quad \downarrow, (1 + f) + \frac{f_3 u_3}{1 + f};$$

$$\downarrow, (1 + f \downarrow u_4) \quad " \quad " \quad \downarrow, (1 + f) + \frac{f_4 u_4}{1 + f}.$$

Examples.

$$\downarrow, (1 + \cdot 86733389 \downarrow 0,3) = 63849769,$$

$$\downarrow, (1 + \cdot 86733389) + \frac{867333 \cdot 89}{1 \cdot 86733389} = 63844605,$$

Results nearly equal, but the latter is less than the former.

$$\downarrow, (1 + \cdot 25000000 \downarrow 4) = 31190496,$$

$$\downarrow, (1 + \cdot 25000000) + \frac{(2500000) \times 4}{1 \cdot 25} = 30299713.$$

Results approaching equality, but the latter is less than the former.

Lastly, $\downarrow, (1 + f \downarrow u_1) \text{ nearly equal to, but less than } \downarrow, (1 + f) - \frac{f_1 u_1}{1 + f};$

$$\downarrow, (1 + f \downarrow u_2) \quad " \quad " \quad \downarrow, (1 + f) - \frac{f_2 u_2}{1 + f};$$

$$\downarrow, (1 + f \downarrow u_3) \quad " \quad " \quad \downarrow, (1 + f) - \frac{f_3 u_3}{1 + f};$$

$$\downarrow, (1 + f \downarrow u_4) \quad " \quad " \quad \downarrow, (1 + f) - \frac{f_4 u_4}{1 + f}.$$

Examples.

$$\downarrow, (1 + \cdot 86733389 \downarrow 0,3) = 61062079,$$

$$\downarrow, (1 + \cdot 86733389) - \frac{(867333 \cdot 89) \times 3}{1 \cdot 86733389} = 61057741.$$

These results are also nearly equal; the latter, as in the former case, being less than the former.

$$\downarrow, (1 + \cdot 25000000 \downarrow 4) = 15188886,$$

$$\downarrow, (1 + \cdot 25000000) - \frac{(2500000) \times 4}{1 \cdot 25} = 14299713.$$

Results approaching equality, but the latter is less than the former, as in previous cases.

Lemma II.—As in Lemma I., if f be put for any decimal fraction, $\cdot 34567822$ and $f_1 = 3456782 \cdot 2$; $f_2 = 345678 \cdot 22$; $f_3 = 34567 \cdot 822$; &c.

Then, for dual numbers of not more than eight consecutive dual digits, we have

$$\left. \begin{aligned} \downarrow, (1 - f \downarrow u_6) &= \downarrow, (1 - f) + \frac{f_6 u_6}{1 - f}; \\ \downarrow, (1 - f \downarrow u_7) &= \downarrow, (1 - f) + \frac{f_7 u_7}{1 - f}; \end{aligned} \right| \left. \begin{aligned} \downarrow, (1 - f \downarrow u_6) &= \downarrow, (1 - f) + \frac{f_6 u_6}{1 - f}; \\ \downarrow, (1 - f \downarrow u_8) &= \downarrow, (1 - f) + \frac{f_8 u_8}{1 - f}. \end{aligned} \right.$$

These equations coincide exactly, while the places of figures in the whole number f are not greater than half the places of figures in $1 - f$.

$$\begin{array}{rcl} & \text{Examples.} & \\ 1 - .18000000 & = & .82000000 \\ 1 - .18009237 & = & .81990763 \\ \hline 9237 & & 9237 \text{ difference,} \end{array}$$

which, when taken as a whole number, gives $\frac{9237}{.82} = '11267$, the difference of the dual logarithms of .82000000 and .81990763.

$$\begin{array}{l} \text{Proof.} \\ \downarrow, (1 - .18009237) = '19856360 = \downarrow, (.81990763) \\ \downarrow, (1 - .18000000) = '19845093 = \downarrow, (.82000000) \\ \hline '11267 \text{ difference.} \end{array}$$

$$\begin{array}{l} \text{Ex. 2.} \\ \downarrow, (1 - .27702856) = '32438457 \\ \downarrow, (1 - .27700000) + \frac{2856}{.723} = '32438457 \\ \text{For } \downarrow, (1 - .27000000) = '32434506 = \downarrow, (.723) \\ \text{and } \frac{2856}{.723} = '3951 \\ \hline '32438457 \end{array}$$

When the digits are of the descending branch then $\downarrow, 'u_1 = '10536052 u_1$; $\downarrow, 'u_2 = 1005034 u_2$; $\downarrow, 'u_3 = '100050 u_3$; $\downarrow, 'u_4 = '10001 u_4$; &c.

$$\begin{array}{l} \downarrow, (1 - f \downarrow 'u_6) = \downarrow, (1 - f) - \frac{f_6 u_6}{1 - f}; \quad \downarrow, (1 - f \downarrow 'u_6) = \downarrow, (1 - f) - \frac{f_6 u_6}{1 - f}; \\ \downarrow, (1 - f \downarrow 'u_7) = \downarrow, (1 - f) - \frac{f_7 u_7}{1 - f}; \quad \downarrow, (1 - f \downarrow 'u_8) = \downarrow, (1 - f) - \frac{f_8 u_8}{1 - f}. \end{array}$$

If $1 - f = 1 - .25000000$; then $f_8 = .25000000$; $f_7 = 2 \cdot 5000000$; $f_6 = 25 \cdot 000000$; $f_5 = 250 \cdot 00000$; $f_4 = 2500 \cdot 0000$; &c.

$$\begin{array}{l} \text{Example.} \\ \downarrow, (1 - .30000000 \downarrow '7_5) = '35664495 \\ \downarrow, (1 - .30000000) - \frac{(300 \cdot) \times 7}{1 - .3} = '35664495 \end{array}$$

In this example $f_5 = 30 \cdot 00000$

$$\frac{(300 \cdot) \times (7)}{1 - .3} = '3000$$

$$\downarrow, (70000000) = '35667495; \downarrow, (1 - .29997900) = '35664495.$$

Generally $\downarrow, (1 - f \downarrow 'u_n) = \downarrow, (1 - f) \pm \frac{f_n \times u_n}{1 - f}$, holds true to the designed degree of accuracy, which may be as great as we please, while the places of figures in the whole number represented by $f_n \times u_n$ are not greater than half the places of figures in $1 - f$.

$$\begin{array}{l} \downarrow, (1 - f \downarrow 'u_4) \text{ nearly } =, \text{ but greater than } \downarrow, (1 - f) + \frac{f_4 u_4}{1 - f}; \\ \downarrow, (1 - f \downarrow 'u_3) \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \downarrow, (1 - f) + \frac{f_3 u_3}{1 - f}; \\ \downarrow, (1 - f \downarrow 'u_2) \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \downarrow, (1 - f) + \frac{f_2 u_2}{1 - f}; \\ \downarrow, (1 - f \downarrow 'u_1) \quad \quad \quad \quad \quad \quad \quad \quad \quad \quad \downarrow, (1 - f) + \frac{f_1 u_1}{1 - f}. \end{array}$$

Examples.—Let $1 - f \downarrow u_2 = 1 - .28000000 \downarrow 0.2$, then $u_2 = 2$ and $f = .280000$.

$$\downarrow, (1 - .28000000 \downarrow 2_{27}) = '33635146$$

$$\downarrow, (1 - .28000000) + \frac{(280000 \cdot) \times 2}{1 - .28} = '33628185$$

These results approach equality, but the latter is less than the former.

$$\downarrow, (1 - .28000000) = \downarrow, (.72000000) = '32850408 \text{ and } \frac{(28000 \cdot) \times 2}{.72} = '777777.$$

Ex. 2.—Let $1 - f \downarrow u_1 = 1 - .20000000 \downarrow 3$, then $u_1 = 3$ and $f = .2000000$.

$$\downarrow, (1 - .20000000 \downarrow 3_{\cdot}) = '30951877$$

$$\downarrow, (1 - .20000000) + \frac{(2000000 \cdot) \times 3}{1 - .2} = '29689437.$$

These results also approach equality, but the latter is less than the former.

$$\downarrow, (1 - \cdot 20000000) = \downarrow, (\cdot 80000000) = \cdot 22189437 \text{ and } \frac{(2000000 \cdot) \times 3}{1 - \cdot 2} = 7500000.$$

Lastly,

$$\begin{aligned} \downarrow, (1 - \cdot f \downarrow u_1) & \text{ nearly } =, \text{ but greater than } \downarrow, (1 - \cdot f) - \frac{f_1 u_1}{1 - \cdot f}; \\ \downarrow, (1 - \cdot f \downarrow u_3) & \quad \quad \quad \downarrow, (1 - \cdot f) - \frac{f_3 u_3}{1 - \cdot f}; \\ \downarrow, (1 - \cdot f \downarrow u_2) & \quad \quad \quad \downarrow, (1 - \cdot f) - \frac{f_2 u_2}{1 - \cdot f}; \\ \downarrow, (1 - \cdot f \downarrow u_1) & \quad \quad \quad \downarrow, (1 - \cdot f) - \frac{f_1 u_1}{1 - \cdot f}. \end{aligned}$$

Ex. 1.

$$\begin{aligned} \downarrow, (1 - \cdot 28000000 \downarrow \cdot 2_8) & = \cdot 32079496 \\ \downarrow, (1 - \cdot 28000000) - \frac{(280000 \cdot) \times 2}{1 - \cdot 28} & = \cdot 32072631 \end{aligned}$$

Ex. 2.

$$\begin{aligned} \downarrow, (1 - \cdot 20000000 \downarrow \cdot 3) & = \cdot 15758995 \\ \downarrow, (1 - \cdot 20000000) - \frac{(2000000 \cdot) \times 3}{1 - \cdot 2} & = \cdot 14689437 \end{aligned}$$

Generally, if $\downarrow u_1 u_2 u_3 \dots u_n$ be a dual development, and $u_1 u_2 u_3 \dots$ either ascending or descending dual digits; then if p be greater than half n , and q not greater than half n ,

$$\downarrow, (1 + \cdot f \downarrow u_p) = \downarrow, (1 + \cdot f) + \frac{f_p u_p}{1 + \cdot f}; \text{ and } \downarrow, (1 + \cdot f \downarrow u_p) = \downarrow, (1 + \cdot f) - \frac{f_p u_p}{1 + \cdot f};$$

true to the designed degree of accuracy, which may be as great as we please. But

$$\downarrow, (1 + \cdot f \downarrow u_q) \text{ is nearly } =, \text{ but greater than } \downarrow, (1 + \cdot f) + \frac{f_q u_q}{1 + \cdot f};$$

and $\downarrow, (1 + \cdot f \downarrow u_q) \quad \quad \quad \downarrow, (1 + \cdot f) - \frac{f_q u_q}{1 + \cdot f};$
also, generally,

$$\downarrow, (1 - \cdot f \downarrow u_p) = \downarrow, (1 - \cdot f) + \frac{f_p u_p}{1 - \cdot f}; \quad \downarrow, (1 - \cdot f \downarrow u_p) = \downarrow, (1 - \cdot f) - \frac{f_p u_p}{1 - \cdot f};$$

true to the designed degree of accuracy; but

$$\downarrow, (1 - \cdot f \downarrow u_q) \text{ is nearly } =, \text{ but greater than } \downarrow, (1 - \cdot f) + \frac{f_q u_q}{1 - \cdot f};$$

and $\downarrow, (1 - \cdot f \downarrow u_q) \quad \quad \quad \downarrow, (1 - \cdot f) - \frac{f_q u_q}{1 - \cdot f}.$

When operating with the digits $\cdot u_q u_n$, it will be found that, in these latter cases, the inequalities are of much importance, when results are sought in their lowest terms.

To solve any equation of the form

$$1 + \frac{1}{y^2} = c \frac{1}{y^m}; \quad [1]$$

in which m represents any given number, whole or fractional, positive or negative; the coefficient c being also given.

$$\therefore \downarrow, \left(1 + \frac{1}{y^2}\right) = \downarrow, (c) - m \downarrow, (y). \quad [2]$$

We have before shown that all numerical values of $1 + \frac{1}{y^2}$ exist between the limits 1 and 2; hence, by putting $\downarrow, (c) - m \downarrow, (y) = \downarrow, (2)$,

$$\downarrow, (y) = \frac{\downarrow, (c) - \downarrow, (2)}{m}. \quad [3]$$

Again, if $\downarrow, (c) - m \downarrow, (y)$ be put = 0, then

$$\downarrow, (y) = \frac{\downarrow, (c)}{m}, \quad [4]$$

from which the other limiting value of y is obtained.

Now suppose L to be any convenient number existing between these limits, in putting $\frac{1}{s}$ = $\frac{1}{L^2}$, and substituting $\frac{1}{s} \downarrow u_1$, or $\frac{1}{s} \uparrow u_1$ for $\frac{1}{y^2}$ in [2], we have in the first case

$$\downarrow, \left(1 + \frac{1}{s} \downarrow u_1\right) = \downarrow, (c) - m \downarrow, \left(s^{\frac{1}{2}} \frac{1}{\downarrow \frac{u_1}{2}}\right)$$

$$\begin{aligned} \therefore \downarrow \left(1 + \frac{1}{s}\right) + \frac{\frac{1}{s} u_1}{1 + \frac{1}{s}} &= \downarrow(c) - \frac{m}{2} \downarrow(s) + \frac{m}{2} \downarrow u_1, \\ \therefore u_1 &= \frac{\downarrow(c) - \frac{m}{2} \downarrow(s) - \downarrow\left(1 + \frac{1}{s}\right)}{\frac{1}{s} - \frac{1}{1 + \frac{1}{s}} - \frac{m}{2} (9531018),} \\ \text{or } u_1 &= \frac{\downarrow(c) - \frac{m}{2} \downarrow\left(\frac{1}{f_1}\right) - \downarrow(1 + f_1)}{\frac{f_1}{1 + f_1} - \frac{m}{2} (9531018),} \end{aligned} \quad [5]$$

according to the notation previously established.

$$u_2 = \frac{\downarrow(c) - \frac{m}{2} \downarrow\left(\frac{1}{f_2}\right) - \downarrow(1 + f_2)}{\frac{f_2}{1 + f_2} - \frac{m}{2} (995033),} \quad [6]$$

in which $f_2 = f_1 \downarrow u_1 = \frac{1}{s} \downarrow u_1$;

$$u_3 = \frac{\downarrow(c) - \frac{m}{2} \downarrow\left(\frac{1}{f_3}\right) - \downarrow(1 + f_3)}{\frac{f_3}{1 + f_3} - \frac{m}{2} (99950),} \quad [7]$$

in which $f_3 = f_2 \downarrow u_2 = f_1 \downarrow u_1, u_2 = \frac{1}{s} \downarrow u_1, u_3$;

$$u_4 = \frac{\downarrow(c) - \frac{m}{2} \downarrow\left(\frac{1}{f_4}\right) - \downarrow(1 + f_4)}{\frac{f_4}{1 + f_4} - \frac{m}{2} (10000),} \quad [8]$$

in which $f_4 = f_3 \downarrow u_3 = f_2 \downarrow u_2, u_3 = f_1 \downarrow u_1, u_2, u_3$. This process may be continued to any required extent and to any degree of accuracy.

When $\frac{1}{y_2} = \frac{1}{s} \downarrow u_1, u_2, u_3, \dots$ becomes known, y is easily found. In order to find a dual expression for $\frac{1}{y_2}$ in its lowest terms, it is important that we are able to select either a descending or an ascending dual digit at any stage of the development.

In the second case, if $\frac{1}{s} \downarrow u_1$ be substituted for $\frac{1}{y_2}$ in [2], we have

$$\begin{aligned} \downarrow \left(1 + \frac{1}{s} \downarrow u_1\right) &= \downarrow(c) - m \downarrow \left(s^{\frac{1}{2}} \frac{1}{\downarrow \frac{u_1}{2}}\right) \\ \therefore \downarrow \left(1 + \frac{1}{s}\right) - \frac{\frac{1}{s} u_1}{1 + \frac{1}{s}} &= \downarrow(c) - \frac{m}{2} \downarrow(s) + \frac{m}{2} \downarrow u_1 \\ \therefore u_1 &= \frac{\downarrow(c) - \frac{m}{2} \downarrow(s) - \downarrow\left(1 + \frac{1}{s}\right)}{\frac{1}{s} - \frac{1}{1 + \frac{1}{s}} + \frac{m}{2} (10536052)} \\ \text{or } u_1 &= \frac{\downarrow(c) - \frac{m}{2} \downarrow\left(\frac{1}{f_1}\right) - \downarrow(1 + f_1)}{-\frac{f_1}{1 + f_1} + \frac{m}{2} (10536052)}, \end{aligned} \quad [9]$$

according to the established notation.

$$u_2 = \frac{\downarrow, (c) - \frac{m}{2} \downarrow, \left(\frac{1}{f_2} \right) - \downarrow, (1 + f_2)}{-\frac{f_2}{1 + f_2} + \frac{m}{2} (1005034)}, \quad [10]$$

in which $f_2 = f_1 \downarrow u_1 = \frac{1}{s} \downarrow u_1$;

$$u_3 = \frac{\downarrow, (c) - \frac{m}{2} \downarrow, \left(\frac{1}{f_3} \right) - \downarrow, (1 + f_3)}{-\frac{f_3}{1 + f_3} + \frac{m}{2} (100050)}, \quad [11]$$

in which $f_3 = f_2 \downarrow u_2 = f_1 \downarrow u_1, u_2 = \frac{1}{s} \downarrow u_1, u_2$;

$$u_4 = \frac{\downarrow, (c) - \frac{m}{2} \downarrow, \left(\frac{1}{f_4} \right) - \downarrow, (1 + f_4)}{-\frac{f_4}{1 + f_4} + \frac{m}{2} (10000)}, \quad [12]$$

in which $f_4 = f_3 \downarrow u_3 = f_2 \downarrow u_2 u_3 = f_1 \downarrow u_1, u_2, u_3 \therefore$ the value of $\frac{1}{s}$ may be found under the dual form $\frac{1}{s} \downarrow u_1, u_2 u_3 u_4 \dots$ to any required degree of accuracy, and this form may be found in its lowest terms, by a direct process, without resorting to the different systems of trial and error practised in applying all other known methods for finding the roots of equations. See 'General Method of Solving Equations of all Degrees,' by O. Byrne.

Hydraulic System of the Reservoir on the River Furens.—The town of Saint-Etienne is supplied with water to some extent by means of a subterranean passage or aqueduct which conveys the water directly from the springs at the source of the Furens. In the year 1858, for the purpose of protecting the town from inundations, the French Government undertook to construct an immense reservoir upon this river at a cost of about 1,570,000 francs, and it was agreed that the excess of the cost above 570,000 francs should be borne by the town on the condition that it should have a right to a portion of the reservoir to store up for its own use the surplus water of the river. Fig. 2233 shows the general arrangements adopted to secure the proper working of the reservoir under the complex conditions imposed on it.

Previous to the construction of these works, the Furens followed the course $M A P C D G S$. A barrage 50 metres in height bars the valley at the point C. Its section and elevation are shown by Figs. 2234, 2235. At B, Fig. 2233, a by-wash BND has been constructed, and this now forms the bed of the Furens, the portion APCD of the former bed being now covered by the reservoir. At A and B are two water-gates or sluices, one of which communicates with the reservoir by the old bed AP, and the other with the by-wash BND which restores the water to the river at D.

Let us now see how the water in the reservoir is utilized, and first we must remark that the level at which the town of Saint-Etienne may retain its water is fixed at $44^m \cdot 50$ above the bottom in front of the great wall, as shown in Figs. 2234, 2235. Above this level there is a height of $5^m \cdot 50$, which is always to be kept empty to receive the surplus water in the case of a sudden rise of the river. As soon as the river has returned to its ordinary state, the surplus water is drawn off by a subterranean passage E'N, Fig. 2235, into the by-wash or present bed of the Furens. We shall now see how the reservoir is adapted to supply both the town of Saint-Etienne and the factories in accordance with the conditions stated above.

A subterranean channel is cut in the counter-fort against which the great wall rests, in the direction of the line EF, Fig. 2233, and in this channel, stopped with masonry at the reservoir end, see Fig. 2235, there are two cast-iron pipes, each of $0^m \cdot 40$ in diameter, running through this masonry, which pipes convey the water to a bag F, by means of cocks capable of opening to any degree. When the water has been brought into the bag F the double duty of supplying the town and the factories remains to be performed; to accomplish this, an open canal FdG, Fig. 2233, has been constructed with a regulator-sluice at d to convey the reserved water into the bed of the

Furens at G, and a second covered channel F/H K, provided at I with a regulator-sluice, conveys the water into the Saint-Etienne aqueduct, either directly at H by means of a cock, or through a small reservoir K L which communicates with the aqueduct by a pipe L V, provided at V with a regulator-cock. Fig. 2235 gives a sectional view of the arrangements of the channel which connects the bay F with the Saint-Etienne aqueduct.

During the summer the watering of the streets and the washing of the sewers is done by means of the resources of the reservoir, the water of the aqueduct being insufficient for this purpose. For this operation communication is established between the aqueduct and the reservoir by the canal F/H K, Figs. 2233 and 2235. If it is required during this season, when the factories on the Furens are obliged to cease work for considerable periods, to increase the discharge of the river, communication is opened with the reservoir by the canal F d G.

The aqueduct which conveys the water from the source of the Furens is everywhere quite independent of the reservoir, with which it communicates only by the

Section through A C, Fig. 2233.

Section through line T E F N H K, Fig. 2233.

channel F/H K. Fig. 2236 shows the relative positions of the aqueduct and the Furens near the point A at the mouth of the reservoir.

Functions of the Water-gates above the Reservoir.—

We have now to explain the working of the water-gates A and B placed at the head of the feed-canal of the reservoir A P, Fig. 2233, and the by-wash B N D. When the discharge of the river reaches the point M, where there is a scale showing the depth of the water, 93 cubic mètres a second, which discharge corresponds to a height of 2 mètres on the scale, the town of Saint-Etienne begins to be inundated. Let us suppose the rise to take place when the reservoir is full, that is to the permanent height of $44^m.50$, the most unfavourable case. The gate A will be left shut and the gate B open so long as the water does not rise above this height of 2 mètres on the scale at the point M, the height corresponding to a discharge of 93 cubic mètres, and below which no injury is to be feared. In this case all the water will flow through the by-wash to join the river again at D. But as soon as the water rises on the scale M above 2 mètres, that is as soon as danger becomes imminent, the gate B remaining open, the gate A is opened and by its action the height of the water will be kept at 2 mètres on the scale M. This is easily accomplished, as the gate A is constructed to discharge the difference, 33 cubic mètres, between the maximum discharge, 131 cubic mètres, a second of the greatest known rise, and 93 cubic mètres. The excess of water will thus be received into the reservoir, and will accumulate in the space of $5^m.50$ reserved above the line of the permanent level.

Let us now consider the working of these gates A and B in furnishing the permanent reserve, and to this end we will suppose the reservoir empty, which is the case at the close of the summer.

In the first place it is of course necessary to ensure the regular working of the factories under the conditions which existed before the construction of the reservoir, and for this we will suppose a discharge of 350 litres a second requisite. The depth of water corresponding to this discharge is marked on the scale M. So long as the level of the water in the bed of the river remains below this mark, the gate A must be left closed, as all the water will be needed by the factories situated below the reservoir. But as soon as the mark is submerged the gate A may be opened, so as to maintain the proper depth, and then all the excess of the discharge above 350 litres will pass into the reservoir by its feed-canal A P. If the flow of water that produced the rise ceases, the gate A

Section through M R, Fig. 2233.

must be progressively closed, and entirely shut when the discharge of the river has sunk to 350 litres.

It will be seen from this that only that portion of the water which is not required by the factories is taken from the river. When the Furens discharges more than 350 litres a second, the useless surplus is stored up, to be used in the summer when the river, as always happens in dry summers, discharges only from 80 to 100 litres a second. The advantages accruing to the manufacturers from this arrangement will be at once perceived.

Discharge of the Furens.—Capacity of the Reservoir.—According to the daily measurements made during eight years by the engineers who constructed the barrage, in very dry years the quantity of water discharged by the Furens descends as low as 100 and even 80 litres a second; the mean quantity a second throughout the year being about 500 litres. The superficies of that portion of the bed of the river, situated above the reservoir, which furnishes this discharge, is about 2500 hectares, and the mean depth of water falling into it a year is 1 metre.

The discharge during the greatest rises observed in the Furens between 1858 and 1868 did not exceed 15 cubic metres a second; but on the 10th of July, 1849, a water-spout having burst in the upper part of the valley, an extraordinary rise took place, inundating the town of Saint-Etienne.

This was the discharge which it was necessary to determine approximatively in order to fix the capacity of the reservoir; this the engineers to whom the work was entrusted were enabled to do from information obtained on the spot, the value which they found for this unusual rise being 131 cubic metres. Fig. 2237 is the curve of the discharges of this exceptional rise of 1849. The capacity of the empty portion of the reservoir ought evidently to be equal to the area of the portion of the curve situated above the discharge of 93 cubic metres, when the inundation of the town begins, which portion is detached in the figure. Now this area is equal to $\left(\frac{131 - 93}{2}\right) \times 3 \times 3600 = 205,200$

cubic metres. The upper portion of the reservoir to be left empty for the purpose of receiving the surplus water in case of a rise should, therefore, be capable of containing, in round numbers, 200,000 cubic metres.

It was seen above that the portion in question was comprised between the horizontal planes situated at 50 metres and at 44^m·50 above the bottom of the reservoir, near the barrage, and, consequently, was 5^m·50 in depth. From very exact calculations made since the completion of the works, it was found that the contents corresponding to the permanent level of 44^m·50 were equal to 1,200,000 cubic metres, and that the contents corresponding to the height of 50 metres were equal to 1,600,000 cubic metres. It follows from this that the capacity of the portion intended to receive the surplus water is 400,000 cubic metres, or the double of that required to contain the destructive portion of the water-spout which burst upon the Furens in 1849. A rise like that of 1849 would give in the reserve portion a depth of only 3 metres, corresponding to a cube of 200,000 cubic metres, and to a height of 47^m·50 above the bottom of the reservoir, whilst the depth of this portion is 5^m·50, corresponding to a cube of 400,000 cubic metres. Thus it will be seen that arrangements have been made so as to remove all danger from mistakes in calculation.

From measurements and calculations made during a period of eight years, and from the experience of the years 1865 and 1866 had of the reservoir itself, it has been ascertained that the permanent contents of 1,200,000 cubic metres are renewed twice a year, in autumn and in spring. The quantity required for the supplementary service of the town of Saint-Etienne can in no case exceed 600,000 cubic metres a year, so that there remain to be distributed among the factories 2,400,000 - 600,000 = 1,800,000 cubic metres; or 120 litres a second for six months. Thus the advantages derived from the construction of this reservoir are very great. We have now to explain why a barrage 50 metres in height, that is, the highest that has ever been constructed, was preferred to two reservoirs with barrages of moderate height.

In the valley in question two reservoirs would have required two barrages each 38 metres in height, at a cost of 1,840,000 francs, to obtain the capacity of 1,600,000 cubic metres, offered by the barrage of 50 metres for a single reservoir at a cost of 1,600,000 francs. Thus by constructing only one reservoir a saving was effected of 240,000 francs.

In narrow valleys, the cost of retaining a given quantity of water increases with the number of reservoirs employed. This consequence, which we have drawn practically from the numerous comparative studies of reservoirs which we have made, may be arrived at also by theory.

Suppose the reservoir divided into horizontal portions, Fig. 2238, and let A and A' be the lower and the upper sections of one of these portions, the height being K. The expression of the volume of this portion would be $W = aK + \frac{bK^2}{2} + \frac{cK^3}{3}$. The values of a, b, c, are, if S and S', D and D' represent the surfaces and the developments of the perimeters of the sections A and A',

$$A = S \quad b = \frac{2D(S' - S)}{K(D + D')} \quad c = \frac{(S' - S)(D' - D)}{K^2(D + D')}$$

When the talus is uniform as in this case, we may admit only one portion, and then K represents

the height of the contents in front of the barrage. Now we see that the expression of W , by substituting the values of a, b, c , becomes

$$W = \frac{D(2S' + S) + D'(2S + S')}{3(D + D')} K.$$

But here S and D , that is, the lower section of the reservoir and its perimeter, are very small with respect to S' and D' , or the upper section, and we may write, neglecting S and D , $W = \frac{S'}{3} K$, which is nothing but the volume of a cone with a base S' , as might have been expected.

Hence we see with what rapidity the volume of the contents increases with the height, and what advantages may be derived from constructing very high barrages in narrow valleys.

There is in Spain, near Alicante, a barrage 41 mètres in height, the construction of which dates back as far as the sixteenth century. With the excellent hydraulic lime employed by the builders of the barrage of the Furens, there was, therefore, no danger to be apprehended from carrying it up to a height of 50 mètres.

Form and Mode of Construction adapted for Large Dams.—*Plan of a Barrage or Dam 50 mètres in height.*—We need not in this case consider earthen barrages which are of very doubtful security at a height of 20 mètres; at 50 mètres they would, of course, be quite out of the question. We have, therefore, to discuss only stone barrages, and the first question that presents itself is, Ought a barrage to be curvilinear or straight?

In France, previous to the construction of the Furens, the curved form had never been adopted; in Spain they are nearly all of this form. Theoretically it is admitted that they cannot act as an arch against the pressure of the water when they have the curved form, an opinion that is open to grave doubts if we take sufficiently into consideration the cohesion of good hydraulic mortar. But there is another and we think a sufficient reason for giving the preference to the curvilinear form. This reason is derived from the elasticity of blocks of masonry which in the present day is a proved fact. And if we admit this elasticity, it is obvious that the form which offers the greatest safety is the curved. This form was adopted for the barrage of the Furens, and is shown in Fig. 2239. The versed sine of the arc forming the axis of the crown is 5 mètres, and the chord 100 mètres.

Division of a reservoir by sections—Plan.

With respect to the profile to be adopted, M. de Sazilly had already (Annales, 1853) pointed out the only rational arrangements; but his profile was open to the objection of being constructed in a graduated form, which requires a larger cube of cut stone and, consequently, a greater cost. M. Delocre, in his pamphlet, which is far more complete than M. de Sazilly's, has determined the plans of a barrage 50 mètres in height in the two cases of very broad and very narrow valleys, and in the two hypotheses of continuous and graduated facings. Figs. 2240, 2241, represent the former case, and Figs. 2242, 2243, the latter.

M. Delocre's profiles are nearly profiles of equal resistance giving a maximum pressure of 6 kilogrammes to the square centimetre, so that they are available for any height; thus to construct a barrage 26 mètres in height, it would be sufficient to adopt that portion which is situated below the horizontal line AB , Fig. 2240.

There are in France barrages in which the pressure greatly exceeds this limit of 6 kilogrammes to the square centimetre. At Almanza, in Spain, there is a barrage of which we shall have occasion to speak later, and in which this pressure is as great as 14 kilogrammes. This barrage, which dates from the sixteenth century, is still in a good state of preservation, which is explained by the fact that in calculating the theoretical type abstraction

the thickness at this level, it became necessary, in order to have continuous and graceful curves on the facings, to increase also the thickness of the summit at the height of 50 metres from 5 to 5^m.70. Above this level there is a guard-wall to prevent the waves from leaping over, and to serve as a means of communication from one side of the valley to the other.

In calculating for the type of the barrage of the Furens, the pressures in the case of a valley of indefinite breadth, we see that in no point of the profile does the pressure exceed 6^k.50 to the square centimetre; but it must be remarked that here we are in a narrow valley, and that the thickness of the barrage begins to be equal to the breadth of the valley at 32 metres downwards from the general summit. At this level the type of the Furens is 23^m.49 in breadth, and the theoretical type, Fig. 2242, 23^m.40. The profile to be adopted should, therefore, from this line be in accordance with the profile of Fig. 2242, and thus in the one executed the portion of the masonry *acb* and *deh*, Fig. 2245, is excess. Hence it follows that downwards from the line in question the pressures must be considerably less than those marked on Fig. 2245, which were calculated as for a valley of indefinite breadth. If, therefore, the pressure reaches 6 kilogramsmes at the lower portion of the barrage, it will certainly not exceed this limit, and hence we see that this barrage has been constructed with a considerable excess of resistance, which must in part be attributed to the timidity of the engineers, who had to face for the first time the enormous height of 50 metres.

Scale 0^m.002 to the metre.

We come now to consider the surfaces of the facings; the following is the way in which they are generated:—Suppose the profile of Fig. 2245 placed in the vertical plane passing through the axis *CD*, Fig. 2239, in such a way that the middle point of the top, 5^m.70 thick, Fig. 2245, shall fall upon the arc of the circle *ACB*, Fig. 2239, and the whole profile to move successively in

vertical planes cutting each other in the direction of the vertical axis passing through the centre D, Fig. 2239, of the circle, the middle point above mentioned remaining during this movement upon the axis ACB of the circle. The stream-ward and opposite lines of the profile will trace the stream-ward and opposite facings of the barrage, which will be surfaces very graceful to the eye. To enable scaffolding to be placed against the facings when the joints in the masonry need repairing, cut stones, jutting out 0^m·30, have been placed in quincunx order in the outside facing 4^m·60 apart. These projecting stones have also a good effect in breaking the monotony of such an extensive facing. In the facing on the side of the reservoir where these projections were impracticable on account of the action of the waves, rings have been placed in the same order, through which ropes may be passed to fix the scaffolding; these rings serve also to tie the boats to which are used on the reservoir.

Mode of Construction.—The soil upon which the barrage of the Furens is built is mica schist. The barrage is sunk into the rock at its foundations and its sides. For the foundations, all the loose or doubtful blocks were carefully removed until the solid bed of rock was reached which joins the two slopes against which the structure is fixed, and which, as shown in Fig. 2245, is at the base let into this compact bed. For the sides, the earth and rock loosened by contact with the atmosphere where removed until, as before, the solid rock was reached, into which the masonry is inserted in the same way as for the foundations. The structure may be said to be held in a vice, which renders any slipping impossible, and the only movement to which it is liable is the vertical sinking of the masonry.

We think that for works of this nature this founding upon the solid rock both at the base and at the sides is a condition *sine quâ non*, and if it is not to be obtained, the work ought not to be undertaken. M. Aymard has given, in his interesting work on Irrigation in Spain, the history of the barrage of Puente; this barrage, 50 mètres in height, gave way in 1802 at the base, the builder having conceived the unfortunate notion of founding it upon piles in an alluvial soil, instead of going down at any cost to the solid rock.

All the masonry of the barrage of the Furens is composed of common stone, the finest being reserved for the facings, the joints in which are irregular, being built without regular courses like the mass of the masonry. In our opinion, in structures which have to bear a great pressure of water, care should be taken not to lay the stones in horizontal courses, and bonders should be placed in all directions. Indeed, the upper surface of the work during construction should look like a field studded with projecting stones; in a word, the masonry should be so executed as to form a monolith. It was to avoid breaking the continuity of the mass that the lateral tunnels were adopted of which we have already spoken. Any opening in a barrage of so great a height as that of the Furens would be a source of danger.

One essential condition in the construction of such works is not to employ materials of too different a character. Masonry consisting of cut stone and stones of regular shape sinks less than the rough mass used for the inner filling. We continually see in canal locks the cut-stone facings become detached after a certain number of years; and when the water can penetrate between the two kinds of masonry the facings fall with the first frost. In walls not subject to the action of water, the same phenomenon occurs: only it is less marked, and the facing of a wall may stand many years though partly detached from the mass. In a wall of the height of that of the Furens and subject to the action of water, this displacement would have been certain and inevitable. On this account, one of the principal conditions of building this barrage was that "only materials of a similar nature should be employed and the interior should not be filled up with concrete." This latter device would have separated the wall into two parts by the certain disruption of the concrete and the masonry due to the different degree of sinking or settling down, as it is called, and neither of these two parts would have possessed the thickness necessary to resist the pressure.

All the masonry of the barrage, including the foundations and the facings, is thus of rough common stone. It is almost useless to add that this masonry requires the greatest perfection of workmanship, and that this cannot be had except under the immediate and continual superintendence of the engineer. In some parts, where the removal of the rocks caused the surfaces to be too regular, in order to give a firmer hold to the masonry the following method was adopted. On the surface of the rock, previously roughened, a layer of Vassy cement was spread, into which building stones were stuck. In a few hours these stones were very solidly joined to the rock by the hardening of the cement, and by this means an excellent hold was provided for the masonry.

It was at first decided to use Vassy cement for the joints of the facing on the side of the reservoir, to render it more water-tight; but this was discontinued after a height of about 15 mètres had been reached, the successive introductions of water as the work progressed proving that the ordinary mortar held quite as well.

The only portions of the barrage in cut stone are the angle of the upper retreat, the plinths, the parapets, and the corbels upon the outside facing.

The masonry was subjected to the action of the water as the work advanced. The work of one season was left to settle down and harden till the next season, when it was submerged. It was not till the end of the season of 1865 that the work could be tested by a great depth of water. At the beginning of December in that year, the Furens was greatly swollen, and the reservoir was filled up to the height of 46 mètres. In March, 1866, this height was increased to 47 mètres, that is up to the level of the part completed in the season of 1865. These tests produced no movement in the mass nor any escape at the sides. The only phenomenon that occurred was traces of dampness upon the open facing without any apparent local leakage. This fact is explained by the inevitable sinking of such a mass, and by the porous nature of the mortar and the stone itself, which becomes visible only when they are subjected to enormous pressures. A small ditch was dug at the foot of the barrage to show the amount of leakage; but though 46^m·60 of water was retained in the reservoir for four months, it remained quite dry.

In short, the results of this great undertaking have been in all respects satisfactory. The success is rendered more conspicuous by the fact that important leakages at the sides, where the masonry is joined to the rock, seemed inevitable; the absence of this leakage must be attributed to the care and foresight with which the work was executed. We have also to call attention to an excellent means of preventing these lateral leakages employed at the reservoir of the Furens. This consists in hermetically closing with cement in the immediate neighbourhood of the barrage all the fissures in the rocks and in cementing as thickly as possible the joint in the angle formed by the facing of the barrage with that of the rocks on each side. The cement is made to cover from 8 to 10 centimètres of the rocks and the masonry. This method was practised by the Romans on the inner angles of their aqueducts, as shown in Fig. 2246.

Comparison of various kinds of Stone Dams.—We have already stated that a barrage was to be constructed on the Ban, a tributary of the Gier, for the service of the town of Saint-Chaumont and the factories on the Gier. The profile of this barrage, which has been calculated by M. Mongolfier, is given in Fig. 2247; this barrage will be 42 mètres in height, that is eight less than that of the Furens.

Comparing the portion of the profile above the line RS, situated at 42 mètres below the top, with the corresponding part of the profile of the Furens, Fig. 2245, we see that the thickness has been considerably reduced; and if we increase the profile to the height of 50 mètres and calculate the pressures, we see by the figures given in Fig. 2247 that in no point will the pressure exceed 8 kilogrammes to the square centimètre, a limit that may be adopted with the excellent Theil time. This profile, which has been approved by the "Administration," is bolder than that of the Furens, and offers a saving of 105 cubic mètres of masonry a lineal mètré.

The curves of the pressures, when empty and when full, shown in Figs. 2240, 2244, 2245, 2247, enable us to see that these curves leave the middle curve between them, and that they approach it in proportion as the pressure to the square centimètre becomes less. This is shown clearly by the following Table;—

Profiles.	Distances	
	From the curve of the Pressures to the outside facing when full.	From the curve of the Pressures to the inside facing when empty.
Fig. 2240; 6 kilogrammes to the square centimètre	22.76	20.67
Fig. 2245; 6 ^k .30 to the square centimètre	22.50	20.18
Fig. 2247; 7 ^k .30 to the square centimètre	12.90	19.00
Fig. 2244; 14 kilogrammes to the square centimètre	7.10	9.10

It will be seen that for the same general type the more the limit of pressure is increased the nearer the curves approach the lines of the facings and, consequently, recede from the middle line. The conditions of stability, therefore, necessarily diminish in proportion as the limit of pressure to be adopted is increased. It will be for the builder to consider well the nature of his materials and the circumstances of the place before fixing this limit, and then to choose one of the profiles which we have been examining.

Let us now compare some existing types of barrages with those which we considered in connection with the barrage of the Furens. Figs. 2248 to 2253 represent some Spanish barrages from designs which M. Aymard has given of these structures in his work on Irrigation in Spain.

The first thing that strikes the attention is the colossal proportions of these structures, with the exception of the barrage of Almanza, Fig. 2251, which is the oldest. This barrage is of unusual boldness, at least in its upper portion, which throughout a height of 8^m.20 has a mean thickness of only 3^m.50. Five of these barrages, those of Puente, Val de Inferno, Nijar, Almanza, and Alicante, are of the graduated type represented by Figs. 2241 and 2243, and one only, that of Elche, Fig. 2252, is of the type with continuous facings, the theoretical form of which is given in Figs. 2240 and 2242.

Calculating in these theoretical types the cubes of masonry corresponding to the heights of the several barrages, and taking into account the pressures at the outer edge when loaded, which pressures we have calculated for each of these barrages, we obtain the following comparative Table;—

Height of the Barrages.	Name of Barrage.	Maxi-mum Pressure to the square centimetre.	Cubes of Masonry to the lineal mètre of Barrage.			Dif-ferences.	Observations.
			According to the type executed.	According to the theoretical type of Figs. 2241 and 2243.	According to the theoretical type of Figs. 2240 and 2242.		
mètres.		kilos.	cub. mètr.	cub. mètr.	cub. mètr.	cub. mètr.	
50·00	Barrages of Puentès ..	7·90	1519	1029	..	490	Graduated facings.
35·70	Barrages of Val de Inferno ..	6·50	1084	391	..	693	"
27·50	Barrage of Nijar ..	7·50	499	308	..	191	"
20·70	Barrage of Almanza ..	14·00	139	141	..	-2	"
23·20	Barrage of Elche ..	12·70	213	..	187	56	Continuous facings.
41·00	Barrage of Alicante ..	11·30	1100	566	..	534	Graduated facings.

We see that these great pressures might have been reduced, by adopting the rational type, to the lower limit of 6 kilogrammes to the square centimètre, with a large gain in the masonry in all except the barrage of Almanza; and in this case with the same cube within 2 mètres, we might, by a better arrangement, have reduced the pressure from 14 to 6 kilogrammes.

Figs. 2254, 2255, represent the barrages of Bosméléac and Gros-Bois. The former of these two profiles is similar to the type of Figs. 2240 and 2242, and the latter to that of Figs. 2241 and 2243.

The profile of the barrage of Bosméléac gives a cube of 90 cubic mètres to the lineal mètre, and a pressure of $6^k \cdot 09$; the profile of Figs. 2240 and 2242 would give for the height of 15 mètres, which is the height of this barrage, a maximum pressure of 6 kilogrammes and a cube of 91 cubic mètres. The barrage of Bosméléac is thus well designed. As to the barrage of Gros-Bois, its profile is the most irrational of all, and it is the only one in which the two curves of the pressures leave the middle one on the same side, the curve of the pressures when loaded passing within 3 mètres of the lower outside edge. Besides this it gives, with a pressure of $10^k \cdot 40$, an excess of masonry equal to 226—156, or 70 cubic mètres above the type, Figs. 2241 and 2243, applied to its height of $21^m \cdot 80$.

It is obvious that if the profile of this barrage were turned the other way, with the retreats or gradations on the outside instead of on the water-side, it would have deviated from the theoretical type only by an excess of resistance.

The faulty arrangement of the profile of this barrage must, in our opinion, have tended considerably to cause the giving way of the masonry which has occurred, and which has necessitated the erection of counterforts.

Our readers will perceive, from what we have said on the subject of barrages, the importance of selecting a good profile, and we hope that we have practically demonstrated by the experiment of the barrage of the Furens, the superiority of the form of profile arrived at theoretically by M. Delocre.

The Form of the Profile to be adopted for Large Stone Dams.—We have already had occasion to refer to the treatise of M. Delocre on the form of stone dams; in the following pages we will reproduce the methods of calculation by which he arrived at his decisions.

Type of Rectilinear Barrage or Dam in Valleys of considerable Breadth.—*Condition of Stability.*—A barrage which does not transmit laterally to the sides of the valley the pressures which it supports, must resist these pressures in all its points by its own weight. We may, therefore, in seeking the conditions of stability of a structure of this nature, consider a single section only equal in length to a lineal unit. If the materials employed were of indefinite resisting power, as well as the soil of the foundation, and if there were between them an unlimited degree of adhesion, the only condition of stability to be fulfilled would be to give to the wall such a profile that the resultant of the thrust of the water and of the weight of the structure should pass within the polygon of the base. But this condition is not sufficient in practice; the materials and the soil of the foundations will, in fact, support only a limited pressure depending upon their nature, and they have not between them an unlimited degree of adhesion. Hence the two following indispensable conditions:—1. In no point of the structure may the materials employed, or the soil of the foundations, be required to bear too great a pressure; 2. The several courses of masonry in the wall must be incapable of slipping one over another, and the wall must be incapable of sliding upon its base.

Hitherto none of the walls that have given way have done so by slipping; these accidents have occurred in all cases from the first condition not having been fulfilled. We shall, therefore, in the study on which we are about to enter, determine first the dimensions of a barrage with respect to this condition, and then ascertain if the second is satisfied.

A B C D, Fig. 2256, being the profile of a barrage, any section of this barrage equal in length to a lineal unit may be considered as subject to the action of two forces; the vertical component P

of the resultant of the weight of the structure and of the thrust against the facing D A, and the horizontal component F of the thrust. These two forces produce a resultant R which cuts the base A B in the point E. The force R may be considered as applied to the point E and resolved into two at this point, the vertical force being equal to the force P and the horizontal equal to the component F. The horizontal force tends to cause the wall to slide upon its foundations; this effect we will consider later. The vertical force spreads itself over the base from the extremity B, which is nearest the point of application of the resultant, according to a decreasing law.

Denoting the breadth of the base A B by l , and the distance B E by u , the pressure p' at the point B will be given by one of the following formulæ;

$$p' = 2 \left(2 - \frac{3u}{l} \right) \frac{P}{l}, \quad [1] \qquad p' = \frac{2}{3} \frac{P}{u}, \quad [2]$$

according as u is greater or less than $\frac{1}{3} l$.

These formulæ follow naturally from those given by O. Byrne in his 'Essential Elements of Practical Mechanics,' page 236;

$$p = \frac{N}{\Omega} (1 + 3n) \quad [\alpha] \qquad p = \frac{N}{\Omega} \times \frac{4}{3(1-n)} \quad [\beta]$$

and which apply to a homogeneous rectangle pressed by a force acting upon one of the symmetrical axes.

In these formulæ N represents the whole load, Ω the whole area of the surface, and n a quantity which, with our notation, is equal to $\frac{l-2u}{l}$. We have represented the load N by P and the surface Ω is replaced by l .

Making in the above formulæ $N = P$, $\Omega = l$, $n = \frac{l-2u}{l}$, and substituting p' for p , they become

$$p' = \frac{P}{l} \left(1 + \frac{3l-6u}{l} = 2 \left(2 - \frac{3u}{l} \right) \frac{P}{l} ; \quad p' = \frac{P}{l} \times \frac{4}{3 \left(1 - \frac{l-2u}{l} \right)} = \frac{2}{3} \frac{P}{u}.$$

The formula [a] is applicable when $n < \frac{1}{3}$, and consequently formula [1] is adapted to the case in which $\frac{l-2u}{l} < \frac{1}{3}$, that is, $u > \frac{1}{3}l$.

The formula [β] is applicable when $n < \frac{1}{3}$, and consequently the formula [2] is adapted to the case in which $\frac{l-2u}{l} > \frac{1}{3}$, that is, $u < \frac{1}{3}l$.

The stability of the wall requires that this pressure at the point B be equal to or less than the limit of pressure R' which each superficial unit may be made to bear. We ought, therefore, to have, according as u is greater or less than $\frac{1}{3}l$,

$$2 \left(2 - \frac{3u}{l} \right) \frac{P}{l} \leq R', \quad [3] \qquad \frac{2}{3} \frac{P}{u} \leq R', \quad [4]$$

and this condition should be fulfilled for each horizontal section made in the profile, neglecting the force of cohesion in the mortar, which is unfavourable to resistance.

The expressions [1] and [2] may be put under another form by introducing into the calculation the maximum height λ that may be given to a wall with vertical sides, so that the pressure upon the base shall not exceed the limit R' . Indeed, representing the density of the masonry or the weight of the cubic mètre by δ' , we have $R' = \delta' \lambda$.

And the expressions [2] and [3] become

$$2 \left(2 - \frac{3u}{l} \right) \frac{P}{\delta' l} \leq \lambda, \quad [5] \qquad \frac{2}{3} \frac{P}{\delta' u} \leq \lambda. \quad [6]$$

The preceding conditions would be sufficient if the reservoir were to be always full of water, but the wall must be capable, when the reservoir is empty, of supporting its own weight without being subject in any of its points to a pressure, by unit of surface, exceeding the limit $\delta' \lambda$. In this case the resultant of all the forces acting upon the wall is reduced to the weight P' ; and, denoting the distance $K'A$ from the vertical passing through the centre of gravity of the figure $ABCD$, Fig. 2256, to the nearest extremity A of the base by u , the pressure at A will be given according to the case by the formulæ [1] and [2], and the stability of the wall will require that one of the relations [5] and [6] be satisfied when P' is substituted for P .

Form to be given to a Wall having its own weight only to support.—To examine the subject from every point of view, it is important to know what form should be given to a wall having only its own weight to support, so that no point of the masonry may be subject to a pressure above the limit adopted.

It is clear that so long as the height of this wall is less than the limit λ , it will be sufficient to give it vertical facings, and that the pressure to the unit of surface in the lower part will not exceed $\delta' \lambda$. If the wall is to be higher, vertical facings may be adopted throughout a distance from the top equal to λ , and from this point the thickness of the structure must be increased to prevent the pressure upon any horizontal section from exceeding the limit $\delta' \lambda$.

The form to be given to the facings to satisfy this condition is easily determined. We might choose arbitrarily one of the facings of the wall and determine the other; but if we wish to obtain the minimum cube of masonry, we shall give the wall a symmetrical form with respect to its axis. It is clear from the formulæ [1] and [2] that the maximum pressure p' cannot acquire a value less than $\frac{P}{l}$; u being by hypothesis greater than $\frac{l}{2}$, or at least equal to $\frac{l}{2}$, and that this minimum value is reached for $u = \frac{l}{2}$.

This being allowed, the curve sought, DNY , Fig. 2258, must satisfy the condition, that if in any section MN the pressure to the unit of surface is equal to a given quantity, this pressure will remain the same for a section $M'N'$, infinitely near. This condition will evidently be satisfied if the increase of the surface of the base is proportional to the increase of the pressure, or, as all is symmetrical with respect to the axis OS , if the increase of the half-surface LN is proportional to the increase of the pressure upon this half-surface.

This condition is expressed by the equation $dP = K dB$, P representing the pressure exerted upon the half-section LN by the upper part of the structure, and B the surface of this section. Representing by b the dimension of the wall in the direction perpendicular to the section under

consideration, by x the breadth LN , or the abscissa of the curve sought, DNY , and by y the distance from the section MN to a horizontal line taken as the axis of x , we have

$$dB = dbx,$$

$$dP = \delta' b x dy.$$

The differential equation of the curve DNY is therefore $\delta' b x dy = K b dx$, $dy = \frac{K}{\delta'} \frac{dx}{x}$.

The constant K expresses the limit of pressure to the unit of surface, and, consequently, it is equal to $\delta' \lambda$; the equation thus becomes $dy = \lambda \frac{dx}{x}$, or, integrating,

$$y - y_0 = \lambda \log. \left(\frac{x}{x_0} \right); \quad [7]$$

thus the curve DNY is logarithmic.

If we make $x_0 = \lambda$, the two equations above give $\frac{dy_0}{dx_0} = 1$, and $y_0 = 0$.

So that the origin of the co-ordinates should be taken at the point where the value of x is equal to λ , and in this point the tangent to the curve makes an angle of 45° with the axis of the x 's.

Substituting their values for x_0 and y_0 , equation [7] becomes

$$y = \lambda \log. \frac{x}{\lambda}, \quad [8]$$

or, passing from hyperbolic to common logarithms, $y = 2.302658509 \lambda \log. \frac{x}{\lambda}$.

The complete curve, which has as an asymptote the axis of the y 's, would give the form of the facings of a wall indefinite in height, for which the pressure to the unit of surface would be equal to the limit K upon any horizontal section.

Fig. 2259 shows the curve constructed, admitting the limit of pressure adopted for the masonry to be 60,000 kilogrammes to the square metre, or 6 kilogrammes to the square centimetre; and, supposing it be required to give a breadth of 5 metres to the top part of the wall, we have

$$K = 60,000;$$

and admitting the density of the masonry to be double that of water, say $\delta' = 2000$, we have $\lambda = 30$; the equation of the curve becomes $y = 2.3026 \times 30 \log. \frac{x}{30}$.

It must not be forgotten, in making use of this formula, that the direction in which the y 's are usually reckoned has been reversed; in other words, the increment dy has been reckoned with the sign + downwards. The values of y negative must therefore be taken in the direction LO .

It will be seen from Fig. 2258 that if a wall 50 metres in height and 5 metres in breadth at the top has a breadth of 9^m.7392 at the base, in no point will it have to support a pressure above the limit of 6 kilogrammes to the square centimetre.

Substituting right lines for the arcs CMH , DNY , the breadth to be given to the wall at its base would be 10 metres. Fig. 2260 is constructed on this hypothesis.

The equation giving the breadth x of the base is immediately found,

$$\left[30 \times 5 + 20 \left(\frac{5+x}{2} \right) \right] \frac{2000}{x} = 2000 \times 30.$$

The influence of the concave profile which we have given to the wall may be clearly seen by finding the thickness to be given to the base in the case of rectilinear facings inclined from the summit.

This thickness, putting H for the height of the wall, and a for the breadth at the top, will be given by the equation, Fig. 2261, $H \left(\frac{a+x}{2} \right) \frac{\delta'}{x} = \delta' \lambda$, whence $x = \frac{H a}{2 \lambda - H}$.

It will be seen that for $H = 2 \lambda$, x will become infinite, and that for any value of H greater than 2λ , λ will be negative. Whence we infer that the maximum height that may be given to a wall constructed with rectilinear sides inclined equally from the top, without exceeding the limit of resistance in the masonry, is twice that of a wall with vertical sides.

Admitting 6 kilogrammes to the square centimetre as the limit of pressure, the limit of the height to be given to the wall is 60 metres; this limit is reduced to 40 metres, if we take 4 kilogrammes to the square centimetre as the limit of resistance in the materials.

Making $H = 50$ metres, and $a = 5$ metres, as in Fig. 2260, we find $x = 25$ metres. The breadth of the wall at the base is therefore 25 metres, instead of $9^m \cdot 739$.

The preceding results show of what importance it may be not to have any point in a structure at which the pressure is much less than that taken as the limit; by uselessly admitting excesses of thickness at certain points, it soon happens that we are unable to maintain the pressures within the required limits at other points. In the following considerations we shall endeavour to find a profile of equal resistance, or at least one that shall deviate but little from such a profile.

Stability of a Wall having to support a Load of Water.—Theoretical Profile of Equal Resistance.—We saw, Fig. 2256, that if $A B C D$ represent a wall having to support a pressure of water, the conditions of stability in this wall are given by one of the relations

$$2 \left(2 - \frac{3u}{l} \right) \frac{P}{\delta' l} < \lambda, \quad [5]$$

$$\frac{2}{3} \frac{P}{\delta' u} < \lambda, \quad [6]$$

according as we have $u > \frac{1}{3} l$, or $u < \frac{1}{3} l$.

Keeping to the limiting values which correspond to the sign $=$, we shall have for the equations giving the conditions of stability

$$2 \left(2 - \frac{3u}{l} \right) \frac{P}{\delta' l} = \lambda, \quad [9]$$

$$\frac{2}{3} \frac{P}{u \delta'} = \lambda. \quad [10]$$

Substituting in the formulæ [9] and [10] for the quantities u , l , and P , their respective values as a function of the height of the wall, of its reduced thickness, and of the inclination of its sides, we see—

1. That the profile offering the least thickness, while satisfying the conditions of stability, is that, the face of which is vertical on the side of the water and inclined on the opposite side.

2. That when the height is increased, the reduced thickness increases less rapidly, so that a profile constructed with a vertical facing on the side of the water, and with a talus on the opposite side, combined so as to satisfy the limiting condition of stability for its base, will offer an excess of stability over the surplus height. A wall satisfying the limiting conditions throughout its height will therefore present, with a vertical face on the side of the water, a concave curve on the opposite side.

Let us suppose for a moment this curve constructed, and let $A C N B$, Fig. 2262, be the profile determined by the condition that for each horizontal section $M N$, the pressure is equal to the limit R' which it is required not to exceed.

This profile would have sufficient resistance if the reservoir were always full, but we have to take care that the pressure arising from the weight of the wall do not exceed the limit R' when the reservoir is empty. It is certain that this pressure will not be exceeded for the face $C N B$; indeed, the developments into which we have already entered show that the effect of the thrust is to drive towards this side the vertical component equal to the weight of the wall: it remains, therefore, to be seen if the limit R' is reached in any point of the face $C M A$. If we refer to the calculations which we have already made with respect to the stability of walls having only their own weight to

support, we shall see that this limit will be passed at a very small height. It will be necessary, from the point M where the limit R' is reached, to carry out the wall according to a curve M L S; from the section M N the two curves N P B, M L S, should be determined by the condition that for any horizontal section L P, the pressure at the point P when the reservoir is full should be equal to R', and, when the reservoir is empty, equal to the same limit at the point L.

To solve the question completely, it only remains now to determine exactly the two curves C N B, M L S.

Let us take as the axis of the x 's, Fig. 2264, the vertical face A B of the wall, and for the axis of the y 's, the perpendicular A y to this face passing through the summit, and let M be any point in the curve.

If B M = y and M = x , the problem to be solved is to find a relation between x and y which shall be the equation of the curve.

We shall continue to consider a section of the wall of a unit of length in the direction perpendicular to the figure. This wall is acted upon by two forces; its weight P and the thrust F. These two forces are represented by the following expressions; $P = \delta \int_0^y y dx$, $F = \frac{\delta x^2}{2}$.

The curve A N L should be determined by the condition that the pressure in M to the unit of surface is to be equal to the limit $\lambda \delta'$, which must not be exceeded. This condition is expressed according to the cases by one of the equations [9] and [10].

We have $l = y$, and it remains to determine in functions of x and y , the quantity $u = E M$. Now E M = K M = K E. The two similar triangles O K E, O P R give

$$\frac{K E}{P R} = \frac{O K}{O P}, \text{ or } \frac{K E}{F} = \frac{x}{3 P}.$$

Whence, substituting for F and P their values, and for brevity making $\frac{\delta}{\delta'} = \theta$, we deduce

$$K E = \frac{\theta x^3}{6 \int_0^y y dx}.$$

Again we have K M = $y - B K$.

B K is the distance from the centre of gravity of the area A B M N to the axis A x; this distance is obtained by considering that the moment of the total area with respect to this axis is equal to the sum of the moments of the elementary areas such as $a b c d$.

$$B K \int_0^y y dx = \int_0^y \frac{y^2 dx}{2} = \frac{1}{2} \int_0^y y^2 dx. \text{ Whence } B K = \frac{\int_0^y y^2 dx}{2 \int_0^y y dx};$$

$$\text{consequently, } K M = y - B K = \frac{2 y \int_0^y y^2 dx - \int_0^y y^2 dx}{2 \int_0^y y dx}, \text{ and } u = \frac{6 y \int_0^y y dx - 3 \int_0^y y^2 dx - \theta x^3}{6 \int_0^y y dx}.$$

This value of u substituted in equation [9] gives

$$3 \int_0^y y^2 dx - 2 y \int_0^y y dx - \lambda y^2 + \theta x^3 = 0. \quad [11]$$

The same value of u substituted in equation [10] would give

$$4 \left(\int_0^y y dx \right)^2 - 6 \lambda y \int_0^y y dx + 3 \lambda \int_0^y y^2 dx + \lambda \theta x^3 = 0. \quad [12]$$

We have endeavoured to integrate the formulæ [11] and [12] by an exact method, but without success; we have been able to obtain y developed only as a series in function of x ; the series belonging to equation [11] is of the form, $y = a x^{\frac{1}{2}} + b x^{\frac{3}{2}} + c x^{\frac{5}{2}} + d x^{\frac{7}{2}} + \text{etc.}$

The series belonging to equation [12] is of the form $y = a x + b x^2 + c x^3 + d x^4 + e x^5 + \text{etc.}$

We had calculated the coefficients of the first terms admitting for θ and λ the values $\theta = \frac{1}{2}$, $\lambda = 30$; but it seems to us useless to reproduce these calculations here; the above formulæ

are, indeed, of no use in determining a practical profile; they are applicable only to the portion C N of the inner curve of Fig. 2263, and the calculations into which we should be led in determining the two curves N P B, M L S, of the lower portion of the profile are quite impracticable even if we have recourse to approximative methods.

Conditions which Profiles of Barrages must satisfy in practice.—We shall avoid the difficulties of integration, and solve, in a manner sufficiently accurate for practice, the problem of finding a profile of equal resistance by replacing the curves C N B, M L S, of Fig. 2263 by the polygonal circumferences O b' b'' N n' n'' B, M m' m'' S, of Fig. 2265 calculated for the condition that for each horizontal section such as $n' m'$ passing through the corresponding summits of the polygons forming the profile of the face, the pressures to the unit of surface in n' and m' according as the reservoir is full or empty, are to be equal to the limit R'. The smaller these horizontal sections such as $c' b'$, $c'' b''$, the less will the circumferences differ from the curves corresponding to an exact solution. This solution offers no difficulty, as we shall see later.

But before proceeding farther we must remark that if the profile of Fig. 2263, supposed to be calculated in an exact manner, were sufficient theoretically to resist the load of water which it would be required to support, a thickness that became nul at the summit could not be admitted in practice. The masonry in the upper portion of the wall must be capable of resisting the action of waves, and if it have sufficient dimensions to serve as a passage for vehicles, or, at least, foot-passengers, something will be gained in point of convenience.

These considerations lead us to substitute Fig. 2266 for Fig. 2263, having in its upper portion a part C D B A with vertical sides. In this part the masonry will be subject to pressures less than the limit R' . The method of calculating this profile would be analogous to that employed for Fig. 2265; but the breadth C D at the top of the barrage being determined, we must begin by calculating the height A D for the condition that the pressure to the unit of surface at the point A when the barrage is full shall be equal to the limit R' .

The height is readily calculated by the following method;—Let C D = a , Fig. 2267, the breadth chosen for the top of the barrage, and D A = x the height to be calculated.

When the reservoir is full, the upper portion C D B A of the barrage is subject to two forces, its weight P and the thrust F; these two forces produce a resultant R cutting the base B A in the point E; the resultant is decomposed into two at this point, a horizontal force tending to make the part C D B A slide upon the plane B A, and a vertical force equal to P; this latter force spreads itself over the base A B according to a law which we have already alluded to.

By expressing the pressure at the point A as equal to the limit $R' = \lambda \delta'$ which is not to be exceeded, we shall put the problem into an equation; this will lead us to one of the equations [9] and [10] found by solving a similar question.

$$2 \left(2 - \frac{3u}{l} \right) \frac{P}{\delta' l} = \lambda, \quad [9] \qquad \frac{2}{3} \frac{P}{u \delta'} = \lambda. \quad [10]$$

We have now to express in these equations the quantity $u = A E$ as functions of the lengths a and x . Now we have $A E = K A - E K = \frac{a}{2} - E K$, and again $K E = \frac{O K \times P R}{O P} = \frac{x \times F}{3 P}$.

But $P = a x \delta'$, and $F = \frac{x^2 \delta}{2}$. Therefore $K E = \frac{x^2 \delta}{6 a \delta'}$. And consequently,

$$u = \frac{a}{2} - \frac{x^2 \delta}{6 a \delta'} = \frac{1}{6 a} (3 a^2 - \theta x^2). \quad [13]$$

Substituting this value in the equations [9] and [10], we deduce as the equations connecting the quantities a and x , remarking that $l = a$;

$$\theta x^3 + a^2 x - a^2 \lambda = 0. \quad [14] \qquad \theta \lambda x^2 + 4 a^2 x - 3 \lambda a^2 = 0. \quad [15]$$

We must employ equation [14] or equation [15] according as a is greater or less than $\frac{a}{3}$, or, which is the same thing (as may be seen by referring to the value of u given above), according as x^2 is greater or less than $\frac{a^2}{\theta}$.

Having determined the upper portion of the profile in this way, the other two portions A N T, B M S, Fig. 2266, may be calculated by the method indicated for Fig. 2263.

The difficulties of integration will be avoided by substituting polygonal lines for the curves A N T, B M S, as shown in Fig. 2268, and the smaller the horizontal sections into which the barrage is supposed to be divided, such as $m'n$, $m''n''$, the nearer will the profile approximate to one of equal resistance.

The calculation of this profile offers no difficulty; it is, however, of great length. We will give later the formulæ arrived at.

To determine a practical Profile.—The important matter in constructing a barrage is not to allow in any point of the structure a pressure greater than the limit R' , but it is obviously not indispensable that this pressure should be reached in every point, and plain that profiles may be admitted which deviate slightly from one of equal resistance if they offer other advantages.

We see at a glance that the execution of facings such as those of Fig. 2268 would offer some difficulty, and that the frequent change of inclination which they present would not produce a very happy effect. A more practical form will be obtained by lessening the number of sections into which the wall is supposed to be divided.

This consideration leads us to calculate a profile of the form of Fig. 2269.

The method of calculation will be the same whatever the height of the horizontal sections may be, and it will apply with slight modifications to the determining of the profile of equal resistance by the approximative method.

The profile of Fig. 2269, like that of Fig. 2265, divides itself naturally into two parts, one C D A B, in which the face on the side of the water is vertical, the other A B, A' B', the facings of which are inclined on both sides. One of the horizontal planes dividing the profile into sections must be made to pass through the point B from which the inside face is inclined; the first thing to be calculated is, therefore, the height C B. We will suppose in the first place that the outside facing slopes regularly from D to A, as in Fig. 2270; the problem will be expressed as an equation by making the pressure to the unit of surface at the point A when the reservoir is full, and at the point B when the reservoir is empty, equal to the limit R'.

Denoting the weight of the portion C D B A of the wall by P, the thrust by F, and the distance A E by u , the equation expressing the above conditions will be one of the following;

$$2 \left(2 - \frac{3u}{l} \right) \frac{P}{\delta' l} = \lambda, \quad [9] \qquad \frac{2}{3} \frac{P}{u \delta'} = \lambda, \quad [10]$$

according as u is greater or less than $\frac{l}{3}$.

Let C D = a , C B = z , and A V = x . We shall have first,

$$P = \left(\frac{2a+x}{2} \right) \delta' z, \quad F = \frac{z^2 \delta}{2}, \quad l = a+x, \quad u = A E = K A - K E.$$

Now we have

$$K E = O K \times \frac{F}{P} = \frac{z^2 \delta}{3(2a+x) \delta'} = \frac{z^2 \theta}{3(2a+x)}.$$

We shall obtain K A by considering that the moment of the whole weight of the figure C B A D, with respect to the point A, is equal to the sum of the moments of the two parts B C D V, D V A, of which it is composed.

$$K A \times \frac{(2a+x) z \delta'}{2} = \frac{(2x+a) a z \delta'}{2} + \frac{z x^2 \delta'}{3}.$$

Whence we deduce, $K A = \frac{2x(x+3a)+3a^2}{3(2a+x)}$, and, consequently, $u = \frac{2x(x+3a)-\theta z^2+3a^2}{3(2a+x)}$.

This value of u substituted successively in the equations [9] and [10] gives us the two following;

$$\theta z^3 - \lambda x^2 - 2a \lambda x + a^2 z - \lambda a^2 = 0. \quad [16]$$

$$x^2 z - 2 \lambda x^2 + 4 a x z + \theta \lambda x^2 - 6 a \lambda x + 4 a^2 z - 3 a^2 \lambda = 0. \quad [17]$$

Equations [16] or [17] will be employed according as u is greater or less than $\frac{l}{3}$.

Hitherto we have only one equation between the unknowns x and z , but we may obtain a second by expressing the pressure to the unit of surface at the point B when the reservoir is empty as equal to the limit R'. This condition will always be given by the relations [9] and [10], but the quantity u will not remain the same; the thrust of the water no longer existing, the vertical force P acts in the direction O P, and we have $u = B K$.

This quantity is immediately deduced from the preceding calculations; we have

$$u = B K = A B - A K = \frac{x(x+3a)+3a^2}{3(2a+x)}.$$

Substituting the preceding value in the expressions [9] and [10], we obtain the two equations

$$x^2 z - \lambda x^2 + 3 a x z - 2 a \lambda x + a^2 z - \lambda a^2 = 0, \quad [18]$$

$$x^2 z - \lambda x^2 + 4 a x z - 3 a \lambda x + 4 a^2 z - 3 a^2 \lambda = 0. \quad [19]$$

The values of x and z may be determined in each particular case by combining one of the equations [16] and [17] with one of the equations [18] and [19]. This operation must be effected by tentative experiments, for the value of u being a function of the unknowns, we cannot ascertain in a precise manner *a priori* which equation is required. It will be necessary, in this case, to have recourse to an hypothesis on the relation of the value of u to that of $\frac{r}{3}$. Having solved the two equations chosen in accordance with this hypothesis, we must verify the supposition, and if it be untrue we shall be driven to take those of the equations which suit the values found for u and z , which, though inexact, will be near enough to enable us to choose the equations that will determine the true values.

The equations [16], [17], [18], and [19] being of the third degree, by combining two of them, we shall be led to the solution of an equation of the sixth degree. This solution will offer no difficulty in practice, the equations to be dealt with being numerical. Supposing, for example, the two values of u , AE and BK to be less than $\frac{BA}{3} = \frac{l}{3}$, the equations [17] and [19] must be combined. Equation [19] being of the first degree in z , we may deduce from it the value of this unknown as a function of x ; and substituting it in equation [17] we shall obtain the following final equation;

$$x^6 + 11ax^5 + (48a^2 - \lambda^2\theta)x^4 + 2a(52a^2 - 3\theta\lambda^2)x^3 + a^2(112a^2 - 15\theta\lambda^2)x^2 + 6a^3(8a^2 - 3\theta\lambda^2)x - 9a^4\lambda^2\theta = 0. \quad [20]$$

The values of x and z being found, the portion $CDBA$ of the barrage, constructed by means of these values, possesses this property, namely, the pressures to the unit of surface in the points A and B according as the reservoir is full or empty are equal to the limit R' , and we are at the same time certain, as was shown in our considerations on the profile of equal resistance, that the pressure in any point a of the face DA is less than the limit R' .

It will be very easy to ascertain what pressure is borne by any point of the face DA ; if it happen that in certain points the difference between this pressure and the limit R' is considerable, a marked advantage will be gained by subdividing the height CD into two and calculating a profile of the form of Fig. 2271. This calculation may be effected in the manner we have already pointed out, and will offer no difficulty whatever.

In this case, for the upper portion $CDMN$ of the profile, the height CM is given; the only unknown is $V'N = x$, and as the pressure in M when the reservoir is empty is necessarily less than R' , we have only one equation for determining x ; this is evidently one of the equations [16] and [17], in which the value h chosen as the height CM will be substituted for the unknown z .

The value of x will therefore be given by one of the following equations;

$$\lambda x^2 + 2a\lambda x + \lambda a^2 - \theta h^3 - a^2 h = 0, \quad [21]$$

$$(2\lambda - h)x^3 + 2a(3\lambda - 2h)x + 3a^2\lambda - 4a^2h - \theta\lambda h^2 = 0. \quad [22]$$

The portion $MNBA$ of the profile may be determined by employing a method analogous to that followed in calculating the profile of Fig. 2270, taking as unknown the height $MB = z$ and $NA = x$.

The equations of the problem will always be the relations [9] and [10], in which the quantities P , l , and u , will be expressed as functions of the data of the question.

Representing by s the surface of the upper portion $MCDN$ of the profile, by β the distance NG from the vertical passing through the centre of gravity of this portion to the point N , and by b the length MN , we shall have

$$P = s\delta' + bz\delta' + \frac{zx\delta'}{2} = \left(\frac{2s + 2bz + zx}{2}\right)\delta', \quad F = \frac{(h+z)^2\delta}{2}, \quad l = b+x, \quad u = AE = x + VK - KE.$$

KE will be given immediately by the relation

$$KE = OK \times \frac{F}{P} = \frac{(h+z)^2\delta}{3(2s + 2bz + zx)\delta'} = \frac{(h+z)^2\theta}{3(2s + 2bz + zx)}.$$

VK may be found by considering the moment of the resultant P of the vertical forces with respect to the point N as equal to the sum of the moments of the components with respect to the same point.

$$P \times VK = \beta s\delta' + bz\delta' \times \frac{b}{2} - \frac{zx\delta'}{2} \times \frac{x}{3},$$

whence we deduce, substituting the value of P , $VK = \frac{6\beta s + 3b^2z - zx^2}{3(2s + 2bz + zx)}$. And, consequently,

$$\text{the equation } u = x + VK - KE \text{ gives } u = \frac{3x(2s + 2bz + zx) + 6\beta s + 3b^2z - zx^2 - (h+z)^2\theta}{3(2s + 2bz + zx)}.$$

Substituting the values of P , l , and u , in the relations [9] and [10], we obtain the following equations;

$$\theta x^3 - \lambda x^2 + 3h\theta x^2 - 2(s + \lambda b)x + (b^2 + 3h^2\theta)z + 4bs - 6\beta s + \theta h^3 - \lambda b^2 = 0, \quad [23]$$

$$x^2 x^2 - 2\lambda x^2 + 4bz^2x + \theta\lambda x^3 + 2(2s - 3\lambda b)zx + (4b^2 + 3h\theta\lambda)z^2 - 6\lambda sx +$$

$$(8bs + 3h^2\theta\lambda - 3\lambda b^2)z + 4s^2 - 6\lambda\beta s + \theta\lambda h^3 = 0. \quad [24]$$

The first or the second of these equations will be employed according as u is greater or less than $\frac{b+x}{3}$.

A second equation between x and z may be obtained by expressing the pressure to the unit of surface at the point B as equal to the limit R' when the reservoir is empty. The relations [9] and [10] will still be the equations of the problem.

The value of u will thus be equal to BK , and this quantity may be obtained as a function of

2271.

We thus obtain one of the two following equations [28] and [29], writing for the sake of brevity;

$$\left\{ \begin{array}{l} s + \frac{b\lambda}{b^2\lambda'} = \sigma, \\ s\beta + \frac{b^2\lambda'}{2} = \mu, \\ \frac{\lambda}{2\lambda} + \frac{\lambda'}{\lambda'} = \frac{H}{H'}, \end{array} \right. \quad [27]$$

$$\left. \begin{array}{l} \frac{2\lambda}{-H'\theta} \quad \left| \begin{array}{l} y^2 + 4\lambda \\ + 2H'\theta \end{array} \right| \quad \left| \begin{array}{l} xy + y + 2\lambda \\ - 2\lambda' \end{array} \right| \quad \left| \begin{array}{l} x^2 + 4b\lambda \\ + 2bH'\theta \\ + 2b\lambda' \\ - 8\sigma \end{array} \right| \quad \left| \begin{array}{l} y + 4b\lambda \\ - 4b\lambda' \\ + 4\sigma \end{array} \right| \quad \left| \begin{array}{l} x + 2b^2\lambda \\ - 8b\sigma \\ - 2H^3\theta \\ + 12\mu \end{array} \right| \end{array} \right\} = 0. \quad [28]$$

$$\left. \begin{array}{l} \frac{2\lambda'\lambda}{+ 3H'\lambda\theta} \quad \left| \begin{array}{l} y^2 + 6\lambda'\lambda \\ + 6H'\lambda\theta \end{array} \right| \quad \left| \begin{array}{l} xy + 4\lambda'\lambda \\ - 2\lambda'^2 \end{array} \right| \quad \left| \begin{array}{l} x^2 + 6b\lambda'\lambda \\ + 6bH'\lambda\theta \\ - 8H'\theta\sigma \\ - 8H'\sigma \end{array} \right| \quad \left| \begin{array}{l} y + 12\lambda\sigma \\ - 8\lambda'\sigma \end{array} \right| \quad \left| \begin{array}{l} x + 12\lambda\mu \\ - 2H^3\lambda\theta \\ - 8\sigma^2 \end{array} \right| \end{array} \right\} = 0. \quad [29]$$

We have now to express the pressure to the unit of surface at the point B' as equal to the limit R', when the reservoir is empty.

The value of u is thus equal to $B'K' = y + HK'$, and the value of HK is found by stating the moment of the whole weight with respect to the point B as equal to the sum of the moments of the components of this weight with respect to the same point.

The pressure of the water no longer existing, the value of P is

$$P = \frac{2(s + b\lambda')\delta' + \lambda(x + y)\delta'}{2} = \frac{(2\sigma + \lambda'x + \lambda'y)\delta'}{2}.$$

And we find $u = \frac{2\lambda'y^2 + 3\lambda'xy + \lambda'x^2 + 6\sigma y + 3b\lambda'x + 6\mu'}{3(h'y + \lambda'x + 2\sigma)}$, making $sa + \frac{b^2\lambda'}{2} = \mu'$.

This value of u , substituted in the relations [9] and [10], gives the two following equations [30] and [31];

$$\left. \begin{array}{l} \frac{\lambda y^2 + 2\lambda}{- \lambda'} \quad \left| \begin{array}{l} xy + \lambda \\ - \lambda' \end{array} \right| \quad \left| \begin{array}{l} x^2 + 2b\lambda \\ - 2b\lambda' \\ + 2\sigma \end{array} \right| \quad \left| \begin{array}{l} y + 2b\lambda \\ + b\lambda' \\ - 4\sigma \end{array} \right| \quad \left| \begin{array}{l} x + \lambda b^2 \\ + 6\mu' \\ - 4\sigma b \end{array} \right| \end{array} \right\} = 0. \quad [30]$$

$$\left. \begin{array}{l} \frac{2\lambda'\lambda}{- \lambda'^2} \quad \left| \begin{array}{l} y^2 + 3\lambda'\lambda \\ - 2\lambda'^2 \end{array} \right| \quad \left| \begin{array}{l} xy + \lambda'\lambda \\ - \lambda'^2 \end{array} \right| \quad \left| \begin{array}{l} x^2 + 6\lambda\sigma \\ - 4\lambda'\sigma \end{array} \right| \quad \left| \begin{array}{l} y + 3b\lambda'\lambda \\ 4\lambda'\sigma \end{array} \right| \quad \left| \begin{array}{l} x + 6\mu'\lambda \\ - 4\sigma^2 \end{array} \right| \end{array} \right\} = 0. \quad [31]$$

Equation [30] or equation [31] will be required, according as u is greater or less than $\frac{l}{3}$.

The values of x and y will be obtained by combining one of the equations [28] and [29] with one of the equations [30] and [31]. These equations being of the second degree in x and y , there will be no difficulty in the matter of elimination, the rather complicated coefficients of the different terms being, in each particular case, replaced by numbers.

The choice of the equation, adapted to the question, may give occasion for tentative experiments as we have already explained, the value of the relation of u to $\frac{l}{3}$ which serves to determine this choice being a function of the unknowns. It will be necessary to make some hypotheses on the value of this relation, and having solved the equations chosen, to verify the suppositions; if this verification be unsatisfactory, the equations must be chosen by the aid of the values of the relation of u to $\frac{l}{3}$, calculated with the values found for x and y , which will be sufficiently near to enable us to follow out the indications given by this relation.

The first section $ABm'n'$ of the lower portion $AB, A'B'$, of the profile, Fig. 2269, being determined, the dimensions of the second section $m'n'A'B'$ may be calculated in the same manner with the equations just found by modifying them as follows;—

$s\delta'$ representing in the calculations the total weight of the portion of the barrage situate above the section considered, we must take into account the weight of the column of water which presses upon the face $B'm'$, a weight equal to $s''\delta$ if we represent by s'' the vertical section $c'Bm'$ of this column; in the case under consideration we have $s'' = \left(h + \frac{\lambda'}{2}\right)y_1$, denoting by y_1 the value of $m'm''$ from y which has been determined.

The weight of that portion of the barrage situate above the section considered will thus be $s'\delta' + s''\delta$, s' representing the surface $cBm'n'A'D$.

This quantity must be substituted for $s\delta'$ in the equations [28], [29], [30], and [31], by making $s\delta' = s'\delta' + s''\delta$, whence $s = s' + s''\theta$.

But the modifications to be introduced into the formulæ will not end here; the moment of the weight $s'\delta'$ with respect to the point n' will be changed: we must take into account the moment of the weight $s''\delta$ of the water. Denoting by β' the distance from the centre of gravity of the surface s'' to the point n' , we may state $s'\delta'\beta = s'\delta'\beta + s''\delta\beta$, or $s\beta = s'\beta + s''\theta\beta$.

Substituting in the formulæ [28], [29], [30], and [31], for s and $s\beta$ the values so determined,

these formulæ become perfectly applicable to the determination of the dimensions of the section $A n' n' B$, and in general to the calculation of any section, knowing the preceding ones.

Determination by an Approximative Method of the Profile of Equal Resistance.—The profile to be adopted in practice consists, as we have seen, of three portions. The first $C D B A$, Fig. 2268, has a vertical face on each side; the second $A B M N$ offers a vertical face on the side of the water and an inclined face on the outside, and the third $M N S T$ has an inclined face on each side.

We have seen how the portion $C D B A$ is determined. Below the horizontal plane $B A$ we will suppose the barrage divided into sections of equal height, and the question is to calculate for each section the projections, such as $b' b''$, $N n$, $n' n''$, of the elements of the face upon the lower horizontal plane which serves as its base.

Let us see, in the first place, how any section $A B$, $c' b'$, of the portion $B A M N$ may be determined. The height of this section is known, we will represent it by h' .

The problem will be solved at once by referring to the determination of the part $M N B A$ of Fig. 2269 developed above.

We have merely to substitute in the equations [23] and [24] h' for the unknown height x , and we thus obtain the following equations;—

$$\lambda x^2 + 2(\lambda b + s)x + \lambda b^2 + 6\mu - 4b\sigma - \theta H^3 = 0, \quad [32]$$

$$(2\lambda h' - h'^2)x^2 + 2\sigma(3\lambda - 2h')x + 6\mu\lambda - 4s^2 - \theta\lambda H^3 = 0. \quad [33]$$

Making, as before [34],

$$\begin{cases} s + b h' = \sigma, \\ s b + \frac{b^2 h'}{2} = \mu, \\ h + h' = H. \end{cases}$$

These equations might be obtained directly by the method given for equations [23] and [24].

The first or the second will be employed according as u is greater or less than $\frac{b+x}{3}$.

The preceding formulæ will serve to calculate successively all the sections of the portion $B A M N$ of the profile, Fig. 2268. Having determined each of them, it will be necessary to ascertain if the pressure in the points c' , M , of the inner facing is below the limit R' ; when this limit is exceeded, a talus must be given to both facings, and we pass on to determine the last portion $M N S T$ of the profile.

This problem has been solved above in determining the lower part of the profile of Fig. 2272. The formulæ to be employed are the equations [28], [29], [30], and [31].

M. de Sazilly, in his considerations, published in 1853 in the 'Annales des Ponts et Chaussées,' on the walls of reservoirs, adopted a profile differing slightly from that of Fig. 2268, for the calculation of a wall the form of which should deviate but little from that of equal resistance. This engineer, instead of supposing the faces of the wall formed of successive inclined surfaces, assumed that they ought to be composed of a system of vertical facings of inconsiderable height, separated by gradations or retreats, as shown in Fig. 2273.

The profile is calculated for the condition that the pressure exerted upon each of the inner angles of the outer facing, when the reservoir is full, shall be equal to the limit R' , and that this limit shall be reached upon the inner angles of the inside facing when the reservoir is empty.

The upper portion $C D B A$ of the profile is determined in exactly the same way as in Fig. 2268. The breadth of the summit a and the height $A D = x$, are connected according to the case by one of the equations [14] and [15].

$$\theta x^3 + a^2 x - a^2 \lambda = 0, \quad [14] \quad \theta \lambda x^2 + 4a^2 x - 3\lambda a^2 = 0. \quad [15]$$

To put these equations in the form of those given by M. Sazilly, they must be solved with respect to a ; we thus obtain the formulæ [35] and [36], which, with the difference of notation, are precisely those given in p. 244 of Graeff's paper, 'Annales des Ponts et Chaussées,' 1866.

$$a = x \sqrt{\frac{\theta x}{\lambda - x}}, \quad [35] \quad a = x \sqrt{\frac{\theta \lambda}{3\lambda - 4x}}. \quad [36]$$

The gradations of the second portion $A B M N$ of the barrage may be calculated in the manner described for the corresponding part $A B M N$ of Fig. 2268. We thus get the following equations;—

$$\begin{aligned} (\lambda - h')(b + x)^2 + 2(\sigma - b h')(b + x) - \theta H^3 + 6\mu - 6b\sigma + 3b^2 h' &= 0, \\ h'(3\lambda - 4h')x^2 + 2\sigma(3\lambda - 4h')x - 4\sigma^2 + 6\mu\lambda - \theta H^3 \lambda &= 0. \end{aligned}$$

Solving these equations, we arrive at the following formulæ;—

$$\begin{aligned} x + b &= -\frac{\sigma - b h'}{\lambda - h'} + \sqrt{\left(\frac{\sigma - b h'}{\lambda - h'}\right)^2 + \frac{\theta H^3 - 6\left(\mu - \sigma b + \frac{1}{2}b^2 h'\right)}{\lambda - h'}}, \quad [37] \\ x &= -\frac{\sigma}{h'} + \sqrt{\left(\frac{\sigma}{h'}\right)^2 + \frac{4\sigma^2 - \lambda(6\mu - \theta H^3)}{h'(3\lambda - 4h')}}. \quad [38] \end{aligned}$$

The first or second of these will be employed according as

$$u = \frac{\mu + \sigma x + \frac{h' x^2}{2} - \frac{\theta H^3}{6}}{\sigma + h' x} < \text{or} > \frac{1}{3} (b + x).$$

The third portion M N S T of the profile may be determined by the methods employed above for Fig. 2268. The following equations must be substituted for those [28, 29, 30, 31] relative to this latter profile.

$$\left. \begin{array}{c} \lambda \\ -h\theta \\ -h' \end{array} \right| \begin{array}{c} y^2 + 2\lambda \\ + 2h\theta \\ -2h' \end{array} \left| \begin{array}{c} xy + \lambda \\ -h' \end{array} \right| \begin{array}{c} x^2 + 2b\lambda \\ + 2bh\theta \\ + 2bh' \\ -4\sigma \end{array} \left| \begin{array}{c} y + 2b\lambda \\ -4bh' \\ + 2\sigma \end{array} \right| \left. \begin{array}{c} x + b'\lambda \\ -4b\sigma \\ -H^2\theta \\ + 6\mu \end{array} \right\} = 0. \quad [39]$$

$$\left. \begin{array}{c} 3h'\lambda \\ + 3h\lambda\theta \\ -4h^2\theta^2 \\ -8h'h'\theta \\ -4h'^2 \end{array} \right| \begin{array}{c} y^2 + 6h'\lambda \\ + 6h\lambda\theta \\ -8h'h'\theta \\ -4h'^2 \end{array} \left| \begin{array}{c} xy + 3h'\lambda \\ -4h'^2 \end{array} \right| \begin{array}{c} x^2 + 6bh'\lambda \\ + 6bh\lambda\theta \\ -8h'\theta\sigma \\ -8h'\sigma \end{array} \left| \begin{array}{c} y + 6\lambda\sigma \\ -8h'\sigma \end{array} \right| \left. \begin{array}{c} x + 6\lambda\mu \\ -H^2\lambda\theta \\ -4\sigma^2 \end{array} \right\} = 0. \quad [40]$$

$$\left. \begin{array}{c} \lambda \\ -h' \end{array} \right| \begin{array}{c} y^2 + 2\lambda \\ -2h' \end{array} \left| \begin{array}{c} xy + \lambda \\ -h' \end{array} \right| \begin{array}{c} x^2 + 2\sigma \\ + 2b\lambda \\ -4bh' \end{array} \left| \begin{array}{c} y + 2b\lambda \\ -4\sigma \\ + 2bh' \end{array} \right| \left. \begin{array}{c} x + \lambda b^2 \\ + 6\mu' \\ -4b\sigma \end{array} \right\} = 0. \quad [41]$$

$$\left. \begin{array}{c} 3h'\lambda \\ -4h'^2 \end{array} \right| \begin{array}{c} y^2 + 6h'\lambda \\ -8h'^2 \end{array} \left| \begin{array}{c} xy + 3h'\lambda \\ -4h'^2 \end{array} \right| \begin{array}{c} x^2 + 6\lambda\sigma \\ -8h'\sigma \end{array} \left| \begin{array}{c} y + 6bh'\lambda \\ -8h'\sigma \end{array} \right| \left. \begin{array}{c} x + 6\lambda\mu \\ -4\sigma^2 \end{array} \right\} = 0. \quad [42]$$

These equations must be employed in the same way as those relative to Fig. 2268.

Conditions of Stability with respect to Slipping.—Having calculated the profile of a barrage in accordance with the preceding considerations, it will be necessary to ascertain if its dimensions are such as to hinder the wall from slipping horizontally upon one of its courses or upon its foundation.

Denoting by H the distance of a course below the top, the force which tends to make this course slide upon its bed is equal to the horizontal component of the thrust of the water against that portion of the inner facing which is situated above this course, and it is given by the equation

$$F = \frac{\delta H^2}{2}.$$

The resistances to the action of this force are friction and the cohesion of the masonry. The friction is proportional to the weight of the upper portion of the structure, and the force of cohesion to the thickness of the wall.

Representing the coefficient of friction by f , the force of cohesion to the unit of surface by γ , the surface of that portion of the profile situated above the course considered by s , and the thickness of the wall at this point by b , the resistance R to slipping will be $R = s\delta'f + \gamma b$, and we must have

$$s\delta'f + \gamma b > \frac{\delta H^2}{2}, \text{ or } 2 \frac{(s\delta'f + \gamma b)}{\delta H^2} > 1. \quad [43]$$

This inequality must be verified for all the horizontal sections of the profile. It must also be verified for the base of the foundations; f and γ then representing the coefficients relative to the soil upon which the structure stands.

It will be prudent in practice, for greater safety, not only to make the quantity $\frac{2(s\delta'f + \gamma b)}{\delta H^2}$ greater than unity, but equal to the value found for existing reservoirs which have not yielded in any degree. We will consider later the application of formula [43].

Having determined by the aid of the preceding formulæ the dimensions of the profile and proved the conditions of stability with respect to slipping between the courses to be satisfactory, we have now to ascertain if the soil of the foundation is capable of supporting the limit of pressure adopted for the masonry, and if the wall is not liable to slip upon the soil which supports it. The precautions to be taken in these cases are to render the soil of the foundations more solid by processes usually employed in important works and to diminish the pressure upon the soil by widening the base of the profile.

Dams or Barrages suitable to Narrow Valleys.—Barrages constructed in the form of an Arch.—Hitherto we have not considered the length of the barrages whose dimensions we have determined; the profiles calculated are such that any length of the structure resists by its own weight only the action of the forces to which it is subject. In the case in which the valleys to be barred are narrow and formed of a resisting soil, it is possible, by giving the barrages the form of an arch, to transmit the thrust horizontally to the sides of the valley, and we have to see if, in certain cases, this arrangement will enable us to reduce the dimensions of the profile.

It is easy to ascertain the influence of the arrangement by which the thrust is transmitted laterally to the sides of the valley. Take Fig. 2256 as an example. This profile is subject to the action of two forces, the weight P and the thrust F . In the case in which the wall is rectilinear or indefinite, these two forces combine to produce a resultant R , and to ensure the stability of the structure the point E , where this resultant meets the foundation, must be within the base AB ,
